An operational-amplifier circuit for offsetting is shown in Figure 16.21. Since the input, v_i , is connected to the negative lead of the opamp, we have an *inverting amplifier*, and the input signal will appear in the output, v_o , with its sign reversed. This is also a *summing amplifier* because two signals can be added together by this circuit. If the input, v_i , is connected to the positive lead of the opamp, we will have a *noninverting amplifier*.

The DC voltage, v_{ref} , provides the offsetting voltage. The resistor, R_c (compensating resistor), is variable so that different values of offset can be compensated using the same circuit. To obtain the circuit equation, we write the current balance equation for node A, using the usual assumption that the current through an input lead is zero for an opamp because of very high input impedance; thus

$$\frac{v_{\text{ref}} - v_A}{R_c} = \frac{v_A}{R_o}$$

or

$$v_A = \frac{R_o}{(R_o + R_c)} v_{\text{ref}} \quad (\text{i})$$

Similarly, the current balance at node B gives

$$\frac{v_i - v_B}{R} + \frac{v_o - v_B}{R} = 0$$

or

$$v_o = -v_i + 2v_B \quad (\text{ii})$$

FIGURE 16.21 An inverting amplifier circuit for offset compensation.

Since $v_A = v_B$ for the opamp (because of very high open-loop gain), we can substitute Equation i into Equation ii. Then,

$$v_o = -v_i + \frac{2R_o}{(R_o + R_c)} v_{\text{ref}} \quad (16.97)$$

Note the sign of v_i is reversed at the output (because this is an inverting amplifier). This is not a problem because polarity can be reversed at input or output in connecting this circuit to other circuitry, thereby recovering the original sign. The important result here is the presence of a constant offset term on the RHS of Equation 16.97. This term can be adjusted by picking the proper value for R_c so as to compensate for a given offset in v_i .

16.7.5 Proportional-Output Circuitry

An operational-amplifier circuit may be employed to linearize the output of a capacitive transverse-displacement sensor. In constant-voltage and constant-current resistance bridges and in a constant-voltage half bridge, the relation between the bridge output, δv_o , and the measurand (the change in resistance in the active element) is nonlinear. The nonlinearity is least for the constant-current bridge and it is highest for the half bridge. Since δR is small compared with R , however, the nonlinear relations can be linearized without introducing large errors. However, the linear relations are inexact and are not suitable if δR cannot be neglected in comparison to R . Under these circumstances, the use of a linearizing circuit would be appropriate.

One way to obtain a proportional output from a Wheatstone bridge is to feed back a suitable factor of the bridge output into the bridge supply, v_{ref} . Another way is to use the opamp circuit shown in Figure 16.22. This should be compared with the Wheatstone bridge shown in Figure 16.17(a). Note that R represents the only active element (e.g., an active strain gage).

First, let us show that the output equation for the circuit in Figure 16.22 is similar to Equation 16.68. Using the fact that the current through an input lead of an unsaturated opamp can be neglected, we have the following current balance equations for nodes A and B:

$$\begin{aligned} \frac{v_{\text{ref}} - v_A}{R_4} &= \frac{v_A}{R_2} \\ \frac{v_{\text{ref}} - v_B}{R_3} + \frac{v_o - v_B}{R_1} &= 0 \end{aligned}$$

Hence,

$$v_A = \frac{R_2}{(R_2 + R_4)} v_{\text{ref}}$$

and

$$v_B = \frac{R_1 v_{\text{ref}} + R_3 v_o}{(R_1 + R_3)}$$

Now, using the fact $v_A = v_B$ for an opamp, we obtain

$$\frac{R_1 v_{\text{ref}} + R_3 v_o}{(R_1 + R_3)} = \frac{R_2}{(R_2 + R_4)} v_{\text{ref}}$$

FIGURE 16.22 A proportional-output circuit for an active resistance element (strain gage).

Accordingly, we have the circuit output equation

$$v_o = \frac{(R_2 R_3 - R_1 R_4)}{R_3(R_2 + R_4)} v_{\text{ref}} \quad (16.98)$$

Note that this relation is quite similar to the Wheatstone bridge equation (Equation 16.68). The balance condition (i.e., $v_o = 0$) is again given by Equation 16.69.

Suppose that $R_1 = R_2 = R_3 = R_4 = R$ in the beginning (the circuit is balanced), so $v_o = 0$. Then suppose that the active resistance R_1 is changed by δR (say, owing to a change in strain in the strain gage R_1). Then, using Equation 16.98, we can write an expression for the change in circuit output as

$$\delta v_o = \frac{[R^2 - R(R + \delta R)]}{R(R + R)} v_{\text{ref}} - 0$$

or

$$\frac{\delta v_o}{v_{\text{ref}}} = -\frac{1}{2} \frac{\delta R}{R} \quad (16.99)$$

By comparing this result with Equation 16.71, we observe that the circuit output, δv_o , is proportional to the measurand, δR . Furthermore, note that the sensitivity of the circuit in Figure 16.22 (1/2) is double that of a Wheatstone bridge that has one active element (1/4), which is a further advantage of the proportional-output circuit. The sign reversal is not a drawback because it can be accounted for by reversing the load polarity.

16.7.5.1 Curve-Shaping Circuitry

A curve shaper can be interpreted as an amplifier whose gain is adjustable. A typical arrangement for a curve-shaping circuit is shown in Figure 16.23. The feedback resistance, R_f , is adjustable by some means. For example, a switching circuit with a bank of resistors (say, connected in parallel through solid-state switches as in the case of weighted-resistor DAC) can be used to switch the feedback resistance to the required value. Automatic switching can be realized by using Zener diodes that will start conducting at certain voltage levels. In both cases (external switching by switching pulses or automatic switching using Zener diodes), amplifier gain is variable in discrete steps. Alternatively, a potentiometer can be used as R_f so that the gain can be continuously adjusted (manually or automatically).

The output equation for the curve-shaping circuit shown in Figure 16.23 is obtained by writing the current balance at node A, noting that $v_A = 0$; thus

$$\frac{v_i}{R} + \frac{v_o}{R_f} = 0$$

or

$$v_o = -\frac{R_f}{R} v_i \quad (16.100)$$

It follows that the gain (R_f/R) of the amplifier can be adjusted by changing R_f .

FIGURE 16.23 A curve-shaping circuit.

16.8 Miscellaneous Signal Modification Circuitry

In addition to the signal modification devices discussed so far in this chapter, there are many other types of circuitry that are used for signal modification and related tasks. Examples are phase shifters, voltage-to-frequency converters, frequency-to-voltage converters, voltage-to-current converts, and peak-hold circuits. The objective of the present section is to discuss briefly several of such miscellaneous circuits and components that are useful in the instrumentation of dynamic systems.

16.8.1 Phase Shifters

A sinusoidal signal given by

$$v = v_a \sin(\omega t + \phi) \quad (16.101)$$

has the following three representative parameters:

- v_a = amplitude
- ω = frequency
- ϕ = phase angle

Note that the phase angle represents the *time reference* (starting point) of the signal. The phase angle is an important consideration only when two or more signal components are compared. The Fourier spectrum of a signal is presented as its amplitude (magnitude) and the phase angle with respect to the frequency.

Phase-shifting circuits have many applications. When a signal passes through a system, its phase angle changes due to dynamic characteristics of the system. Consequently, the phase change provides very useful information about the dynamic characteristics of the system. Specifically, for a linear constant-coefficient system, this phase shift is equal to the phase angle of the *frequency-response function* (*frequency-transfer function*) of the system at that particular frequency. This phase-shifting behavior is, of course, not limited to electrical systems and is equally exhibited by other types of systems including mechanical vibrating systems. The phase shift between two signals can be determined by converting the signals into the electrical form (using suitable transducers) and shifting the phase angle of one signal through known amounts, using a phase-shifting circuit, until the two signals are in phase.

Another application of phase shifters is in signal demodulation. For example, one method of amplitude demodulation involves processing the modulated signal together with the carrier signal. This, however, requires the modulated signal and the carrier signal to be in phase. Usually, however, since the modulated signal has already transmitted through electrical circuitry having impedance characteristics, its phase angle has changed. Then, it is necessary to shift the phase angle of the carrier until the two signals are in phase, so that demodulation can be performed accurately. Hence, phase shifters are used in demodulating, for example, when demodulating LVDT displacement-sensor outputs.

A phase-shifter circuit, ideally, should not change the signal amplitude while changing the phase angle by a required amount. Practical phase shifters can introduce some degree of amplitude distortion (with respect to frequency) as well. A simple phase-shifter circuit can be constructed using resistance (R) and capacitance (C) elements. A resistance or a capacitor of such an RC circuit is made fine-adjustable so as to obtain a variable phase shifter.

An opamp-based phase shifter circuit is shown in Figure 16.24. We can show that this circuit provides a phase shift without distorting the signal amplitude. The circuit equation is obtained by writing the current balance equations at nodes A and B, noting, as usual, that the current through the opamp leads

FIGURE 16.24 A phase-shifter circuit.

can be neglected due to high input impedance; thus

$$\frac{v_i - v_A}{R_C} = C \frac{dv_A}{dt}$$

$$\frac{v_i - v_B}{R} + \frac{v_o - v_B}{R} = 0$$

On simplifying and introducing the Laplace variable, we obtain

$$v_i = (\tau s + 1)v_A \quad (i)$$

and

$$v_B = \frac{1}{2}(v_i + v_o) \quad (ii)$$

in which, the circuit *time constant*, τ , is given by

$$\tau = R_C C$$

Since $v_A = v_B$ as a result of very high gain in the opamp, by substituting Equation ii into Equation i, we obtain

$$v_i = \frac{1}{2}(\tau s + 1)(v_i + v_o)$$

It follows that the transfer function $G(s)$ of the circuit is given by

$$\frac{v_o}{v_i} = G(s) = \frac{(1 - \tau s)}{(1 + \tau s)} \quad (16.102)$$

It is seen that the magnitude of the frequency-response function $G(j\omega)$ is

$$|G(j\omega)| = \frac{\sqrt{1 + \tau^2 \omega^2}}{\sqrt{1 + \tau^2 \omega^2}}$$

or

$$|G(j\omega)| = 1 \quad (16.103)$$

and the phase angle of $G(j\omega)$ is

$$\angle G(j\omega) = -\tan^{-1} \tau \omega - \tan^{-1} \tau \omega$$

or

$$\angle G(j\omega) = -2 \tan^{-1} \tau \omega = -2 \tan^{-1} R_C C \omega \quad (16.104)$$

As needed, the transfer function magnitude is unity, indicating that the circuit does not distort the signal amplitude over the entire bandwidth. Equation 16.104 gives the *phase lead* of the output, v_o , with respect to the input, v_i . Note that this angle is negative, indicating that actually a *phase lag* is introduced. The phase shift can be adjusted by varying the resistance, R_C .

16.8.2 Voltage-to-Frequency Converter

A voltage-to-frequency converter (VFC) generates a periodic output signal whose frequency is proportional to the level of an input voltage. Since such an *oscillator* generates a periodic output according to the voltage excitation, it is also called a *voltage-controlled oscillator* (VCO).

A common type of VFC uses a capacitor. The time needed for the capacitor to be charged to a fixed voltage level will depend on the charging voltage (it is inversely proportional). Suppose that this voltage is governed by the input voltage. Then, if the capacitor is made to periodically charge and discharge, we have an output whose frequency (inverse of the charge–discharge period) is proportional to the charging voltage. The output amplitude will be given by the fixed voltage level to which the capacitor is charged in

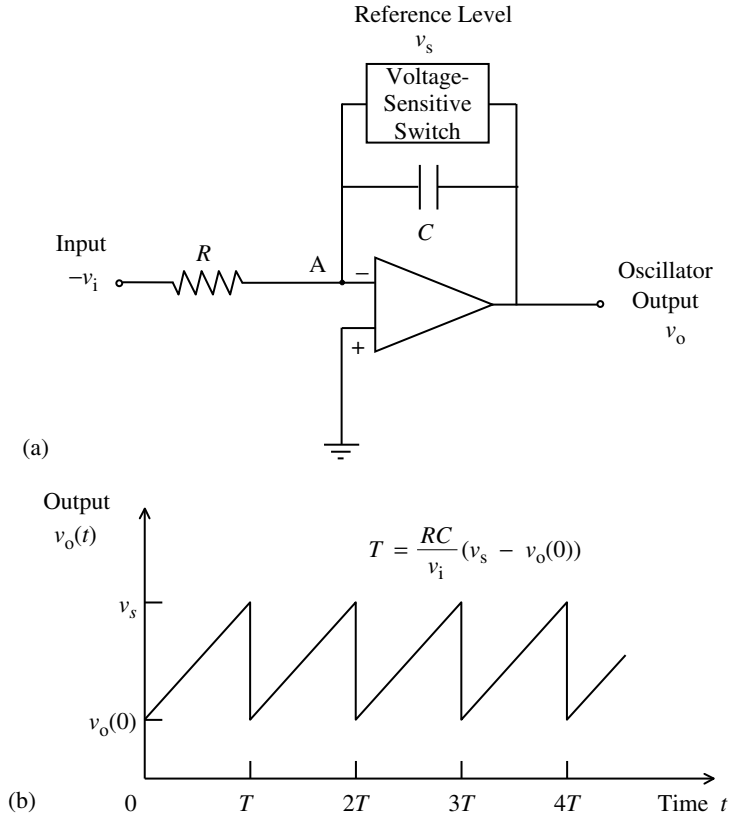

FIGURE 16.25 A voltage-to-frequency converter (voltage-controlled oscillator): (a) circuit; (b) output signal.

each cycle. Consequently, we have a signal with a fixed amplitude and a frequency that depends on the charging voltage (input).

A VFC (or VCO) circuit is shown in Figure 16.25(a). The voltage-sensitive switch closes when the voltage across it exceeds a reference level, v_s , and it opens again when the voltage across it falls below a lower limit, $v_o(0)$. The *programmable unijunction transistor* (PUT) is such a switching device.

Note that the polarity of the input voltage, v_i , is reversed. Suppose that the switch is open. Then, current balance at node A of the opamp circuit gives

$$\frac{v_i}{R} = C \frac{dv_o}{dt}$$

As usual, $v_A = \text{voltage at positive lead} = 0$ because the opamp has a very high gain, and current through the opamp leads $= 0$ because the opamp has a very high input impedance. The capacitor charging equation can be integrated for a given value of v_i . This gives

$$v_o(t) = \frac{1}{RC} v_i t + v_o(0)$$

The switch is closed when the voltage across the capacitor $v_o(t)$ equals the reference level v_s . Then, the capacitor will be immediately discharged through the closed switch. Hence, the capacitor charging time, T , is given by

$$v_s = \frac{1}{RC} v_i T + v_o(0)$$

Accordingly,

$$T = \frac{RC}{v_i}(v_s - v_o(0)) \quad (16.105)$$

The switch opens again when the voltage across the capacitor drops to $v_o(0)$, and the capacitor again begins to charge from $v_o(0)$ up to v_s . This charging and instantaneous discharge cycle repeats periodically. The corresponding output signal is as shown in Figure 16.25(b). This is a periodic (*sawtooth*) wave with period T . The frequency of oscillation of the output ($1/T$) is given by

$$f = \frac{v_i}{RC(v_s - v_o(0))} \quad (16.106)$$

It is seen that the oscillator frequency is proportional to the input voltage v_i . The oscillator amplitude is v_s , which is fixed.

VCOs have many applications. One application is in *analog-to-digital conversion*. In the VCO type analog-to-digital converters, the analog signal is converted into an oscillating signal using a VCO. Then, the oscillator frequency is measured using a *digital counter*. This count, which is available in the digital form, is representative of the input analog signal level. Another application is in digital voltmeters. Here, the same method as for ADC is used. Specifically, the voltage is converted into an oscillator signal and its frequency is measured using a digital counter. The count can be scaled and displayed to provide the voltage measurement. A direct application of the VCO is apparent from the fact it is actually a *frequency modulator*, providing a signal whose frequency is proportional to the input (modulating) signal. Hence, the VCO is useful in applications that require frequency modulation. Also, a VCO can be used as a signal (wave) generator for variable-frequency applications; for example, it can be used for excitation inputs for shakers in vibration testing, excitations for frequency-controlled DC motors, and pulse signals for translator circuits of stepping motors.

16.8.3 Frequency-to-Voltage Converter

A frequency-to-voltage converter (FVC) generates an output voltage whose level is proportional to the frequency of its input signal. One way to obtain a FVC is to use a digital counter to count the signal frequency and then use a DAC to obtain a voltage proportional to the frequency. A schematic representation of this type of FVC is shown in Figure 16.26(a).

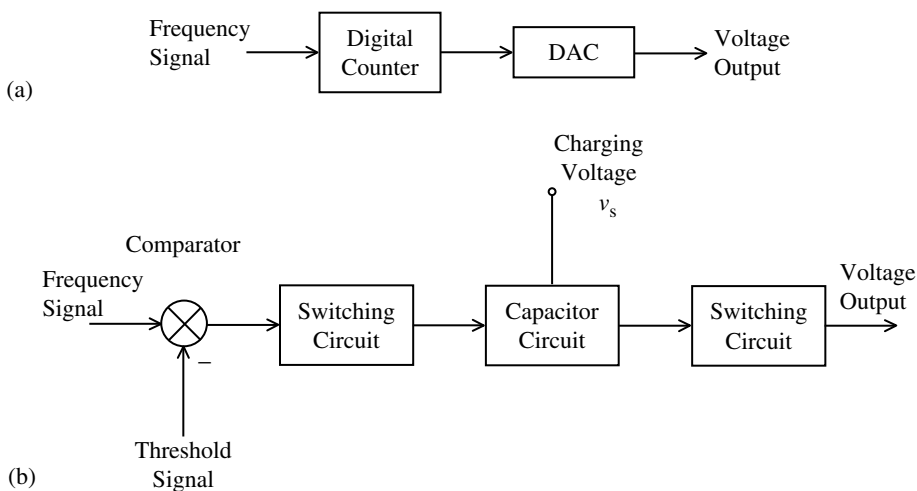

FIGURE 16.26 Frequency-to-voltage converters: (a) digital counter method; (b) capacitor charging method.

An alternative FVC circuit is schematically shown in Figure 16.26(b). In this method, the frequency signal is supplied to a comparator along with a threshold voltage level. The sign of the comparator output will depend on whether the input signal level is larger or smaller than the threshold level. The first sign change (negative to positive) in the comparator output is used to trigger a switching circuit that will respond by connecting a capacitor to a fixed charging voltage. This will charge the capacitor. The next sign change (positive to negative) of the comparator output will cause the switching circuit to short the capacitor, thereby instantaneously discharging it. This charging–discharging process will be repeated in response to the oscillator input. Note that the voltage level to which the capacitor is charged each time will depend on the switching period (charging voltage is fixed), which is in turn governed by the frequency of the input signal. Hence, the output voltage of the capacitor circuit will be representative of the frequency of the input signal. Since the output is not steady due to the ramp-like charging curve and instantaneous discharge, a smoothing circuit is provided at the output to remove the noisy ripples.

Applications of FVC include demodulation of frequency-modulated signals, frequency measurement in mechanical vibration applications, and conversion of pulse outputs in some types of sensors and transducers into analog voltage signals.

16.8.4 Voltage-to-Current Converters

Measurement and feedback signals are usually transmitted as current levels in the range of 4 to 20 mA rather than as voltage levels. This is particularly useful when the measurement site is not close to the monitoring room. Since the measurement itself is usually available as a voltage, it has to be converted into current by using a voltage-to-current converter (VCC). For example, pressure transmitters and temperature transmitters in operability testing systems provide current outputs that are proportional to the measured values of pressure and temperature.

There are many advantages to transmitting current rather than voltage. In particular, the voltage level will drop due to resistance in the transmitting path, but the current through a conductor will remain unchanged unless the conductor is branched. Hence, current signals are less likely to acquire errors due to signal weakening. Another advantage of using current instead of voltage as the measurement signal is that the same signal can be used to operate several devices in series (for example, a display, a plotter, and a signal processor simultaneously), without causing errors through signal weakening due to the power lost at each device, because the same current is applied to all devices. A VCC should provide a current proportional to an input voltage without being affected by the load resistance to which the current is supplied.

An operational-amplifier-based voltage-to-current convert circuit is shown in Figure 16.27. Using the fact that the currents through the input leads of an unsaturated opamp can be neglected (due to very high input impedance), we write the current summation equations for the two nodes, A and B, thus:

$$\frac{v_A}{R} = \frac{v_P - v_A}{R}$$

and

$$\frac{v_i - v_B}{R} + \frac{v_P - v_B}{R} = i_o$$

Accordingly, we have

$$2v_A = v_P \quad (i)$$

FIGURE 16.27 A voltage-to-current converter.

and

$$v_i - 2v_B + v_P = Ri_o \quad (\text{ii})$$

Now, using the fact that $v_A = v_B$ for the opamp (due to very high gain), we substitute Equation i into Equation ii. This gives

$$i_o = \frac{v_i}{R} \quad (16.107)$$

in which

i_o = output current

v_i = input voltage

It follows that the output current is proportional to the input voltage, irrespective of the value of the load resistance, R_L , as required for a VCC.

16.8.5 Peak-Hold Circuits

Unlike a S/H circuit that holds every sampled value of the signal, a peak-hold circuit holds only the largest value reached by the signal during the monitored period. Peak holding is useful in a variety of applications. In signal processing for shock and vibration studies, what are known as *response spectra* (e.g., a *shock response spectrum*) are determined by using a *response spectrum analyzer* that exploits a peak holding scheme. Suppose that a signal is applied to a simple oscillator (a single-degree-of-freedom second-order system with no zeros) and the peak value of the response (output) is determined. A plot of the peak output as a function of the natural frequency of the oscillator, for a specified damping ratio, is known as the response spectrum of the signal for that damping ratio. Peak detection is also useful in machine monitoring and alarm systems. In short, when just one representative value of a signal is needed in a particular application, the peak value is a leading contender.

Peak detection of a signal can be conveniently done using digital processing. For example, the signal may be sampled and the previous sample value replaced by the present sample value if and only if the latter is larger than the former. By sampling and then holding one value in this manner, the peak value of the signal is retained. Note that, usually, the time instant at which the peak occurs is not retained.

Peak detection can be done using analog circuitry as well. This is, in fact, the basis of analog spectrum analyzers. A peak-holding circuit is shown in Figure 16.28. The circuit consists of two voltage followers. The first voltage follower has a diode at its output that is forward biased by the positive output of the voltage follower and reverse-biased by a low-leakage capacitor, as shown. The second voltage follower presents the peak voltage that is held by the capacitor to the circuit output at a low output impedance, without loading the previous circuit stage (capacitor and first voltage follower). To understand the operation of the circuit, suppose that the input voltage, v_i , is larger than the voltage to which capacitor is charged (v). Since the voltage at the positive lead of the opamp is v_i and the voltage at the negative lead is v , the first opamp will be saturated. Since the differential input to the opamp is positive under these conditions, the opamp output will be positive. The output will charge the capacitor until the capacitor voltage, v , equals the input voltage, v_i . This voltage (call it v_o) is in turn supplied to the second voltage follower which presents the same value to its output (gain = 1 for a voltage follower), but at a very low impedance level. Note that the opamp output remains at the saturated value only for a very short time (the time taken by the capacitor to charge). Now, suppose that v_i is smaller than v . Then, the differential input of the opamp will be negative, and the opamp output will be saturated at the negative saturation level. This will reverse bias the diode. Hence, the output of the first opamp will be in open circuit, and as a result the voltage supplied to the output voltage follower

FIGURE 16.28 A peak-holding circuit.

would still be the capacitor voltage and not the output of the first opamp. It follows that the voltage level of the capacitor (and hence the output of the second voltage follower) would always be the peak value of the input signal. The circuit can be reset by discharging the capacitor through a solid-state switch that is activated by an external pulse.

16.9 Signal Analyzers and Display Devices

Vibration signal analysis may employ both analog and digital procedures. Since signal analysis results in extracting various useful bits of information from the signal, it is appropriate to consider the topic within the present context of signal modification as well. Here, we will introduce digital signal analyzers.

Signal display devices also make use of at least some signal processing. This may involve filtering and change of the signal level and format. More sophisticated signal display devices, particularly digital oscilloscopes, can carry out more complex signal analysis functions such as those normally available with digital signal analyzers. Oscilloscopes as well are introduced in the present section, though they may be treated under vibration instrumentation.

Signal-recording equipment commonly employed in vibration practice includes digital storage devices such as hard drives, floppy disks, and CD-ROMs, analog devices like tape recorders, strip-chart recorders and X - Y plotters, and digital printers. Tape recorders are used to record vibration data (transducer outputs) that are subsequently reproduced for processing or examination. Often, tape-recorded waveforms are also used to generate (by replay) signals that drive vibration test exciters (shakers). Tape recorders use tapes made of a plastic material that has a thin coating of a specially treated ferromagnetic substance. During the recording process, magnetic flux proportional to the recorded signal is produced by the recording head (essentially an electromagnet), which magnetizes the tape surface in proportion to the signal variation. Reproduction is the reverse process, whereby an electrical signal is generated at the reproduction head by electromagnetic induction in accordance with the magnetic flux of the magnetized (recorded) tape. Several signal-conditioning circuitries are involved in the recording and reproducing stages. Recording by FM is very common in vibration testing.

Strip-chart recorders are usually employed to plot time histories (that is, quantities that vary with time), although they also may be used to plot such data as frequency-response functions and response spectra. In these recorders, a paper roll unwinds at a constant linear speed, and the writing head moves across the paper (perpendicular to the paper motion) proportionally to the signal level. There are many kinds of strip-chart recorders, which are grouped according to the type of writing head that is employed. Graphic-level recorders, which use ordinary paper, employ such heads as ink pens or brushes, fiber pens, and sapphire styli. Visicoders are simple oscilloscopes that are capable of producing permanent records; they employ light-sensitive paper for this. Several channels of input data can be incorporated with a visicoder. Obviously, graphic-level recorders are generally limited by the number of writing heads possible (typically, one or two), but visicoders can have many more input channels (typically, 24). Performance specifications of these devices include paper speed, frequency range of operation, dynamic range, and power requirements.

In vibration experimentation, X - Y plotters are generally employed to plot frequency data (for example, PSD, frequency-response functions, response spectra, transmissibility curves), although they also can be used to plot time-history data. Many types of X - Y plotter are available, most of them using ink pens and ordinary paper. There are also hard-copy units that use heat-sensitive paper in conjunction with a heating element as the writing head. The writing head in an X - Y plotter is moved in the X and Y directions on the paper by two input signals that form the coordinates for the plot. In this manner, a trace is made on stationary plotting paper. Performance specifications of X - Y plotters are governed by such factors as paper size; writing speed (in./sec, cm/sec); dead band (expressed as a percentage of the full scale), which measures the resolution of the plotter head; linearity (expressed as a percentage of the full scale), which measures the accuracy of the plot; minimum trace separation (in., cm) for multiple plots on the same axes; dynamic range; input impedance; and maximum input (mV/in., mV/cm).

Today, the most widespread signal recording device is in fact the digital computer (memory, storage) and printer combination. This and the other (analog) devices used in signal recording and display make use of some signal modification to accomplish their functions. However, we will not discuss these devices in the present section.

16.9.1 Signal Analyzers

Modern signal analyzers employ digital techniques of signal analysis to extract useful information that is carried by the signal. Digital Fourier analysis using FFT is perhaps the single common procedure that is used in the vast majority of signal analyzers. As we have noted before, Fourier analysis will produce the frequency spectrum of a time signal. It should be clear, therefore, why the terms digital signal analyzer, FFT analyzer, frequency analyzer, spectrum analyzer, and digital Fourier analyzer are to some extent synonymous as used in the commercial instrumentation literature.

A signal analyzer typically has two (dual) or more (multiple) input signal channels. To generate results such as frequency response (transfer) functions, cross spectra, coherence functions, and cross-correlation functions, we need at least two data signals and hence a dual-channel analyzer.

In hardware analyzers, digital circuitry rather than software is used to carry out the mathematical operations. Clearly, these are very fast but less flexible (in terms of programmability and functional capability) for this reason. Digital signal analyzers, regardless of whether they use the hardware or the software approach, employ some basic operations. These operations, carried out in sequence, are:

1. Antialias filtering (analog)
2. Analog-to-digital conversion (i.e., single sampling)
3. Truncation of a block of data and multiplication by a window function
4. FFT analysis of the block of data

We have noted the following facts. If the sampling period of the ADC is ΔT (i.e., the sampling frequency is $1/\Delta T$) then the Nyquist frequency $f_c = 1/2\Delta T$. This Nyquist frequency is the upper limit of the useful frequency content of the sampled signal. The cutoff frequency of the antialiasing filter should be set at f_c or less. If there are N data samples in the block of data that is used in the FFT analysis, the corresponding record length is $T = N \cdot \Delta T$. Then, the spectral lines in the FFT results are separated at a frequency spacing of $\Delta F = 1/T$. In view of the Nyquist frequency limit, there will be only $N/2$ useful spectral lines of FFT result.

Strictly speaking, a real-time signal analyzer should analyze a signal instantaneously and continuously as the signal is received by the analyzer. This is usually the case with an analog signal analyzer. However, in digital signal analyzers, which are usually based on digital Fourier analysis, a block of data (i.e., N samples of record length T) is analyzed together to produce $N/2$ useful spectral lines (at frequency spacing $1/T$). This is, then, not a truly real-time analysis. For practical purposes, if the speed of analysis is sufficiently fast, the analyzer may be considered real time, which is usually the case with hardware analyzers and also modern, high-speed software analyzers.

The bandwidth B of a digital signal analyzer is a measure of its speed of signal processing. Specifically, for an analyzer that uses N data samples in each block of signal analysis, the associated processing time may be given by

$$T_c = \frac{N}{B} \quad (16.108)$$

Note that the larger the B , the smaller the T_c . The analyzer is considered real-time if the analysis time (T_c) of the data record is less than the generation time ($T = N \cdot \Delta T$) of the data record. Hence, we need

$$T_c < T$$

or

$$\frac{N}{B} < T$$

or

$$\frac{N}{B} < N \cdot \Delta T$$

or

$$\frac{1}{\Delta T} < B \quad (16.109)$$

In other words, a real-time analyzer has a bandwidth greater than its sampling rate.

A multichannel digital signal analyzer can analyze one or more signals simultaneously and generate (and display) results such as Fourier spectra, power spectral densities, cross spectral densities, frequency-response functions, coherence functions, autocorrelations, and cross correlations. They are able to perform high-resolution analysis on a small segment of the frequency spectrum of a signal. This is termed *zoom analysis*. Essentially, in this case, the spectral line spacing, ΔF , is decreased while keeping the number of lines (N), and hence the number of time data samples, the same. That means the record length ($T = 1/\Delta F$) has to be increased in proportion, for zoom analysis.

16.9.2 Oscilloscopes

An oscilloscope is used to observe one or two signals separately or simultaneously. Amplitude, frequency, and phase information of the signals can be obtained using an oscilloscope. In this sense, the oscilloscope is a signal modification as well as a measurement (monitoring) and display device. Both analog and digital oscilloscopes are available. A typical application of an oscilloscope is to observe (monitor) experimental data such as vibration signals of machinery as obtained from transducers. They are also useful in observing and examining vibration test results, such as frequency-response plots, PSD curves, and response spectra. Typically, only temporary records are available on an analog oscilloscope screen. The main component of an analog oscilloscope is the cathode-ray tube (CRT), which consists of an electron gun (cathode) that deflects an electron ray according to the input-signal level. The oscilloscope screen has a coating of electron-sensitive material, so that the electron ray that impinges on the screen leaves a temporary trace on it. The electron ray sweeps across the screen horizontally, so that waveform traces can be recorded and observed. Usually, two input channels are available. Each input may be observed separately, or the variations in one input may be observed against those of the other. In this manner, signal phasing can be examined. Several sensitivity settings for the input-signal-amplitude scale (in the vertical direction) and sweep-speed selections are available on the panel.

16.9.2.1 Triggering

The voltage level of the input signal deflects the electron gun proportionally in the vertical (y -axis) direction on the CRT screen. This alone will not show the time evolution of the signal. The true time variation of the signal is achieved by means of a sawtooth signal that is generated internally in the oscilloscope and used to move the electron gun in the horizontal (x -axis) direction. As the name implies, the sawtooth signal increases linearly in amplitude until a threshold value then suddenly drops to zero, and then repeats this cycle again. In this manner, the observed signal is repetitively swept across the screen and a trace of it can be observed as a result of the temporary retention of the illumination of the electron gun on the fluorescent screen. The sawtooth signal may be controlled (triggered) in several ways. For example, the *external trigger* mode uses an external signal from another channel (not the observed channel) to generate and synchronize the sawtooth signal. In the *line trigger* mode, the sawtooth signal is synchronized with the AC line supply (60 or 50 Hz). In the *internal trigger* mode, the observed signal (which is used to deflect the electron beam in the y direction) itself is used to generate (synchronize) the

sawtooth signal. Since the frequency and the phase of the observed signal and the trigger signal are perfectly synchronized in the last case, the trace on the oscilloscope screen will appear stationary. Careful observation of a signal can be made in this manner.

16.9.2.2 Lissajous Patterns

Suppose that two signals, x and y , are provided to the two channels of an oscilloscope. If they are used to deflect the electron beam in the horizontal and the vertical directions, respectively, a pattern known as Lissajous pattern will be observed on the oscilloscope screen. Useful information about the amplitude and phasing of the two signals may be observed by means of these patterns. Consider sine waves x and y . Several special cases of Lissajous patterns are given below.

1. *Same frequency, same phase:* Here,

$$x = x_o \sin(\omega t + \phi)$$

$$y = y_o \sin(\omega t + \phi)$$

Then we have

$$\frac{x}{x_o} = \frac{y}{y_o}$$

which gives a straight-line trace with a positive slope, as shown in Figure 16.29(a).

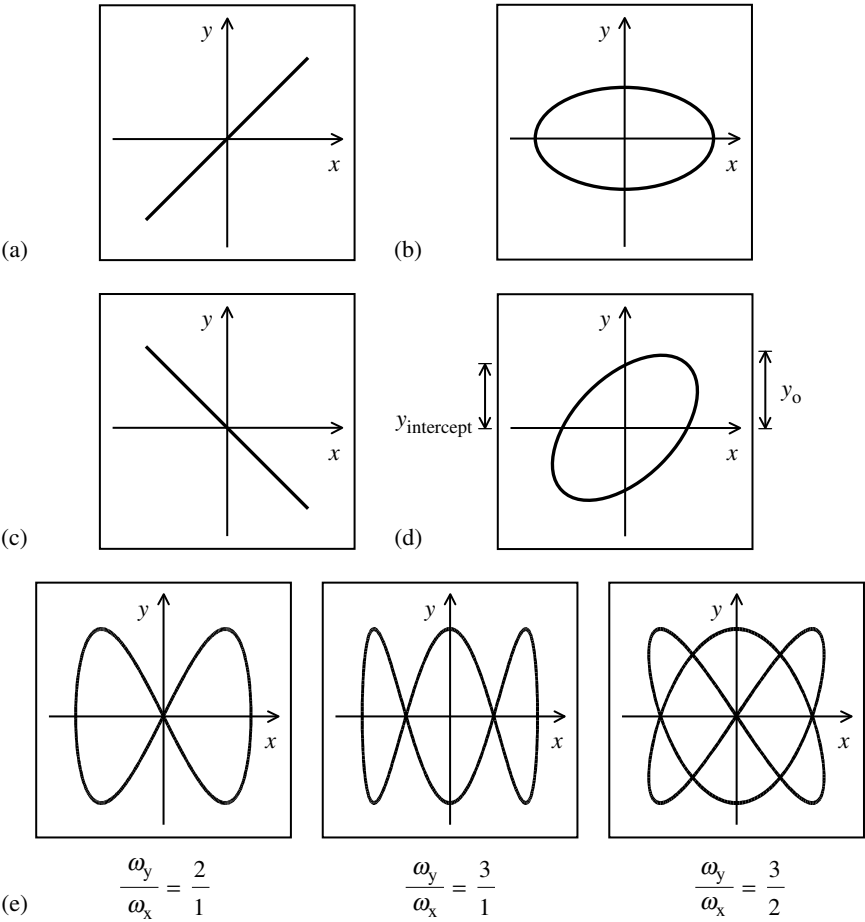

FIGURE 16.29 Some Lissajous patterns: (a) equal frequency and in-phase; (b) equal frequency and 90° out-of-phase; (c) equal frequency and 180° out-of-phase; (d) equal frequency and θ out-of-phase; (e) integral frequency ratio.

2. *Same frequency, 90° out-of-phase:* Here,

$$x = x_o \sin(\omega t + \phi)$$

$$y = y_o \sin(\omega t + \phi + \pi/2) = y_o \cos(\omega t + \phi)$$

Then we have

$$\left(\frac{x}{x_o}\right)^2 + \left(\frac{y}{y_o}\right)^2 = 1$$

which gives an ellipse, as shown in Figure 16.29(b).

3. *Same frequency, 180° out-of-phase:* Here,

$$x = x_o \sin(\omega t + \phi)$$

$$y = y_o \sin(\omega t + \phi + \pi) = -y_o \sin(\omega t + \phi)$$

Hence,

$$\frac{x}{x_o} + \frac{y}{y_o} = 0$$

which corresponds to a straight line with a negative slope, as shown in Figure 16.29(c).

4. *Same frequency, θ out-of-phase:*

$$x = x_o \sin(\omega t + \phi)$$

$$y = y_o \sin(\omega t + \phi + \theta)$$

When $\omega t + \phi = 0$, $y = y_{\text{intercept}} = y_o \sin \theta$.

Hence,

$$\sin \theta = \frac{y_{\text{intercept}}}{y_o}$$

In this case, we obtain a tilted ellipse as shown in Figure 16.29(d). The phase difference θ is obtained from the Lissajous pattern.

5. *Integral frequency ratio:*

$$\frac{\omega_y}{\omega_x} = \frac{\text{Number of } y\text{-peaks}}{\text{Number of } x\text{-peaks}}$$

Three examples are shown in Figure 16.29(e).

$$\frac{\omega_y}{\omega_x} = \frac{2}{1}, \quad \frac{\omega_y}{\omega_x} = \frac{3}{1}, \quad \frac{\omega_y}{\omega_x} = \frac{3}{2}$$

Note: The above observations are true for narrowband signals as well. Broadband random signals produce scattered (irregular) Lissajous patterns.

16.9.2.3 Digital Oscilloscopes

The basic uses of a digital oscilloscope are quite similar to those of a traditional analog oscilloscope. The main differences stem from the manner in which information is represented and processed “internally” within the oscilloscope. Specifically, a digital oscilloscope first samples a signal that arrives at one of its input channels and stores the resulting digital data within a memory segment. This is essentially a typical ADC operation. This digital data may be processed to extract and display the necessary information. The sampled data and the processed information may be stored on a floppy disk, if needed, for further processing using a digital computer. Also, some digital oscilloscopes have the

communication capability so that the information may be displayed on a video monitor or printed to provide a hard copy.

A typical digital oscilloscope has four channels so that four different signals may be acquired (sampled) into the oscilloscope and displayed. Also, it has various triggering options so that the acquisition of a signal may be initiated and synchronized by means of either an internal or an external trigger. Apart from the typical capabilities that are possible with an analog oscilloscope, a digital oscilloscope can automatically provide other useful features such as the following:

1. Automatic scaling of the acquired signal
2. Computation of signal features such as frequency, period, amplitude, mean, root-mean-square (rms) value, and rise time
3. Zooming into regions of interest of a signal record
4. Averaging of multiple signal records
5. Enveloping of multiple signal records
6. FFT capability, with various window options and antialiasing

These various functions are menu selectable. Typically, first a channel of the incoming data (signal) is selected and then an appropriate operation on the data is chosen from the menu (through menu buttons).

Summary

Vibration testing involves application of a vibration excitation to a test object and monitoring the resulting response. The first step in vibration testing is the generation of a test excitation according to some specification or objective. The applied excitation and the corresponding responses are measured at designated locations of the test object. Analysis of the test data will generate useful information about the tested object, which may be applicable in design development, manufacture, and utilization of the object. This chapter presents the basics of the planning of vibration tests, test signal representation and generation, vibration testing, and test data acquisition.

17.1 Introduction

Vibration testing is usually performed by applying a vibratory excitation to a test object and monitoring the structural integrity of the object and its performance of its intended function. The technique may be useful in several stages: (1) *design development*, (2) *production*, and (3) *utilization* of a product. In the initial design stage, the design weaknesses and possible improvements can be determined through the vibration testing of a preliminary design prototype or a partial product. In the production stage, the quality of the workmanship of the final product can be evaluated using both destructive and nondestructive vibrating testing. A third application termed *product qualification*, is intended for determining the adequacy of a product of good quality for a specific application (e.g., the seismic qualification of a nuclear power plant) or a range of applications.

The technology of vibration testing has evolved rapidly since World War II and the technique has been successfully applied to a wide spectrum of products ranging from small printed circuit boards and microprocessor chips to large missiles and structural systems. Until recently, however, much of the signal processing that was required in vibration testing was performed through analog methods. In these methods, the measured signal is usually converted into an electric signal, which in turn is passed through a series of electrical or electronic circuits to achieve the required processing. Alternatively, motion or pressure signals can be used in conjunction with mechanical or hydraulic (e.g., fluidic) circuits to perform analog processing. Today's complex test programs require the capability for the fast and accurate processing of a large number of measurements. The performance of analog signal analyzers is limited by hardware costs, size, data handling capacity and computational accuracy. Digital processing for the synthesis and analysis of vibration test signals and for the interpretation and evaluation of test results, began to replace the classical analog methods in late 1960s. Today, special-purpose digital analyzers with real-time digital Fourier analysis capability are commonly used in vibration testing applications. The advantages of incorporating digital processing into vibration testing include: flexibility and convenience with respect to the type of the signal that can be analyzed and the complexity of the nature of processing that can be handled; increased speed of processing, accuracy and reliability; reduction in operational costs; practically unlimited repeatability of processing; and reduction in the overall size and weight of the analyzer.

Vibration testing is usually accomplished using a shaker apparatus, as shown by the schematic diagram in Figure 17.1. The test object is secured to the shaker table in a manner representative of its installation during actual use (service). In-service operating conditions are simulated while the shaker table is actuated by applying a suitable input signal. The shakers of different types, with electromagnetic, electromechanical, or hydraulic actuators, are available. The shaker device may depend on the test requirement, availability, and cost. More than one signal may be required to simulate three-dimensional characteristics of the vibration environment. The test input signal is either stored on an analog magnetic tape or generated in real-time by a signal generator. The capability of the test object or a similar unit to withstand a "predefined" vibration environment is evaluated by monitoring the dynamic response (accelerations, velocities, displacements, strains, etc.) and functional operability variables (e.g., temperatures, pressures, flow rates, voltages, currents). Analysis of the response signals will aid in detecting existing defects or impending failures in various components of the test equipment. The control sensor output is useful in several ways, particularly in feedback control of the shaker, frequency-band equalization in real-time of the excitation signal, and the synthesizing of future test signals.

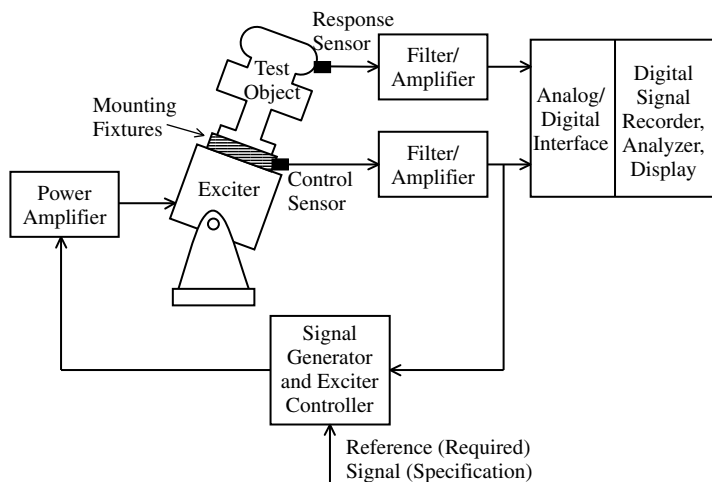

FIGURE 17.1 A typical vibration-testing arrangement.

The excitation signal is applied to the shaker through a shaker controller, which usually has a built-in power amplifier. The shaker controller compares the “control sensor” signal from the shaker–test object interface with the reference excitation signal from the signal generator. The associated error is used to control the shaker motion so as to push this error to zero. This is termed “equalization.” Hence, a shaker controller serves as an equalizer as well.

The signals that are monitored from the test object include test response signals and operability signals. The former category of signals provides the dynamic response of the test object, and may include velocities, accelerations, and strains. The latter category of signals are used to check whether the test object performs in-service functions (i.e., it operates properly) during the test excitation, and may include flow rates, temperatures, pressures, currents, voltages, and displacements. The signals may be recorded in a computer or a digital oscilloscope for subsequent analysis. When using an oscilloscope or a spectrum analyzer, some analysis can be done on line and the results are displayed immediately.

The most uncertain part of a vibration test program is the simulation of the test input. For example, the operating environment of a product such as an automobile is not deterministic and will depend on many random factors. Consequently, it is not possible to generate a single test signal that can completely represent all various operating conditions. As another example, in seismic qualification of equipment, the primary difficulty stems from the fact that the probability of accurately predicting the recurrence of an earthquake at a given site during the design life of the equipment is very small and that of predicting the nature of the ground motions if an earthquake were to occur is even smaller. In this case, the best that one can do is to make a conservative estimate for the nature of the ground motions due to the strongest earthquake that is reasonably expected. The test input should have (1) *amplitude*, (2) *phasing*, (3) *frequency content*, and (4) *damping* characteristics comparable to the expected vibration environment if satisfactory representation is to be achieved. A frequency-domain representation of the test inputs and responses can, in general, provide better insight regarding their characteristics than can a time domain representation, namely, a time history. Fortunately, frequency-domain information can be derived from time domain data by using Fourier transform techniques.

In vibration testing, Fourier analysis is used in three principal ways: first, to determine the frequency response of the test object in prescreening tests; second, to represent the vibration environment by its Fourier spectrum or its power spectral density (PSD) so that a test input signal can be generated to represent it; and third, to monitor the Fourier spectrum of the response at key locations in the test object and at control locations of the test table and use the information diagnostically or in controlling the exciter.

The two primary steps of a vibration testing scheme are:

Step 1: Specify the test requirements;

Step 2: Generate a vibration test signal that conservatively satisfies the specifications of Step 1.

17.2 Representation of a Vibration Environment

A complete knowledge of the vibration environment in which a device will be operating is not available to the test engineer or the test program planner. The primary reason for this is that the operating environment is a random process. When performing a vibration test, however, either a deterministic or a random excitation can be employed to meet the test requirements. This is known as the test environment.

Based on the vibration-testing specifications or product qualification requirements, the test environment should be developed to have the required characteristics of (1) intensity (amplitude), (2) frequency content (effect on the test-object resonances and the like), (3) decay rate (damping), and (4) phasing (dynamic interactions). Usually, these parameters are chosen to represent conservatively the worst possible vibration environment that is reasonably expected during the design life of the test object. So long as this requirement is satisfied, it is not necessary for the test environment to be identical to the operating vibration environment.

In vibration testing, the excitation input (test environment) can be represented in several ways. The common representations are (1) by time signal, (2) by response spectrum, (3) by Fourier spectrum, and (4) by PSD function. Once the required environment is specified by one of these forms, the test should be conducted either by directly employing them to drive the exciter or by using a more conservative excitation when the required environment cannot be exactly reproduced.

17.2.1 Test Signals

Vibration testing may employ both random and deterministic signals as test excitations. Regardless of its nature, the test input should conservatively meet the specified requirements for that test.

17.2.1.1 Stochastic vs. Deterministic Signals

Consider a seismic time-history record. Such a ground-motion record is not stochastic. It is true that earthquakes are random phenomena and the mechanism by which the time history was produced is a random process. Once a time history is recorded, however, it is known completely as a curve of response value versus time (a deterministic function of time). Therefore, it is a deterministic set of information. However, it is also a “sample function” of the original stochastic process, the earthquake, by which it was generated. Hence, valuable information about the original stochastic process itself can be determined by analyzing this sample function on the basis of the *ergodic hypothesis* (see Section 17.2.3). Some may think that an irregular time-history record corresponds to a random signal. It should be remembered that some random processes produce very smooth signals. As an example, consider the sine wave given by $a \sin(\omega t + \phi)$. Let us assume that the amplitude a and the frequency ω are deterministic quantities and the phase angle ϕ is a random variable. This is a random process. Every time this particular random process is activated, a sine wave is generated that has the same amplitude and frequency but, generally, a different phase angle. Nevertheless, the sine wave will always appear as smooth as a deterministic sine wave.

In a vibration-testing program, if we use a recorded time history to derive the exciter, it is a deterministic signal, even if it was originally produced by a random phenomenon such as an earthquake. Also, if we use a mathematical expression for the signal in terms of completely known (deterministic) parameters, it is again a deterministic signal. If the signal is generated by some random mechanism (whether computer simulation or physical) in real time, however, and if that signal is used as the excitation in the vibration test simultaneously as it is being generated, then we have a truly random excitation. Also, if we use a mathematical expression (with respect to time) for the excitation signal for which some of the parameters are not known numerically and the values are assigned to them during the test in a random manner, we again have a truly random test signal.

17.2.2 Deterministic Signal Representation

In vibration testing, time signals that are completely predefined can be used as test excitations. They should be capable, however, of subjecting the test object to the specified levels of intensity, frequency, decay rate, and phasing (in the case of simultaneous multiple test excitations).

Deterministic excitation signals (time histories) used in vibration testing are divided into two broad categories: single-frequency signals and multifrequency signals.

17.2.2.1 Single-Frequency Signals

Single-frequency signals have only one predominant frequency component at a given time. For the entire duration, however, the frequency range covered is representative of the frequency content of the vibration environment. For seismic-qualification purposes, for example, this range should be at least 1 to 33 Hz. Some typical single-frequency signals that are used as excitation inputs in vibration testing of equipment are shown in [Figure 17.2](#). The signals shown in the figure can be expressed by simple mathematical expressions. This is not a requirement, however. It is acceptable to store a very complex signal in a storage device and subsequently use it in the procedure. In picking a particular time history, we should give

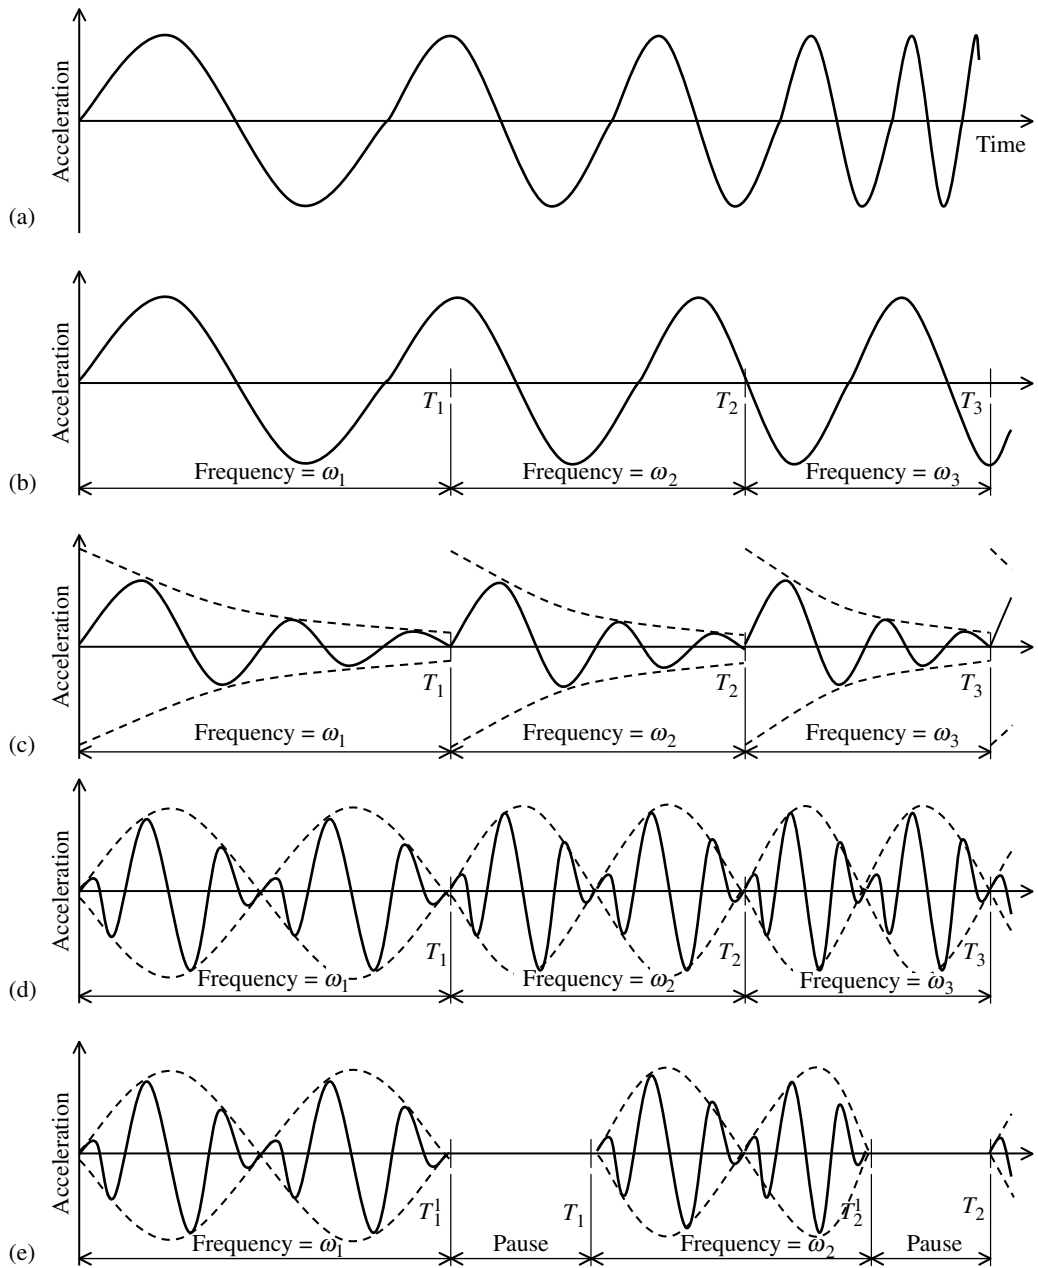

FIGURE 17.2 Typical single-frequency test signals: (a) sine sweep; (b) sine dwell; (c) sine decay; (d) sine beat; (e) sine beat with pause.

proper consideration to its ease of reproduction and the accuracy with which it satisfies the test specifications. Now, let us describe mathematically the acceleration signals shown in Figure 17.2.

17.2.2.2 Sine Sweep

We obtain a sine sweep by continuously varying the frequency of a sine wave. Mathematically,

$$u(t) = a \sin[\omega(t)t + \phi] \tag{17.1}$$

The amplitude, a , and the phase angle, ϕ , are usually constants and the frequency, $\omega(t)$, is a function of time. Both linear and exponential variations of frequency over the duration of the test are in common usage, but exponential variations are more common. For the linear variation (see Figure 17.3), we have

$$\omega(t) = \omega_{\min} + (\omega_{\max} - \omega_{\min}) \frac{t}{T_d} \quad (17.2)$$

in which

ω_{\min} = lowest frequency in the sweep

ω_{\max} = highest frequency in the sweep

T_d = duration of the sweep

For the exponential variation (see Figure 17.3), we have

$$\log \left[\frac{\omega(t)}{\omega_{\min}} \right] = \frac{t}{T_d} \log \left[\frac{\omega_{\max}}{\omega_{\min}} \right] \quad (17.3)$$

or

$$\omega(t) = \omega_{\min} \left[\frac{\omega_{\max}}{\omega_{\min}} \right]^{t/T_d} \quad (17.4)$$

This variation is sometimes incorrectly called logarithmic variation. This confusion arises because of its definition using Equation 17.3 instead of Equation 17.4. It is actually an inverse logarithmic (i.e., exponential) variation. Note that the logarithm in Equation 17.3 can be taken to any arbitrary base. If base ten is used, the frequency increments are measured in *decades* (multiples of ten); if base two is used, the frequency increments are measured in *octaves* (multiples of two). Thus, the number of decades in the frequency range from ω_1 to ω_2 is given by $\log_{10}(\omega_2/\omega_1)$; for example, with $\omega_1 = 1$ rad/sec and $\omega_2 = 100$ rad/sec, we have $\log_{10}(\omega_2/\omega_1) = 2$, which corresponds to two decades. Similarly, the number of octaves in the range ω_1 to ω_2 is given by $\log_2(\omega_2/\omega_1)$. Then, with $\omega_1 = 2$ rad/sec and $\omega_2 = 32$ rad/sec we have $\log_2(\omega_2/\omega_1) = 4$, a range of four octaves. Note that these quantities are ratios and have no physical units. The foregoing definitions can be extended for smaller units; for instance, one-third octave represents increments of $2^{1/3}$. Thus, if we start with 1 rad/sec and increment the frequency successively by one-third octave, we obtain 1, $2^{1/3}$, $2^{2/3}$, 2, $2^{4/3}$, $2^{5/3}$, 2^2 , and so on. It is clear, for example, that there are four one-third octaves in the frequency range from $2^{2/3}$ to 2^2 . Note that ω is known as the angular frequency (or radian frequency) and is usually measured in units of radians per second (rad/sec).

FIGURE 17.3 Frequency variation in some single-frequency vibration-test signals.

The more commonly used frequency is the cyclic frequency which is denoted by f . This is measured in hertz (Hz), which is identical to cycles per second (cps). It is clear that

$$f = \frac{\omega}{2\pi} \quad (17.5)$$

This is true because there are 2π radians in one cycle.

So that all important vibration frequencies of the test object (or its model) are properly excited, the sine sweep rate should be as slow as is feasible. Typically, rates of one octave per minute or slower are employed.

17.2.2.3 Sine Dwell

Sine-dwell signal is the discrete version of a sine sweep. The frequency is not varied continuously but is incremented by discrete amounts at discrete time points. This is shown graphically in [Figure 17.3](#). Mathematically, for the r th time interval, the dwell signal is

$$u(t) = a \sin(\omega_r t + \phi_r), \quad T_{r-1} \leq t \leq T_r \quad (17.6)$$

in which ω_r , a , and ϕ are kept constant during the time interval (T_{r-1}, T_r) . The frequency can be increased by a constant increment or the frequency increments can be made bigger with time (exponential-type increment). The latter procedure is more common. Also, the dwelling-time interval is usually made smaller as the frequency is increased. This is logical because, as the frequency increases, the number of cycles that occur during a given time also increases. Consequently, steady-state conditions may be achieved in a shorter time.

Sine-dwell signals can be specified using either a graphical form (see [Figure 17.3](#)) or a tabular form, giving the dwell frequencies and corresponding dwelling-time intervals. The amplitude is usually kept constant for the entire duration $(0, T_d)$, but the phase angle, ϕ , may have to be changed with each frequency increment in order to maintain the continuity of the signal.

17.2.2.4 Decaying Sine

Actual transient vibration environments (e.g., seismic ground motions) decay with time as the vibration energy is dissipated by some means. This decay characteristic is not present, however, in sine-sweep and sine-dwell signals. Sine-decay representation is a sine dwell with decay (see [Figure 17.2](#)). For an exponential decay, the counterpart of Equation 17.6 can be written as

$$u(t) = a \exp(-\lambda_r t) \sin(\omega_r t + \phi_r), \quad T_{r-1} \leq t \leq T_r \quad (17.7)$$

The damping parameter (the inverse of the time constant), λ , is typically increased with each frequency increment in order to represent the increased decay rates of a dynamic environment (or increased modal damping) at higher frequencies.

17.2.2.5 Sine Beat

When two sine waves having the same amplitude but different frequencies are mixed together (added or subtracted), a sine beat is obtained. This signal is considered to be a sine wave having the average frequency of the two original waves, which is amplitude-modulated by a sine wave of frequency equal to half the difference of the frequencies of the two original waves. The amplitude modulation produces a transient effect which is similar to that caused by the damping term in the sine-decay equation (Equation 17.7). The sharpness of the peaks becomes more prominent when the frequency difference of the two frequencies is made smaller.

Consider two cosine wave having frequencies $(\omega_r + \Delta\omega_r)$ and $(\omega_r - \Delta\omega_r)$ and the same amplitude $a/2$. If the first signal is subtracted from the second (that is, it is added with a 180° phase shift from the first wave), we obtain

$$u(t) = \frac{a}{2} [\cos(\omega_r - \Delta\omega_r)t - \cos(\omega_r + \Delta\omega_r)t] \quad (17.8)$$

By straightforward use of trigonometric identities, we obtain

$$u(t) = a(\sin \omega_r t)(\sin \Delta \omega_r t), \quad T_{r-1} \leq t \leq T_r \tag{17.9}$$

This is a sine wave of amplitude, a , and frequency, ω , modulated by a sine wave of frequency $\Delta\omega_r$. Sine-beat signals are commonly used as test excitation inputs in vibration testing. Usually, the ratio $\omega_r/\Delta\omega_r$ is kept constant. A typical value used is 20, in which case we obtain 10 cycles per beat. Here, cycles refer to the cycles at the higher frequency, ω_r , and a beat occurs at each half cycle of the smaller frequency, $\Delta\omega_r$. Thus, a beat is identified by a peak of amplitude a in the modulated wave and the beat frequency is $2\Delta\omega_r$.

As in the case of a sine dwell, the frequency, ω_r , of a sine-beat excitation signal is incremented at discrete time points, T_r , so as to cover the entire frequency interval of interest ($\omega_{\min}, \omega_{\max}$). It is a common practice to increase the size of the frequency increment and decrease the time duration at a particular frequency, for each frequency increment, just as is done for the sine dwell. The reasoning for this is identical to that given for sine dwell. The number of beats for each duration is usually kept constant (typically at a value over seven). A sine-beat signal is shown in [Figure 17.2\(d\)](#).

17.2.2.6 Sine Beat with Pauses

If we include pauses between sine-beat durations, we obtain a sine-beat signal with pauses. Mathematically, we have

$$u(t) = \begin{cases} a(\sin \omega_r t)(\sin \Delta \omega_r t), & \text{for } T_{r-1} \leq t \leq T_r', \\ 0, & \text{for } T_r' \leq t \leq T_r \end{cases} \tag{17.10}$$

This situation is shown in [Figure 17.2\(e\)](#). When a sine-beat signal with pauses is specified as a test excitation, we must give the frequencies, the corresponding time intervals, and the corresponding pause times. Typically, the pause time is also reduced with each frequency increment.

The single-frequency signal relations described in this section are summarized in [Table 17.1](#).

17.2.2.7 Multifrequency Signals

In contrast to single-frequency signals, multifrequency signals usually appear irregular and can have more than one predominant frequency component at a given time. Three common examples of multifrequency signals are aerodynamic disturbances, actual earthquake records, and simulated road disturbance signals used in automotive dynamic tests.

TABLE 17.1 Typical Single-Frequency Signals Used in Vibration Testing

Single Frequency Acceleration Signal	Mathematical Expression
Sine sweep	$u(t) = a \sin[\omega(t)t + \phi]$ $\omega(t) = \omega_{\min} + (\omega_{\max} - \omega_{\min})t/T_d \text{ (linear)}$ $\omega(t) = \omega_{\min} \left(\frac{\omega_{\max}}{\omega_{\min}} \right)^{t/T_d} \text{ (exponential)}$
Sine dwell	$u(t) = a \sin(\omega_r t + \phi_r) \quad T_{r-1} \leq t \leq T_r, \quad r = 1, 2, \dots, n$
Decaying sine	$u(t) = a \exp(-\lambda_r t) \sin(\omega_r t + \phi_r) \quad T_{r-1} \leq t \leq T_r, \quad r = 1, 2, \dots, n$
Sine beat	$u(t) = a(\sin \omega_r t)(\sin \Delta \omega_r t) \quad T_{r-1} \leq t \leq T_r, \quad r = 1, 2, \dots, n,$ $\omega_r/\Delta\omega_r = \text{constant}$
Sine beat with pauses	$u(t) = \begin{cases} a(\sin \omega_r t)(\sin \Delta \omega_r t), & \text{for } T_{r-1} \leq t \leq T_r' \\ = 0, & \text{for } T_r' \leq t \leq T_r \end{cases}$

17.2.2.8 Actual Excitation Records

Typically, actual excitation records such as overhead guideway vibrations are sample functions of random processes. By analyzing these deterministic records, however, characteristics of the original stochastic processes can be established, provided that the records are sufficiently long. This is possible because of the *ergodic hypothesis*. Results thus obtained are not quite accurate, because the actual excitation signals are usually nonstationary random processes and hence are not quite ergodic. Nevertheless, the information obtained by a Fourier analysis is useful in estimating the amplitude, phase, and frequency-content characteristics of the original excitation. In this manner, we can choose a past excitation record that can conservatively represent the design-basis excitation for the object that needs to be tested.

Excitation time histories can be modified to make them acceptably close to a design-basis excitation by using spectral-raising and spectral-suppressing methods. In spectral-raising procedures, a sine wave of required frequency is added to the original time history to improve its capability of excitation at that frequency. The sine wave should be properly phased such that the time of maximum vibratory motion in the original time history is unchanged by the modification. Spectral suppressing is achieved, essentially, by using a narrowband reject filter for the frequency band that needs to be removed. Physically, this is realized by passing the time history signal through a linearly damped oscillator that is tuned to the frequency to be rejected and connected in series with a second damper. The damping of this damper is chosen to obtain the required attenuation at the rejected frequency.

17.2.2.9 Simulated Excitation Signals

Random-signal-generating algorithms can be easily incorporated into digital computers. Also, physical experiments can be developed that have a random mechanism as an integral part. A time history from any such random simulation, once generated, is a sample function. If the random phenomenon is accurately programmed or physically developed so as to conservatively represent a design-basis excitation, a signal from such a simulation may be employed in vibration testing. Such test signals are usually available either as analog records on magnetic tapes or as digital records on a computer disk. Spectral-raising and spectral-suppressing techniques, mentioned earlier, also may be considered as methods of simulating vibration test excitations.

Before we conclude this section, it is worthwhile to point out that all test excitation signals considered in this section are oscillatory. Though the single-frequency signals considered may possess little resemblance to actual excitations on a device during operation, they can be chosen to possess the required decay, magnitude, phase, and frequency-content characteristics. During vibration testing, these signals, if used as excitations, will impose reversible stresses and strains on the test object, whose magnitudes, decay rates, and frequencies are representative of those that would be experienced during actual operation during the design life of the test object.

17.2.3 Stochastic Signal Representation

To generate a truly stochastic signal, a random phenomenon must be incorporated into the signal-generating process. The signal has to be generated in real time, and its numerical value at a given time is unknown until that time instant is reached. A stochastic signal cannot be completely specified in advance, but its statistical properties may be prespecified. There are many ways of obtaining random processes, including physical experimentation (for example, by tossing a coin at equal time steps and assigning a value to the magnitude over a given time step depending on the outcome of the toss), observation of processes in nature (such as outdoor temperature), and digital-computer simulation. The last procedure is the one commonly used in signal generation associated with vibration testing.

17.2.3.1 Ergodic Random Signals

A random process is a signal that is generated by some random (stochastic) mechanism. Generally, each time the mechanism is operated, a different signal (sample function) is generated. The likelihood of any two sample functions becoming identical is governed by some probabilistic law. The random process is

denoted by $X(t)$, and any sample function by $x(t)$. It should be remembered that no numerical computations can be made on $X(t)$ because it is not known for certain. Its Fourier transform, for instance, can be written as an analytical expression but cannot be computed. Once a sample function, $x(t)$, is generated, however, any numerical computation can be performed on it because it is a completely known function of time. This important difference may be somewhat confusing.

At any given time, t_1 , $X(t_1)$ is a random variable that has a certain probability distribution. Consider a well-behaved function, $f\{X(t_1)\}$, of this random variable (which is also a random variable). Its expected value (statistical mean) is denoted $E[f\{X(t_1)\}]$. This is also known as the ensemble average because it is equivalent to the average value at t_1 of a collection (ensemble) of a large number of sample functions of $X(t)$.

Now, consider the function $f\{x(t)\}$ of one sample function $x(t)$ of the random process. Its temporal (time) mean is expressed by

$$\lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^T f\{x(t)\} dt$$

Now, if

$$E[f\{X(t_1)\}] = \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^T f\{x(t)\} dt \quad (17.11)$$

then the random signal is said to be ergodic. Note that the right-hand side of Equation 17.11 does not depend on time. Hence, the left-hand side also should be independent of the time point t_1 .

As a result of this relation (known as the *ergodic hypothesis*), we can obtain the properties of a random process merely by performing computations using one of its sample functions. The ergodic hypothesis links the stochastic domain of expectations and uncertainties and the deterministic domain of real records and actual numerical computations. Digital Fourier computations, such as correlation functions and spectral densities, would not be possible for random signals if not for this hypothesis.

17.2.3.2 Stationary Random Signals

If the statistical properties of a random signal, $X(t)$, are independent of the time point considered, it is stationary. In particular, $X(t_1)$ will have a probability density that is independent of t_1 , and the joint probability of $X(t_1)$ and $X(t_2)$ will depend only on the time difference, $t_2 - t_1$. Consequently, the mean value $E[X(t)]$ of a stationary random signal is independent of t , and the autocorrelation function defined by

$$E[X(t)X(t + \tau)] = \phi_{xx}(\tau) \quad (17.12)$$

which depends on τ and not on t . Note that ergodic signals are always stationary, but the converse is not always true.

Consider Parseval's theorem:

$$\int_{-\infty}^{\infty} x^2(t) dt = \int_{-\infty}^{\infty} |X(f)|^2 df \quad (17.13)$$

This can be interpreted as an energy integral, and its value is usually infinite for random signals. An appropriate measure for random signals is its power. This is given by its root-mean-square (RMS) value $E[X(t)^2]$. PSD $\Phi(f)$ is the Fourier transform of the autocorrelation function $\phi(\tau)$ and, similarly, the latter is the inverse Fourier transform of the former. Hence,

$$\phi_{xx}(\tau) = \int_{-\infty}^{\infty} \Phi_{xx}(f) \exp(j2\pi f \tau) df \quad (17.14)$$

Now, from Equation 17.12 and Equation 17.14, we obtain

$$\text{RMS value} = E[X(t)^2] = \phi_{xx}(0) = \int_{-\infty}^{\infty} \Phi_{xx}(f) df \quad (17.15)$$

It follows that the RMS value of a stationary random signal is equal to the area under its PSD curve.

17.2.3.3 Independent and Uncorrelated Signals

Two random signals $X(t)$ and $Y(t)$ are independent if their joint distribution is given by the product of the individual distributions. A special case is that of uncorrelated signals, which satisfy

$$E[X(t_1)Y(t_2)] = E[X(t_1)]E[Y(t_2)] \quad (17.16)$$

Consider the stationary case, with mean values

$$\mu_x = E[X(t)] \quad (17.17)$$

$$\mu_y = E[Y(t)] \quad (17.18)$$

The *autocovariance functions* are given by

$$\varphi_{xx}(\tau) = E[\{X(t) - \mu_x\}\{X(t + \tau) - \mu_x\}] = \phi_{xx}(\tau) - \mu_x^2 \quad (17.19)$$

$$\varphi_{yy}(\tau) = E[\{Y(t) - \mu_y\}\{Y(t + \tau) - \mu_y\}] = \phi_{yy}(\tau) - \mu_y^2 \quad (17.20)$$

and the *cross-covariance function* is given by

$$\varphi_{xy}(\tau) = E[\{X(t) - \mu_x\}\{Y(t + \tau) - \mu_y\}] = \phi_{xy}(\tau) - \mu_x\mu_y \quad (17.21)$$

For uncorrelated signals (Equation 17.16)

$$\phi_{xy}(\tau) = \mu_x\mu_y \quad (17.22)$$

and from Equation 17.21 it follows that

$$\varphi_{xy}(\tau) = 0 \quad (17.23)$$

The correlation-function coefficient is defined by

$$\rho_{xy}(\tau) = \frac{\varphi_{xy}(\tau)}{\sqrt{\varphi_{xx}(0)\varphi_{yy}(0)}} \quad (17.24)$$

which satisfies

$$-1 \leq \rho_{xy}(\tau) \leq 1 \quad (17.25)$$

For uncorrelated signals, $\rho_{xy}(\tau) = 0$. This function measures the degree of correlation of the two signals.

The correlation of two random signals, $X(t)$ and $Y(t)$, is measured in the frequency domain by its *ordinary coherence function*

$$\gamma_{xy}^2(f) = \frac{|\Phi_{xy}(f)|^2}{\Phi_{xx}(f)\Phi_{yy}(f)} \quad (17.26)$$

which satisfies the condition

$$0 \leq \gamma_{xy}^2(f) \leq 1 \quad (17.27)$$

17.2.3.4 Transmission of Random Excitations

When the excitation input to a system is a random signal, the corresponding system response will also be random. Consider the system shown by the block diagram in [Figure 17.4\(a\)](#). The response of the system

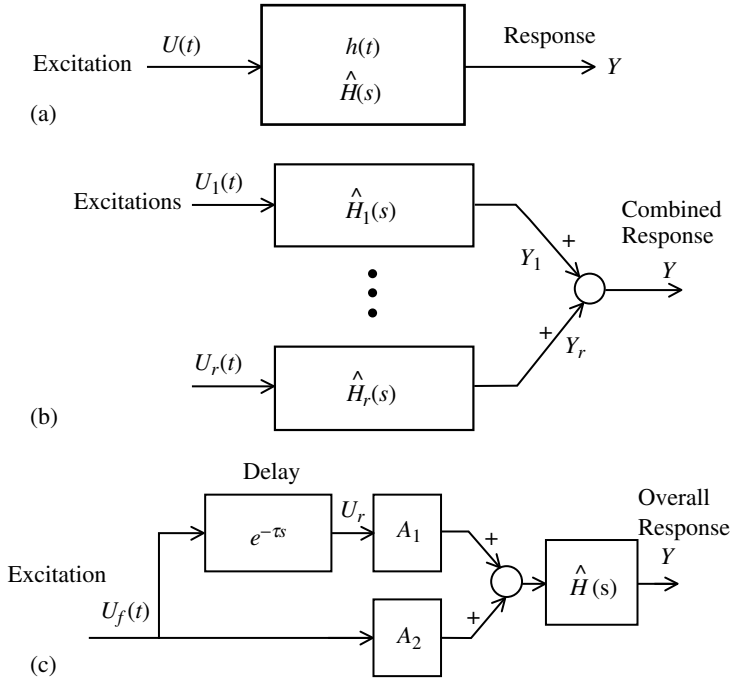

FIGURE 17.4 Combined response of a system to various random excitations: (a) system excited by a single input; (b) response to several random excitations; (c) response to a delayed excitation.

is given by the convolution integral

$$Y(t) = \int_{-\infty}^{\infty} h(t_1)U(t - t_1)dt_1 \quad (17.28)$$

in which the response PSD is given by the Fourier transform

$$\Phi_{yy}(f) = \Im\{E[Y(t)Y(t + \tau)]\} \quad (17.29)$$

Now, by using Equation 17.28 in Equation 17.29, in conjunction with the definition of Fourier transform, we can write

$$\Phi_{yy}(f) = \int_{-\infty}^{\infty} d\tau \exp(-j2\pi f\tau) E\left[\int_{-\infty}^{\infty} dt_1 h(t_1)U(t - t_1) \int_{-\infty}^{\infty} dt_2 h(t_2)U(t + \tau - t_2)\right]$$

which can be expressed as

$$\Phi_{yy}(f) = \int_{-\infty}^{\infty} dt_1 h(t_1) \int_{-\infty}^{\infty} dt_2 h(t_2) \int_{-\infty}^{\infty} d\tau \exp(-j2\pi f\tau) \phi_{uu}(\tau + t_1 - t_2)$$

Now, by letting $\tau' = \tau + t_1 - t_2$, we can write

$$\Phi_{yy}(f) = \left[\int_{-\infty}^{\infty} h(t_1)\exp(j2\pi ft_1)dt_1\right] \left[\int_{-\infty}^{\infty} h(t_2)\exp(-j2\pi ft_2)dt_2\right] \left[\int_{-\infty}^{\infty} \phi_{uu}(\tau')\exp(-j2\pi f\tau')d\tau'\right]$$

Note that $U(t)$ is assumed to be *stationary*.

Next, since the frequency-response function is given by the Fourier transform of the impulse response function, we obtain

$$\Phi_{yy}(f) = H^*(f)H(f)\Phi_{uu}(f) \quad (17.30)$$

in which $H^*(f)$ is the complex conjugate of $H(f)$. Alternatively, if $|H(f)|$ denotes the magnitude of the complex quantity, we can write

$$\Phi_{yy}(f) = |H(f)|^2 \Phi_{uu}(f) \quad (17.31)$$

By using Equation 17.30 or Equation 17.31, we can determine the PSD of the system response from the PSD of the excitation if the system-frequency-response function is known.

In a similar manner, it can be shown that the cross-spectral density function may be expressed as

$$\Phi_{uy}(f) = H(f) \Phi_{uu}(f) \quad (17.32)$$

Now, consider r stationary, independent, random excitations, U_1, U_2, \dots, U_r , (which are assumed to have zero-mean values, without loss of generality) applied to r subsystems, having transfer functions $\hat{H}_1(s), \hat{H}_2(s), \dots, \hat{H}_r(s)$, as shown in Figure 17.4(b). The total response, Y , consists of the sum of individual responses, Y_1, Y_2, \dots, Y_r . It can be shown that Y_1, Y_2, \dots, Y_r are also stationary, independent, zero-mean, random processes. By definition, we have

$$\phi_{yy}(\tau) = E[\{Y_1(t) + \dots + Y_r(t)\}\{Y_1(t + \tau) + \dots + Y_r(t + \tau)\}] \quad (17.33)$$

Now, for independent, zero-mean Y_i , Equation 17.33 becomes

$$\phi_{yy}(\tau) = E[Y_1(t)Y_1(t + \tau)] + \dots + E[Y_r(t)Y_r(t + \tau)] \quad (17.34)$$

Since Y_i are stationary, we have

$$\phi_{yy}(\tau) = \phi_{y_1y_1}(\tau) + \dots + \phi_{y_ry_r}(\tau) \quad (17.35)$$

On Fourier transformation, we obtain

$$\Phi_{yy}(f) = \Phi_{y_1y_1}(f) + \dots + \Phi_{y_ry_r}(f) \quad (17.36)$$

In view of Equation 17.31, it can be written

$$\Phi_{yy}(f) = \sum_{i=1}^r |H_i(f)|^2 \Phi_{u_iu_i}(f) \quad (17.37)$$

from which the response PSD can be determined if the input PSDs are known.

If all inputs, $U_i(t)$, have identical probability distributions (for example, when they are generated by the same mechanism), the corresponding PSDs will be identical. Note that this does not imply that the inputs are equal. They could be dependent, independent, correlated, or uncorrelated. In this case, Equation 17.37 becomes

$$\Phi_{yy}(f) = \left[\sum_{i=1}^r |H_i(f)|^2 \right] \Phi_{uu}(f) \quad (17.38)$$

in which $\Phi_{uu}(f)$ is the common input PSD.

Finally, consider the linear combination of two excitations, $U_f(t)$ and $U_r(t)$, with the latter excitation delayed in time by τ but otherwise identical to the former. This situation is shown in Figure 17.4(c). From Laplace transform tables, it is seen that the Laplace transforms of the two signals are related by

$$U_r(s) = \exp(-\tau s) U_f(s) \quad (17.39)$$

From Equation 17.39, it follows that (see Figure 17.4(c)):

$$Y(s) = (A_1 \exp(-\tau s) + A_2) H(s) U_f(s) \quad (17.40)$$

Consequently, we have

$$\Phi_{yy}(f) = |(A_1 \exp(-j2\pi f\tau) + A_2) H(f)|^2 \Phi_{uu}(f) \quad (17.41)$$

From this result, the net response can be determined when the phasing between the two excitations is known. This has applications, for example, in determining the response of a vehicle to road disturbances at the front and rear wheels.

17.2.4 Frequency-Domain Representations

In this section, we shall discuss the Fourier spectrum method and the PSD method of representing a test excitation. These are frequency-domain representations.

17.2.4.1 Fourier Spectrum Method

Since the time domain and the frequency domain are related through Fourier transformation, a time signal can be represented by its Fourier spectrum. In vibration testing, a required Fourier spectrum may be given as the test specification. Then, the actual input signal that is used to excite the test object should have a Fourier spectrum that envelops the required Fourier spectrum. The generation of a signal to satisfy this requirement might be difficult. Usually, digital Fourier analysis of the control sensor signal is necessary to compare the actual (test) Fourier spectrum with the required Fourier spectrum. If the two spectra do not match in a certain frequency band, the error (i.e., the difference in the two spectra) is fed back to correct the situation. This process is known as *frequency-band equalization*. Also, the sample step of the time signal in the digital Fourier analysis should be adequately small to cover the frequency range of interest in that particular vibration testing application. Advantages of using digital Fourier analysis in vibration testing include flexibility and convenience with respect to the type of the signal that can be analyzed, availability of complex processing capabilities, increased speed of processing, accuracy and reliability, reduction in the test cost, practically unlimited repeatability of processing, and reduction in the overall size and weight of the analyzer.

17.2.4.2 Power Spectral Density Method

The operational vibration environment of equipment is usually random. Consequently, a stochastic representation of the test excitation appears to be suitable for a majority of vibration-testing situations. One way of representing a stationary random signal is by its PSD. As noted before, the numerical computation of the PSD is not possible, however, unless the ergodicity is assumed for the signal. Using the ergodic hypothesis, we can compute the PSD of a random signal simply by using one sample function (one record) of the signal.

Three methods of determining the PSD of a random signal are shown in Figure 17.5. From Parseval’s theorem (Equation 17.13), we notice that the mean square value of a random signal may be obtained from the area under the PSD curve. This suggests the method shown in Figure 17.5(a) for estimating the PSD of a signal. The mean square value of a sample of the signal in the frequency band, Δf , having a certain center frequency is obtained by first extracting the signal components in the band and then squaring them. This is done for several samples and averaged to obtain a high accuracy. It is then divided by Δf . By repeating this for a range of center frequencies, an estimate for the PSD is obtained.

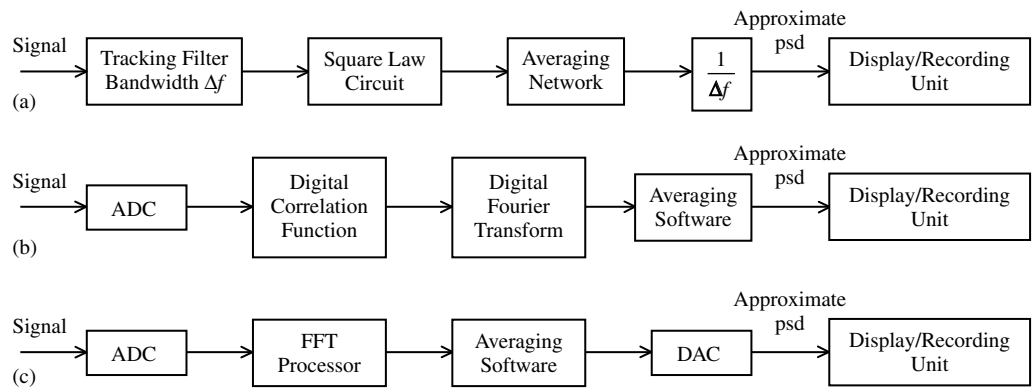

FIGURE 17.5 Some methods of PSD determination: (a) the filtering, squaring, and averaging method; (b) using an autocorrelation function; (c) using direct FFT.

FIGURE 17.6 Effect of filter bandwidth on PSD results.

In the second scheme, shown in Figure 17.5(b), correlation function is first computed digitally. Its Fourier transform (by fast Fourier transform, or FFT) gives an estimate of the PSD.

In the third scheme, shown in Figure 17.5(c), the PSD is computed directly using FFT. Here, the Fourier spectrum of the sample record is computed and the PSD is estimated directly, without first computing the autocorrelation function.

In these numerical techniques of computing PSD, a single sample function will not give the required accuracy, and averaging results for a number of sample records is usually needed. In real-time digital analysis, the running average and the current estimate are normally computed. In the running average, it is desirable to give a higher weighting to the more recent estimates. The fluctuations about the local average in the PSD estimate could be reduced by selecting a larger filter bandwidth, Δf (see Figure 17.6), and a large record length T . A measure of this fluctuation is given by

$$\varepsilon = \frac{1}{\sqrt{\Delta f T}} \quad (17.42)$$

It should be noted that increasing Δf results in reduction of the precision of the estimates while improving the appearance. To offset this, T must be increased further, or averaging must be done for several sample records.

Generating a test-input signal with a PSD that satisfactorily compares with the required PSD can be a tedious task if one attempts to do it manually by mixing various signal components. A convenient method is to use an automatic multiband equalizer. By this means, the mean amplitude of the signal in each small frequency band of interest can be made to approach the spectrum of the specified vibration environment (see Figure 17.7). Unfortunately, this type of random-signal vibration testing can be more costly than testing with deterministic signals.

17.2.5 Response Spectrum

Response spectra are commonly used to represent signals associated with vibration testing. A given signal has a certain fixed response spectrum, but many different signals can have the same response spectrum. For this reason, as will be clear shortly, the original signal cannot be reconstructed from its response spectrum (unlike in the case of a Fourier spectrum). This is a disadvantage. However, the physical significance of a response spectrum makes it a good representation for a test signal.

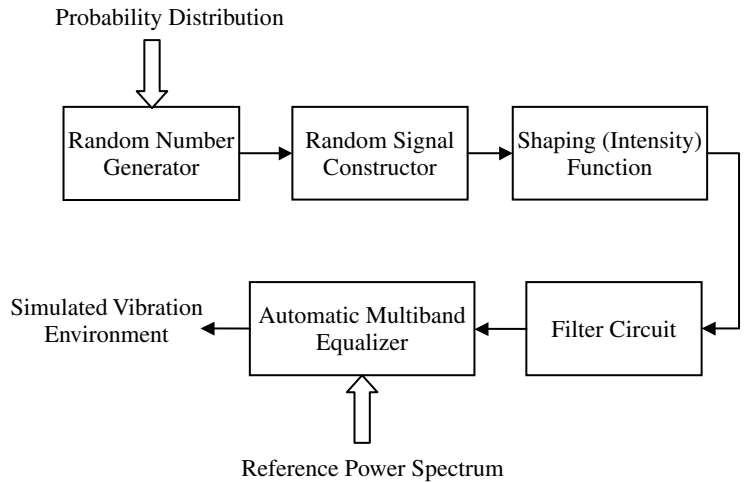

FIGURE 17.7 Generation of a specified random vibration environment.

If a given signal is applied to a single-degree-of-freedom (single-DoF) oscillator (of a specific natural frequency), and the response of the oscillator (mass) is recorded, we can determine the maximum (peak) value of that response. Suppose that we repeat the process for a number of different oscillators (having different natural frequencies) and then plot the peak response values thus obtained against the corresponding oscillator natural frequencies. This procedure is shown schematically in Figure 17.8. For an infinite number of oscillators (or for the same oscillator with continuously variable natural frequency), we get a continuous curve, which is called the response spectrum of the given signal. It is obvious, however, that the original signal cannot be completely determined from the knowledge of its response spectrum alone. As shown in Figure 17.8, for instance, another signal, when passed through a given oscillator, might produce the same peak response.

Note that we have assumed the oscillators to be undamped; the response spectrum obtained using undamped oscillators corresponds to $\zeta = 0$. If all the oscillators are damped, however, and have the same damping ratio, ζ , the resulting response spectrum will correspond to that particular ζ . It is, therefore, clear that ζ is also a parameter in the response-spectrum representation. We should specify the damping value as well when we represent a signal by its response spectrum.

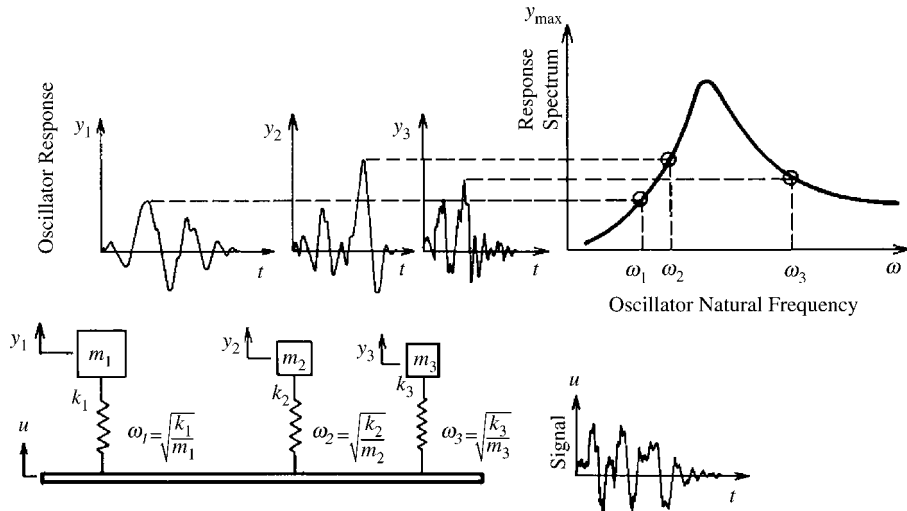

FIGURE 17.8 Definition of the response spectrum of a signal.

17.2.5.1 Displacement, Velocity, and Acceleration Spectra

It is clear that a motion signal can be represented by the corresponding displacement, velocity, or acceleration. First, consider a displacement signal, $u(t)$. The corresponding velocity signal is $\dot{u}(t)$ and the acceleration is $\ddot{u}(t)$.

Now consider an undamped simple oscillator, which is subjected to a support displacement $u(t)$, as shown in Figure 17.9. As usual, assuming that the displacements are measured with respect to a static equilibrium configuration, the gravity effect can be ignored. Then, the equation of motion is given by

$$m\ddot{y}_d = k(u - y_d) \quad (17.43)$$

or

$$\ddot{y}_d + \omega_n^2 y_d = \omega_n^2 u(t) \quad (17.44)$$

where the (undamped) natural frequency is given by

$$\omega_n = \sqrt{\frac{k}{m}} \quad (17.45)$$

Suppose that the support (displacement) excitation, $u(t)$, is a unit impulse $\delta(t)$. Then, the corresponding (displacement) response y is called the impulse-response function, and is denoted by $h(t)$. It is known that $h(t)$ is the inverse Laplace transform (with zero initial condition) of the transfer function of the system (Equation 17.44), as given by

$$H(s) = \frac{\omega_n^2}{(s^2 + \omega_n^2)} \quad (17.46)$$

The impulse-response function (to an impulsive support excitation) for an undamped, single-DoF oscillator having natural frequency ω_n is given by

$$h(t) = \omega_n \sin \omega_n t \quad (17.47)$$

The displacement response $y_d(t)$ of this oscillator, when excited by the displacement signal $u(t)$, is given by the convolution integral

$$y_d(t) = \omega_n \int_0^\infty u(\tau) \sin \omega_n(t - \tau) d\tau \quad (17.48)$$

The “velocity” response of the same oscillator, when excited by the velocity signal, $\dot{u}(t)$, is given by

$$y_v(t) = \omega_n \int_0^\infty \dot{u}(\tau) \sin \omega_n(t - \tau) d\tau \quad (17.49)$$

and the “acceleration” response when excited by the acceleration signal, $\ddot{u}(t)$, is

$$y_a(t) = \omega_n \int_0^\infty \ddot{u}(\tau) \sin \omega_n(t - \tau) d\tau \quad (17.50)$$

These results immediately follow from Equation 17.44. Specifically, differentiate Equation 17.44 once to obtain

$$\ddot{y}_v + \omega_n^2 y_v = \omega_n^2 \dot{u}(t) \quad (17.51)$$

FIGURE 17.9 Undamped simple oscillator subjected to a support excitation.

and differentiate again, to obtain

$$\ddot{y}_a + \omega_n^2 y_a = \omega_n^2 \ddot{u}(t) \quad (17.52)$$

in which

$$y_v = \frac{dy_d}{dt} \quad (17.53)$$

$$y_a = \frac{d^2 y_d}{dt^2} = \frac{dy_v}{dt} \quad (17.54)$$

If the peak value of $y_d(t)$ is plotted against ω_n , we get the *displacement-spectrum* curve of the displacement signal, $u(t)$. If the peak value of $y_v(t)$ is plotted against ω_n , we get the *velocity-spectrum* curve of the displacement signal, $u(t)$. If the peak value of $y_a(t)$ is plotted against ω_n , we get the *acceleration-spectrum* curve of the displacement signal, $u(t)$. Now consider Equation 17.49. Integration by parts gives

$$y_v(t) = [\omega_n u(\tau) \sin \omega_n(t - \tau)]_0^\infty + \omega_n^2 \int_0^\infty u(\tau) \cos \omega_n(t - \tau) d\tau \quad (17.55)$$

The initial and final conditions for $u(t)$ are assumed to be zero. It follows that the first term in Equation 17.55 vanishes. The second term is $\omega_n [y_d(t + \pi/2\omega_n - \tau)]$, which is clear by noting that $\sin \omega_n(t + \pi/2\omega_n - \tau)$ is equal to $\cos \omega_n(t - \tau)$; thus

$$y_v(t) = -\omega_n y_d \left(t + \frac{\pi}{2\omega_n} \right) \quad (17.56)$$

If we integrate Equation 17.50 by parts twice, and apply the end conditions as before, we obtain

$$y_a(t) = -\omega_n^2 y_d(t) \quad (17.57)$$

By taking the peak values of response time histories, we see from Equation 17.56 and Equation 17.57 that

$$v(\omega_n) = \omega_n d(\omega_n) \quad (17.58)$$

$$a(\omega_n) = \omega_n^2 d(\omega_n) \quad (17.59)$$

in which $d(\omega_n)$, $v(\omega_n)$, and $a(\omega_n)$ represent the displacement spectrum, the velocity spectrum, and the acceleration spectrum, respectively, of the displacement time history, $u(t)$. It follows from Equation 17.58 and Equation 17.59 that

$$a(\omega_n) = \omega_n v(\omega_n) \quad (17.60)$$

17.2.5.2 Response-Spectra Plotting Paper

Response spectra are usually plotted on a frequency-velocity coordinate plane or on a frequency-acceleration coordinate plane. Values are normally plotted in logarithmic scale, as shown in [Figure 17.10](#). First, consider the axes shown in Figure 17.10(a). Obviously, constant velocity lines are horizontal for this coordinate system. From Equation 17.58, the constant-displacement line corresponds to

$$v(\omega_n) = c \omega_n$$

By taking logarithms of both sides, we obtain

$$\log v(\omega_n) = \log \omega_n + \log c$$

It follows that the constant-displacement lines have a slope of +1 on the logarithmic frequency-velocity plane. Similarly, from Equation 17.60, the constant-acceleration lines correspond to

$$\omega_n v(\omega_n) = c$$

Hence,

$$\log v(\omega_n) = -\log \omega_n + \log c$$

It follows that the constant-acceleration lines have a slope of negative one on the logarithmic frequency–velocity plane. Similarly, it can be shown from Equation 17.59 and Equation 17.60 that, on the logarithmic frequency–acceleration plane (Figure 17.10(b)), the constant-displacement lines have a slope of +2, and the constant-velocity lines have a slope of +1.

On the frequency–velocity plane, a point corresponds to a specific frequency and a specific velocity. The corresponding displacement at the point is obtained (Equation 17.58) by dividing the velocity value by the frequency value at that point. The corresponding acceleration at that point is obtained (Equation 17.60) by multiplying the particular velocity value by the frequency value. Any units may be used for displacement, velocity, and acceleration quantities. A typical logarithmic frequency–velocity plotting sheet is shown in Figure 17.11. Note that the sheet is already graduated on constant displacement, velocity, and acceleration lines. Also, a period axis (period = 1/cyclic frequency) is given for convenience in plotting. A plot of this type is called a *nomograph*.

17.2.5.3 Zero-Period Acceleration

Frequently, response spectra are specified in terms of accelerations rather than velocities. This is particularly true in vibration testing associated with product qualification, because typical operational disturbance records are usually available as acceleration time histories. No information is lost because the logarithmic frequency–acceleration plotting paper can be graduated for velocities and displacements as well. It is, therefore, clear that an acceleration quantity (peak) on a response spectrum has a corresponding velocity quantity (peak), and a displacement quantity (peak). In vibration testing, however, the motion variable that is in common usage is the acceleration. Zero-period acceleration (ZPA) is an important parameter that characterizes a response spectrum. It should be remembered, however, that zero-period velocity or zero-period displacement can be similarly defined.

ZPA is defined as the acceleration value (peak) at zero period (or infinite frequency) on a response spectrum. Specifically,

$$\text{ZPA} = \lim_{\omega_n \rightarrow \infty} a(\omega_n) \quad (17.61)$$

Consider the damped simple oscillator equation (for support motion excitation):

$$\ddot{y} + 2\zeta\omega_n\dot{y} + \omega_n^2 y = \omega_n^2 u(t) \quad (17.62)$$

By differentiating Equation 17.62 throughout, either once or twice, it is seen, as in Equation 17.51 and Equation 17.52, that if u and y initially refer to displacements, then the same equation is valid when both of them refer to either velocities or accelerations. Let us consider the case in which u and y refer to input and response acceleration variables, respectively. Consider a sinusoidal

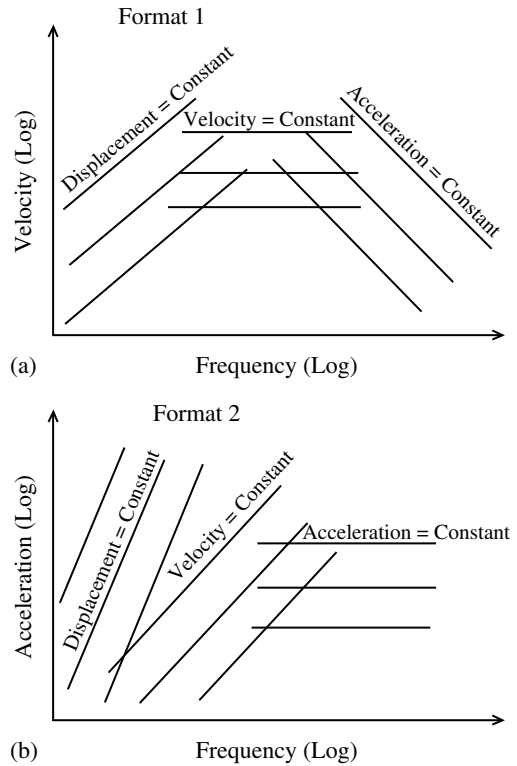

FIGURE 17.10 Response-spectra plotting formats: (a) frequency–velocity plane; (b) frequency–acceleration plane.

FIGURE 17.11 Response-spectra plotting sheet or nomograph (frequency–velocity plane).

signal, $u(t)$, given by

$$u(t) = A \sin \omega t \tag{17.63}$$

The resulting response, $y(t)$, neglecting the transient components (that is, the steady-state value), is given by

$$y(t) = A \frac{\omega_n^2}{\sqrt{(\omega_n^2 - \omega^2)^2 + 4\zeta^2 \omega_n^2 \omega^2}} \sin(\omega t + \phi) \tag{17.64}$$

Hence, the acceleration-response spectrum, given by $a(\omega_n) = [y(t)]_{\max}$, for a sinusoidal signal of frequency, ω , and amplitude, A , is

$$a(\omega_n) = A \frac{\omega_n^2}{\sqrt{(\omega_n^2 - \omega^2)^2 + 4\zeta^2 \omega_n^2 \omega^2}} \quad (17.65)$$

A plot of this response is shown in Figure 17.12. Note that $a(0) = 0$. Also,

$$\text{ZPA} = \lim_{\omega_n \rightarrow \infty} a(\omega_n) = A \quad (17.66)$$

It is worth observing that at the point $\omega_n = \omega$ (i.e., when the excitation frequency, ω , is equal to the natural frequencies, ω_n , of the simple oscillator), we have $a(\omega_n) = A/(2\zeta)$, which corresponds to an amplification by a factor of $1/(2\zeta)$ over the ZPA value.

FIGURE 17.12 Response spectrum and ZPA of a sine signal.

17.2.5.4 Uses of Response Spectra

In vibration testing, response-spectra curves are employed to specify the dynamic environment to which the test object is required to be subjected. This specified response spectrum is known as the *required response spectrum* (RRS). In order to satisfy conservatively the test specification, the response spectrum of the actual test input excitation, known as the test response spectrum (TRS), should envelop the RRS. Note that, when response spectra are used to represent excitation input signals in vibration testing, the damping value of the hypothetical oscillators used in computing the response spectrum has no bearing on the actual damping that is present in the test object. In this application, the response spectrum is merely a representation of the shaker-input signal and, therefore, does not depend on system damping.

Another use of response spectra is in estimating the peak value of the response of a multi-DoF or distributed-parameter system when it is excited by a signal whose response spectrum is known. To understand this concept, we recall the fact that, for a multi-DoF or truncated (approximated) distributed-parameter system having distinct natural frequencies, the total response can be expressed as a linear combination of the individual modal responses. Specifically, the response $y(t)$ can be written

$$y(t) = \sum_{i=1}^r \alpha_i a(\omega_i) \exp \left[\frac{-\zeta_i \omega_i t}{\sqrt{1 - \zeta_i^2}} \right] \sin(\omega_i t + \phi_i) \quad (17.67)$$

in which the spectrum, $a(\omega_i)$, is comprised of the amplitude contributions from each mode (simple oscillator equation), with “damped” natural frequency, ω_i . Hence, $a(\omega_i)$ corresponds to the value of the response spectrum at frequency ω_i . The linear combination parameters, α_i , depend on the modal-participation factors and can be determined from system parameters. Since the peak values of all terms in the summation on the right-hand side of Equation 17.67 do not occur at the same time, we observe that

$$[y(t)]_{\text{peak}} < \sum_{i=1}^r \alpha_i a(\omega_i) \quad (17.68)$$

It follows that the right-hand side of the inequality (Equation 17.68) is a conservative upper-bound estimate (i.e., the absolute sum) for the peak response of the multi-DoF system. Some prefer to make the estimate less conservative by taking the square root of sum of the squares (SRSS):

$$[y(t)]_{\text{SRSS}} = \left[\sum_{i=1}^r \alpha_i^2 a^2(\omega_i) \right]^{1/2} \quad (17.69)$$

The latter method, however, has the risk of giving an estimate that is less than the true value. Note that, in this application, the damping value associated with the response spectrum is directly related to modal damping of the system. Hence, the response spectrum, $a(\omega_i)$, should correspond to the same damping ratio as that of the mode considered within the summation of the inequality (Equation 17.68). If all modal damping ratios, ζ_i , are identical or nearly so, the same response spectrum could be used to compute all terms in the inequality 17.68. Otherwise, different response-spectra curves should be used to determine each quantity, $a(\omega_i)$, depending on the applicable modal damping ratio, ζ_i .

17.2.6 Comparison of Various Representations

In this section, we shall state some major advantages and disadvantages of the four representations of the vibration environment that we have discussed.

Time-signal representation has several advantages. It can be employed to represent either deterministic or random vibration environment. It is an exact representation of a single excitation event. Also, when performing multiexcitation (multiple shaker) vibration testing, phasing between the various inputs can be conveniently incorporated simply by delaying each excitation with respect to the others. There are also disadvantages to time-signal representation. Since each time history represents just one sample function (a single event) of a random environment, it may not be truly representative of the actual vibration excitation. This can be overcome by using longer signals, which, however, will increase the duration of the test, which is limited by test specifications. If the random vibration is truly ergodic (or at least stationary), this problem will not be as serious. Furthermore, the problem does not arise when testing with deterministic signals. An extensive knowledge of the true vibration environment to which the test object is subjected is necessary, however, in order to conclude that it is stationary or that it could be represented by a deterministic signal. In this sense, time-signal representation is difficult to implement.

The response-spectrum method of representing a vibration environment has several advantages. It is relatively easy to implement. Since the peak response of a simple oscillator is used in its definition, it is representative of the peak response or structural stress of simple dynamic systems; hence, there is a direct relation to the behavior of the physical object. An upper bound for the peak response of a multi-DoF system can be conveniently obtained by the method outlined in Section 17.2.5.4. Also, by considering the envelope of a set of response spectra at the same damping value, it is possible to use a single response spectrum to conservatively represent more than one excitation event. The method also has disadvantages. It employs deterministic signals in its definition. Sample functions (single events) of random vibrations can be used, however. It is not possible to determine the original vibration signal from the knowledge of its response spectrum, because it uses the peak value of response of a simple oscillator (more than one signal can have the same response spectrum). Thus, a response spectrum cannot be considered a complete representation of a vibration environment. Also, characteristics such as the transient nature and the duration of the excitation event cannot be deduced from the response spectrum. For the same reason, it is not possible to incorporate information on excitation-signal phasing into the response-spectrum representation. This is a disadvantage in multiple excitation testing.

Fourier spectrum representation also has advantages. Since the actual dynamic environment signal can be obtained by inverse transformation, it has the same advantages as for the time-signal representation. In particular, since a Fourier spectrum is generally complex, phasing information of the test excitation can be incorporated into Fourier spectra, in multiple excitation testing. Furthermore, by considering an envelope Fourier spectrum (like an envelope response spectrum), it can be employed to represent conservatively more than one vibration environment. Also, it gives frequency-domain information (such as information about resonances), which is very useful in vibration testing situations. The disadvantages of Fourier spectrum representation include the following. It is a deterministic representation but, as in the response-spectrum method, a sample function (a single event) of a random vibration can be represented by its Fourier spectrum. Transient effects and event duration are hidden in this representation. Also, it is

somewhat difficult to implement, because complex procedures of multiband equalization might be necessary in the signal synthesis associated with this representation.

PSD representation has the following advantages. It takes the random nature of a vibration environment into account. As in response-spectrum and Fourier-spectrum representations, by taking an envelope PSD, it can be used to represent conservatively more than one environment. It can display important frequency-domain characteristics, such as resonances. Its disadvantages include the following. It is an exact representation only for truly stationary or ergodic random environments. In nonstationary situations, as in seismic ground motions, significant error could result. Also, it is not possible to obtain the original sample function (dynamic event) from its PSD. Hence, the transient characteristics and duration of the event are not known from its PSD. Since mean square values, not peak values, are considered, PSD representation is not structural-stress-related. Furthermore, since PSD functions are real (not complex), we cannot incorporate phasing information into them. This is a disadvantage in multiple excitation testing situations, but this problem can be overcome by considering either the cross spectrum (which is complex) or the cross correlation in each pair of test excitations.

Random vibration testing is compared with sine testing (single-frequency, deterministic excitations) in Box 17.1. A comparison of various representations of test excitations is given in Box 17.2.

Box 17.1

RANDOM TESTING VS. SINE TESTING

Advantages of Random Testing:

1. More realistic representation of the true environment
2. Many frequencies are applied simultaneously
3. All resonances, natural frequencies, and mode shapes are excited simultaneously

Disadvantages of Random Testing:

1. Needs more power for testing
2. Control is more difficult
3. More costly

Advantages of Sine Testing:

Appropriate for:

1. Fatigue testing of products that operate primarily at a known speed (frequency) under in-service conditions
2. Detecting sensitivity of a device to a particular excitation frequency
3. Detecting resonances, natural frequencies, modal damping, and mode shapes
4. Calibration of vibration sensors and control systems

Disadvantages of Sine Testing:

1. Usually not a good representation of the true dynamic environment
2. Because vibration energy is concentrated at one frequency, it can cause failures that would not occur in service (particularly single-resonance failures)
3. Since only one mode is excited at a time, it can hide multiple-resonance failures that might occur in service

Box 17.2

COMPARISON OF TEST EXCITATION REPRESENTATIONS

Property	Time Signal	Response Spectrum	Fourier Spectrum	Power Spectral Density
True representation of a deterministic environment?	Yes	Yes	Yes	No
True representation of a random environment?	One sample function	One sample function	One sample function	Yes
Frequency–time reversible?	Yes	No	Yes	No
Signal phasing possible for multiaxis testing?	Yes	No	Yes	No
Good representation of peak amplitude/stress events?	Yes	Yes	No	No
Explicit accounting for modal responses	No	Yes	Yes	Yes

In practice, the generation of an excitation signal for vibration testing may not follow any one of the analytical procedures and may incorporate a combination of them. For example, a combination of sine-beat signals of different frequencies with random phasing is one practical approach to the generation of a multifrequency, pseudo-random excitation signal. This approach is summarized in Box 17.3.

17.3 Pretest Procedures

The selection of a test procedure for the vibration testing of an object should be based on technical information regarding the test object and its intended use. Vendors usually prefer to use more established, conventional testing methods and are generally reluctant to incorporate modifications and

Box 17.3

TEST SIGNAL GENERATION

- Steps:
1. Generate a set of sine beats at discrete frequencies of interest for the vibration test, having specified amplitudes.
 2. Phase shift (time shift) the signal components from Step 1 according to a random number generator.
 3. Sum the signal components from Step 2.

improvements. This is primarily due to economic reasons, convenience, testing-time limitation, availability of the equipment and facilities (test-lab limitations), and similar factors. Regulatory agencies, however, usually modify their guidelines from time to time, and some of these requirements are mandatory.

Before conducting a vibration test on a test object, it is necessary to follow several pretest procedures. Such procedures are necessary in order to conduct a meaningful test. Some important pretest procedures include the following:

1. Understanding the purpose of the test
2. Studying the service functions of the test object
3. Acquiring information on the test object
4. Planning the test program
5. Conducting pretest inspection of the test object
6. Resonance-searching to gather dynamic information about the test object
7. Mechanically aging the test object

In the following sections, we shall discuss each of the first five items of these procedures to emphasize how they can contribute to a meaningful test. The last two items will be considered separately, in Section 17.4 on Testing Procedures.

17.3.1 Purpose of Testing

As noted before, vibration testing is useful in various stages of (1) design and development, (2) production and quality assurance, and (3) qualification and utilization of a product. Depending on the outcome of a vibration test, design modifications or corrective actions can be recommended for a preliminary design or a partial product. To determine the most desirable location (in terms of minimal noise and vibration), for the compressor in a refrigerator unit, for example, a resonance-search test could be employed. As another example, vibration testing can be employed to determine vibration-isolation material requirements in structures for providing adequate damping. Such tests fall into the first category of system development tests. They are beneficial for the designer and the manufacturer in improving the quality of performance of the product. Government regulatory agencies do not usually stipulate the requirements for this category of tests, but they sometimes stipulate minimal requirements for safety and performance levels of the final product, which can indirectly affect the development-test requirements. Custom-made items are exceptions for which the customers could stipulate the design-test requirements.

For special-purpose products, it is sometimes also necessary to conduct a vibration test on the final product before its installation for service operation. For mass-produced items, it is customary to select representative samples from each batch of the product for these tests. The purpose of such test is to detect any inferiorities in the workmanship or in the materials used. These tests fall into the second category, quality-assurance tests. These usually consist of a standard series of routine tests that are well established for a given product.

Distribution qualification and seismic qualification of devices and components are good examples of the use of the third category, qualification tests. A high-quality product such as a valve actuator, for instance, which is thoroughly tested in the design-development stage and at the final production stage, will need further dynamic tests or analysis if it is to be installed in a nuclear power plant. The purpose in this testing is to determine whether the product (valve actuator) will be crucial for system-safety-related functions. Government regulatory agencies usually stipulate basic requirements for qualification tests. These tests are necessarily application-oriented. The vendor or the customer might employ more elaborate test programs than those stipulated by the regulatory agency, but at least the minimum requirements set by the agency should be met before commissioning the plant.

The purpose of any vibration test should be clearly understood before incorporating it into a test program. A particular test might be meaningless under some circumstances. If it is known, for instance, that no resonances below 35 Hz exist in a particular piece of equipment that requires seismic

qualification, then it is not necessary to conduct a resonance search because the predominant frequency content of seismic excitations occurs below 35 Hz. If, however, the test serves a dual purpose, such as mechanical aging in addition to resonance detection, then it may still be conducted even if there are no resonances in the predominant frequency range of excitation.

If testing is performed on one test item selected from a batch of products to assure the quality of the entire batch or to qualify the entire batch, it is necessary to establish that all items in the batch are of identical design. Otherwise, testing of all items in the batch might be necessary unless some form-design similarity can be identified. "Qualification by similarity" is done in this manner.

The nature of the vibration testing that is employed will be usually governed by the test purpose. Single-frequency tests, using deterministic test excitations, for example, are well suited for design-development and quality-assurance applications. The main reason for this choice is that the test-input excitations can be completely defined; consequently, a complete analysis can be performed with relative ease, based on existing theories and dynamic models. Random or multifrequency tests are more realistic in a qualification test, however, because under typical service conditions, the dynamic environments to which an object is subjected are random and have multiple frequencies by nature (for example, seismic disturbances, ground-transit road disturbances, aerodynamic disturbances). Since random-excitation tests are relatively more expensive and complex in terms of signal generation and data processing, single-frequency tests might also be employed in qualification tests. Under some circumstances, single-frequency testing could add excessive conservatism to the test excitation. It is known, for instance, that single-frequency tests are justified in the qualification of line-mounted equipment (i.e., equipment mounted on pipe lines, cables, and similar "line" structures), which can encounter in-service disturbances that are amplified because of resonances in the mounting structure.

17.3.2 Service Functions

For product qualification by testing, it is required that the test object remain functional and maintain its structural integrity when subjected to a certain prespecified dynamic environment. In seismic qualification of equipment, for instance, the dynamic environment is an excitation that adequately represents the amplitude, phasing, frequency content, and transient characteristics (decay rate and signal duration) of the motions at the equipment-support locations, caused by the most severe seismic disturbance that has a reasonable probability of occurring during the design life of the equipment. Monitoring the proper performance of in-service functions (functional-operability monitoring) of a test object during vibration testing can be crucial in the qualification decision.

The intended service functions of the test object should be clearly defined prior to testing. For active equipment, functional operability is necessary during vibration testing. For passive equipment, however, only structural integrity need be maintained during testing.

17.3.2.1 Active Equipment

Equipment that should perform a mechanical motion (for example, valve closure, relay contact) or that produces a measurable signal (for example, an electrical signal, pressure, temperature, flow) during the course of performing its intended functions is termed active equipment. Some examples of active equipment are valve actuators, relays, motors, pumps, transducers, control switches, and data recorders.

17.3.2.2 Passive Equipment

Passive equipment typically performs containment functions and consequently should maintain a certain minimum structural strength or pressure boundary. Such equipment usually does not perform mechanical motions or produce measurable response signals, but it may have to maintain displacement tolerances. Some examples of passive equipment are piping, tanks, cables, supporting structures, and heat exchangers.

17.3.2.3 Functional Testing

When defining the intended functions of an object for test purposes, the following information should be gathered for each active component of the object that will be tested:

1. The maximum number of times a given function should be performed during the design life of the equipment
2. The best achievable precision (or monitoring tolerance) for each functional-operability parameter and the time duration for which a given precision is required
3. Mechanisms and states of malfunction or failure
4. Limits of the functional-operability parameters (electrical signals, pressures, temperatures, flow rates, mechanical displacements and tolerances, relay chatter, and so forth) that correspond to a state of malfunction or failure

It should be noted that, under a state of malfunction, the object will not perform the intended function properly. Under a failure state, however, the object will not perform its intended function at all.

For objects consisting of an assembly of several crucial components, it should be determined how a malfunction or failure of one component could result in the malfunction or failure of the entire unit. In such cases, any hardware redundancy (that is, when component failure does not necessarily cause unit failure) and possible interactive and chain effects (such as failure in one component overloading another, which could result in subsequent failure of the second component, and so on) should be identified. In considering functional precision, it should be noted that high precision usually means increased complexity of the test procedure. This is further complicated if a particular level of precision is required at a prescribed instant.

It is a common practice for the test object supplier (the customer) to define the functional test, including acceptance criteria and tolerances for each function, for the benefit of the test engineer. This information eventually is used in determining acceptance criteria for the tests of active equipment. Complexity of the required tests also depends on the precision requirements for the intended functions of the test object.

Examples of functional failure are sensor and transducer (measuring instrumentation) failure, actuator (motors, valves, and so forth) failure, chatter in relays, gyroscopic and electronic-circuit drift, and discontinuity of electrical signals because of short-circuiting. It should be noted that functional failures caused by mechanical excitation are often linked with the structural integrity of the test object. Such functional failures are primarily caused in two situations: (1) when displacement amplitude exceeds a certain critical value once or several times, or (2) when vibrations of moderate amplitudes occur for an extended period of time. Functional failures in the first category include, for example, short-circuiting, contact errors, instabilities and nonlinearities (in relays, amplifier outputs, etc.). Such failures are usually reversible, so that, when the excitation intensity drops, the system will function normally. Under the second category, slow degradation of components will occur because of aging, wear, and fatigue, which can cause drift, offset, etc., and subsequent malfunction or failure. This kind of failure is usually irreversible. We must emphasize that the first category of functional failure can be better simulated using high-intensity single-frequency testing and shock testing, and the second category by multifrequency or broadband random testing and low-intensity single-frequency testing.

For passive devices, a damage criterion should be specified. This could be expressed in terms of parameters such as cumulative fatigue, deflection tolerances, wear limits, pressure drops, and leakage rates. Often, damage or failure in passive devices can be determined by visual inspection and other nondestructive means.

17.3.3 Information Acquisition

In addition to information concerning service functions, as discussed in the previous section, and dynamic characteristics determined from a resonance search, as will be discussed later in this chapter, there are other characteristics of the test object that need to be studied in the development of a vibration

testing program. In particular, there are characteristics that cannot be described in exact quantitative terms. In determining the value of a piece of equipment, for instance, the monetary value (or cost) might be relatively easy to estimate, whereas it can be very difficult to assign a dollar value to its significance under service conditions. One reason for this is that a particular piece of equipment alone may not determine the proper operation of a complex system. Interaction of a particular unit with other subsystems in a complex operation would determine the importance attached to it and, hence, its value. In this sense, the true value of a test object is a relatively complex consideration. The service function of the test object is also an important consideration in determining its value. The value of a test object is important in planning a test program, because the cost of a test program and the effort expended therein are governed mainly by this factor.

Many features of a test object that are significant in planning a test program can be deduced from manufacturer's data for the particular object. The following information is representative:

1. Drawings (schematic or to scale when appropriate) of principal components and the whole assembly, with the manufacturer's name, identification numbers, and dimensions clearly indicated
2. Materials used, design strengths, fatigue life, and so on, of various components, and factors determining the structural integrity of the unit
3. Component weight and total weight of the unit
4. Design ratings, capacities, and tolerances for in-service operation of each crucial component
5. Description of the intended functions of each component and of the entire unit, clearly indicating the parameters that determine functional operability of the unit
6. Interface details (inter-component as well as for the entire assembly), including in-service mounting configurations and mounting details
7. Details of the probable operating site or operating environment (particularly with respect to the excitation events if product qualification is intended)
8. Details of any previous testing or analysis performed on that unit or a similar one

Scale drawings and component-weight information describe the size and geometry of the test object. This information is useful in determining the following:

1. The locations of sensors (accelerometers, strain gages, stroboscopes, and the like) for monitoring dynamic response of the test object during tests;
2. The necessary ratings for vibration test (shaker) apparatus (power, force, stroke, bandwidth, and so on);
3. The degree of dynamic interaction between the test object and the test apparatus;
4. The level of coupling between various DoFs and modal interactions in the test object;
5. The assembly level of the test object (for example, whether it can be treated as a single component, as a subsystem consisting of several components, or as an independent, stand-alone system)

In general, as the size and the assembly level increase, the tests become increasingly complex and difficult to perform. To test heavy, complex test objects, we require a large test apparatus with high power ratings and the capability of multiple excitation locations. In this case, the number of operability parameters that are monitored and the number of observation (sensor) locations also will increase.

17.3.3.1 Interface Details

The dynamics of a piece of equipment depend on the way the equipment is attached to its support structure. In addition to the mounting details, the dynamic response of equipments is affected by other interfacing linkages, such as wires, cables, conduits, pipes, and auxiliary instrumentation. In the vibration testing of equipment, such interface characteristics should be simulated appropriately. Dynamics of the test fixture and the details of the test object–fixture interface are very important considerations that affect the overall dynamics of the test object. If the interface characteristics are not properly represented during testing, a nonuniform test could result, in which case some parts of the test object are be overtested and

FIGURE 17.13 Influence of test fixture on the test excitation signal.

other parts undertested. This situation can bring about failures that are not representative of the failures that could take place in actual service. In effect, the testing could become meaningless if interface details are not simulated properly.

The test fixture is a structure attached to the shaker table and used to mount the test object (see Figure 17.13). Test-fixture dynamics can significantly modify the shaker-table motion before reaching the test object. Such modifications include filtering of the shaker motion and the introduction of auxiliary (cross-axis) motions. In the test set-up shown in Figure 17.13, for example, the direct motion will be modified to some extent by fixture dynamics. In addition, some transverse and rotational motion components will be transmitted to the test object by the test fixture because of its overhang.

To minimize interface-dynamic effects in vibration testing situations, an attempt should be made to (1) make the test fixture as light and as rigid as is feasible; (2) simulate in-service mounting conditions at the test object–fixture interface; and (3) simulate other interface linkages, such as cables, conduits, and instrumentation, to represent in-service conditions. Very often, the design of a proper test fixture can be a costly and time-consuming process. A trade-off is possible by locating the control sensors (accelerometers) at the mounting locations of the test object, and then using the error between the actual and the desired excitations through feedback to control the mounting-location excitations during testing.

17.3.3.2 Effect of Neglecting Interface Dynamics

We shall consider a simplified model to study some important effects of neglecting interface dynamics. In the model shown in Figure 17.14, the equipment and the mounting interface are modeled separately as single-DoF systems. Capital letters are used to denote the equipment parameters (mass, M ; stiffness, K ; and damping coefficient, C). When mounting-interface dynamics are included, the model appears as in Figure 17.14(a). When the mounting-interface dynamics are neglected, we obtain the single-DoF model shown in Figure 17.14(b). Note that, in the latter case, the shaker motion, $u(t)$, is directly applied to the equipment mounts whereas, in the former case, it is applied through the interface. If the equipment response in the two cases is denoted by y and \tilde{y} , respectively, one can see, by considering the system-frequency transfer functions, $Y(\omega)/U(\omega)$ and $\tilde{Y}(\omega)/U(\omega)$, that

$$\frac{\tilde{Y}(\omega)}{Y(\omega)} = \frac{Ms^2}{(Ms^2 + Cs + K)} \frac{(Cs + K)}{(cs + k)} + \frac{(ms^2 + cs + k)}{(cs + k)} \quad (17.70)$$

with $s = j\omega$. The following nondimensional parameters are defined:

$$\text{Mass ratio } \alpha = \frac{m}{M} \quad (17.71)$$

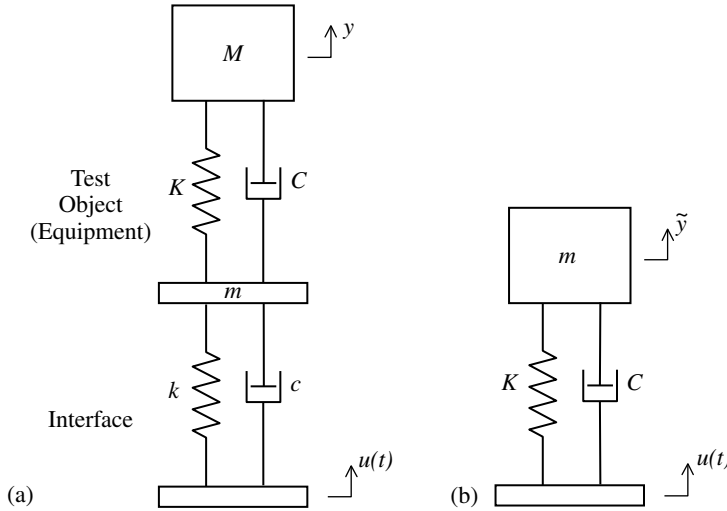

FIGURE 17.14 A simplified model to study the effect of interface dynamics: (a) with interface dynamics; (b) without interface dynamics.

$$\text{Natural frequency ratio } \beta = \frac{\omega_n}{\Omega_n} \quad (17.72)$$

$$\text{Normalized excitation frequency } \bar{\omega} = \frac{\omega}{\Omega_n} \quad (17.73)$$

in which the natural frequency (undamped) of the equipment is

$$\Omega_n = \sqrt{\frac{K}{M}} \quad (17.74)$$

and the mounting-interface natural frequency is

$$\omega_n = \sqrt{\frac{k}{m}} \quad (17.75)$$

Then, Equation 17.70 can be written

$$\frac{\tilde{Y}(\omega)}{Y(\omega)} = \frac{(\beta^2 + 2j\zeta\beta\bar{\omega} - \bar{\omega}^2)}{(\beta^2 + 2j\zeta\beta\bar{\omega})} - \frac{\bar{\omega}(1 + 2jZ\bar{\omega})}{\alpha(\beta^2 + 2j\zeta\beta\bar{\omega})(1 + 2jZ\bar{\omega} - \bar{\omega}^2)} \quad (17.76)$$

in which ζ and Z denote the damping ratios of the interface and the equipment, respectively.

The ratio $\tilde{Y}(\omega)/Y(\omega)$ is representative of the equipment-response amplification when interface-dynamic effects are neglected for a harmonic excitation. Figure 17.15 shows eight curves, corresponding to Equation 17.76, for the parameter combinations given in Table 17.2. Interpretation of the results becomes easier when peak values of the response ratios are compared for various parameter combinations. Sample results are given Table 17.2.

17.3.3.3 Effects of Damping

By comparing the cases from Case 1 to Case 4 in Table 17.2 with the cases from Case 5 to Case 8, respectively (comparing Case 1 with Case 5 and so forth), we see that increasing the interface damping has reduced the peak response (a favorable effect), irrespective of the values of the interface mass and natural frequency (α and β values).

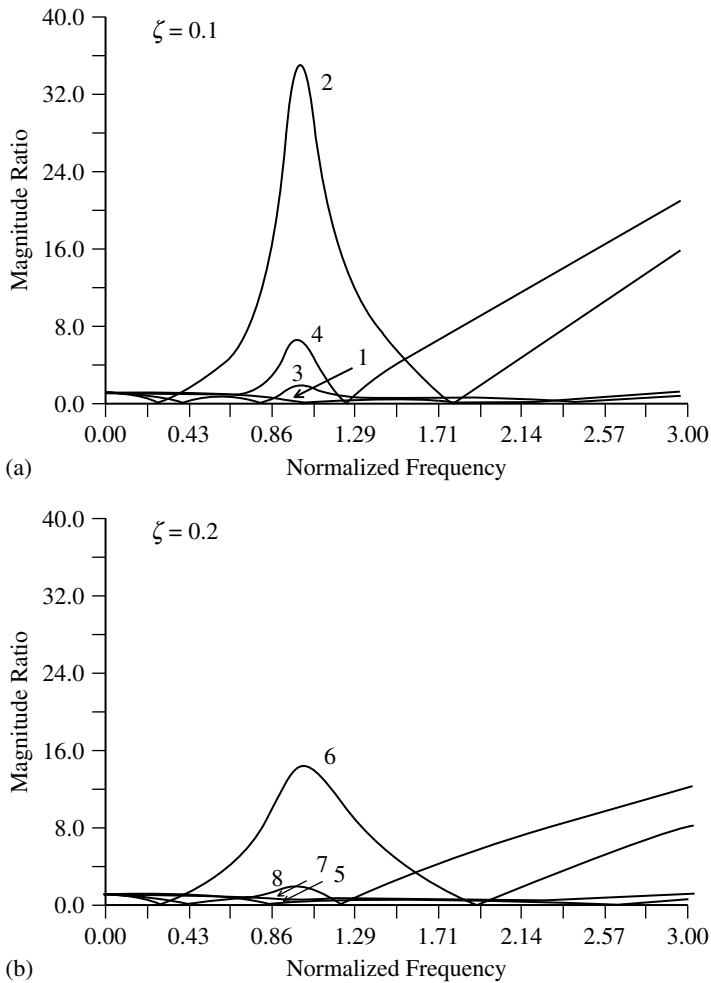

FIGURE 17.15 Response amplification when interface dynamic interactions are neglected.

17.3.3.4 Effects of Inertia

By comparing the cases from Case 1 to Case 4 in Table 17.2 with the cases from Case 5 to Case 8, respectively, we see that the interface inertia has a favorable effect in decreasing dynamic interaction, irrespective of the interface damping and natural frequency.

TABLE 17.2 Response Amplification Caused by Neglecting Interface Dynamics

Case (Curve No.)	Parameter Combination				Peak Value of Response Ratio
	ζ	α	β	Z	
1	0.1	2.0	2.0	0.1	1.11
2	0.1	0.5	0.5	0.1	38.80

17.3.3.5 Effect of Natural Frequency

By comparing the cases from Case 1 to Case 4 in [Table 17.2](#) with the cases from Case 5 to Case 8, respectively, we see that increasing the interface natural frequency has a favorable effect in decreasing dynamic interactions, irrespective of the interface damping and inertia.

17.3.3.6 Effect of Excitation Frequency

All the response plots ([see Figure 17.15](#)) diverge to ∞ as $\bar{\omega}$ increases. This indicates that, at very high excitation-input frequencies, dynamic-testing results can become meaningless because of the interactions with interface dynamics.

It can be concluded that, to reduce dynamic interactions caused by a mechanical interface, we should (1) increase interface damping as much as is feasible, (2) increase interface mass as much as is feasible, (3) increase interface natural frequency as much as is feasible, and (4) avoid testing at relatively high frequencies of excitation. It should be noted that, in the foregoing analysis and discussion, the mechanical interface was considered to include test fixtures and the shaker table as well.

17.3.3.7 Other Effects of Interface

The type of vibration test used sometimes depends on the mechanical interface characteristics. An example is the testing of line-mounted equipment. Single-frequency testing is preferred for such equipment so as to add a certain degree of conservatism because, as a result of interface resonances, line-mounted equipment could be subjected to higher levels of narrowband excitation through the support structure.

In vibration testing of multicomponent equipment cabinets, it is customary to test the empty cabinet first, with the components replaced by dummy weights, and then to test the individual components separately, using different test excitations depending on the component locations and their mounting characteristics. Mechanical interface details of individual components are important in such situations. As a result, interface information is an important constituent of the pretest information that is collected for a test object.

Most of the interface data, particularly information related to size and geometry (for example, mass, dimensions, configurations, and locations), can be gathered simply by observing the test object and using scale drawings supplied by the manufacturer. Knowledge of the size and number of anchor bolts used or the weld thickness, for example, can be obtained in this manner. When analysis is also used to augment testing, however, it is often necessary to know the loads transmitted (forces, moments, and so on), relative displacements, and stiffness values at the mechanical interface under in-service conditions. These must be determined by tests, by analysis (static or dynamic) of a suitable model, or from manufacturer's data.

17.3.4 Test-Program Planning

The test program to which a test object is subjected depends on several factors including the following:

1. The objectives and specific requirements of the test
2. In-service conditions, including equipment-mounting features, the vibration environment, and specifications of the test environment
3. The nature of the test object, including complexity, assembly level, and functional-operability parameters to be monitored
4. Test-laboratory capabilities, available testing apparatus, past experience, conventions, and established practices of testing

Some of these factors are based on solid technical reasons, whereas others depend on economics, convenience, and personal likes and dislikes.

Initially, it is not necessary to develop a detailed test procedure; this is required only at the stage of actual testing. In the initial stage it is only necessary to select the appropriate test method, based on factors such as those listed in the beginning of this section. Before conducting the tests, however, a test procedure should be prepared in sufficient detail. In essence, this is a pretest requirement.

Objectives and specific requirements of a test depend on such considerations as whether the test is conducted at the design stage, the quality-control stage or the utilization stage. The objective of a particular test could be to verify the outcome of a previously conducted test. In that case, it is necessary to assess the adequacy of one or a series of tests conducted at an earlier time (for instance, when the specifications and government regulations were less stringent). Often, this could be done by analysis alone. Some testing might be necessary at times, but it usually is not necessary to repeat the entire test program. If the previous tests were conducted for the frequency range 1 to 25 Hz, for example, and the present specifications require a wider range of 1 to 35 Hz, it might be adequate merely to demonstrate (by analysis or testing) that there are no significant resonances in the test object in the 25 to 35 Hz range.

If it is necessary to qualify the test object for several different dynamic environments, a generic test that represents (conservatively, but without the risk of overtesting) all these environments could be used. For this purpose, special test-excitation inputs must be generated, taking into account the variability of the excitation characteristics under the given set of environments. Alternatively, several tests might be conducted if the dynamic environments for which the test object is to be qualified are significantly different. Operating-basis earthquake (OBE) tests and safe-shutdown earthquake (SSE) tests in seismic qualification of nuclear power plant equipment, for example, represent two significantly different test conditions. Consequently, they cannot be represented by a single test. When qualifying an equipment for several geographic regions or locations, however, we might be able to combine all OBE tests into a single test and all SSE tests into another single test.

Another important consideration in planning a test program is the required accuracy for the test, including the accuracy for the excitation inputs, response and operability measurements, and analysis. This is related to the value of the test object and the objectives of the test.

When it is required to evaluate or qualify a group of equipment by testing a sample, it is first necessary to establish that the selected sample unit is truly representative of the entire group. When the items in the batch are not identical in all respects, some conservatism could be added to the tests to minimize the possibility of an incorrect qualification decision. It might be necessary to test more than one sample unit in such situations.

When planning a test procedure, we should clearly identify the standards, government regulations, and specifications that are applicable to a particular test. The pertinent sections of the applicable documents should be noted, and proper justification should be given if the tests deviate from regulatory-agency requirements.

The excitation input that is employed in a vibration test depends on the in-service vibration environment of the test object. The number of tests needed will also depend on this to some extent. Test orientation depends mainly on the mounting features and the mechanical interface details of the test object under in-service conditions. Mounting features might govern the nature of the test excitations used for a particular test.

Two distinct mounting types can be identified for most equipment: (1) *line-mounted equipment* and (2) *floor-mounted equipment*. Line-mounted equipment is equipment that is mounted upright or hanging from pipelines, cables, or similar line structures that are not rigid. Generally, devices such as valves, nozzles, valve actuators, and transducers are to be considered line-mounted equipment. Any equipment that is not line-mounted is considered floor-mounted. The supporting structure is considered to be relatively rigid in this case. Examples of such mounting structures are floors, walls, and rigid frames. Typical examples of floor-mounted equipment include motors, compressors, and cabinets of relays and switchgear.

Wide-band floor disturbances are filtered by line structures. Consequently, the environmental disturbances to which line-mounted equipment is subjected are generally narrowband disturbances. Accordingly, vibration testing of line-mounted equipment is best performed using narrowband random test excitations or single-frequency deterministic test excitations. Higher test intensities can be necessary for line-mounted equipment, because any low-frequency resonances that are present

in the mounting structure (which is relatively flexible in this case) can amplify the excitations before reaching the equipment.

Floor-mounted equipment often requires relatively wide-band random test excitations. As an example, consider a pressure transducer mounted on (1) a rigid wall, (2) a rigid I-section frame, (3) a pressurized gasline, or (4) a cabinet. In cases (1) and (2), wide-band random excitations with response spectra approximately equal to the floor-response spectra can be employed for vibration testing of the pressure transducer. For cases (3) and (4), however, flexibility of the support structure should be taken into consideration in developing the RRS specifications for vibration testing. In case (3), a single-frequency deterministic test, such as a sine-beat test or a sine-dwell test, can be employed, giving sufficient attention to testing at the equipment-resonant frequencies. In case (4), single-frequency tests can also be employed if the cabinet is considerably flexible and not rigidly attached to a rigid structure (a floor or a wall). Alternatively, a wide-band test on the cabinet itself, with the pressure transducer mounted on it, could be used.

Size, complexity, assembly level, and related features of a test object can significantly complicate and extend the test procedure. In such cases, testing the entire assembly might not be practical and testing of individual components or subassemblies might not be adequate because, in the in-service dynamic environment, the motion of a particular component could be significantly affected by the dynamics of other components in the assembly, the mounting structure, and other interface subsystems.

Functional-operability parameters to be monitored during testing should be predetermined. They depend on the purpose of the test, the nature of the test object, and the availability and characteristics of the sensors that are required to monitor these parameters. Malfunction or failure criteria should be related in some way to the monitored operability parameters; that is, each operability parameter should be associated with one or several components in the test object that are crucial to its operation.

The decision of whether to perform an active test (for example, whether a valve should be cycled during the test) and determination of the actuation time requirements (for example, the number of times the valve is cycled and at what instants during the test) should be made at this stage. The loading conditions for the test (that is, in-service loading simulation) also should be defined.

An important nontechnical factor that determines the nature of a vibration test is the availability of hardware (test apparatus) in the test laboratory. This is especially true when nonconventional vibration tests are required. Some specifications require three-DoF test inputs, for example, but most test laboratories have only one-DoF or two-DoF test machines. When two-DoF or one-DoF tests are used in place of three-DoF tests, it is first required to determine what additional orientations of the test object should be tested in order to add the required conservatism. Additionally, it should be verified by analysis or testing that the modified series of tests does not cause significant undertesting or overtesting of certain parts of the test object. Otherwise, some other form of justification should be provided for replacing the test.

Test plans prepared in the pretest stage should include an adequate description of the following important items:

1. Test purpose
2. Test-object details
3. Test environment, specifications, and standards
4. Functional-operability parameters and failure or malfunction criteria
5. Pretest inspection
6. Aging requirements
7. Test outline
8. Instrumentation requirements
9. Data-processing requirements
10. Methods of evaluation of the test results

17.3.4.1 Testing of Cabinet-Mounted Equipment

In the vibration testing of cabinet-mounted or panel-mounted equipment, the following is a standard procedure.

- Step 1:* Test the cabinet or panel with the equipment replaced by a dummy weight.
- Step 2:* Obtain the cabinet response at equipment-mounting locations and, based on these observations, develop the required vibration environment for testing (the RRS) of the equipment.
- Step 3:* Test the equipment separately, using the excitations developed in Step 2.

This procedure may not be satisfactory if there is a considerable degree of dynamic interaction between the equipment and the mounting cabinet. This could be illustrated by using a simplified model to represent cabinet-mounted equipment. The cabinet and the equipment are represented separately by single-DoF systems, as shown in Figure 17.16. Cabinet parameters are represented by upper-case letters and equipment parameters by lower-case letters. The cabinet responds when the equipment is replaced by a dummy weight of equal mass, which is denoted by $\tilde{y}(t)$. The test excitation applied to the cabinet base is denoted by $u(t)$. It can be shown that the frequency-response ratio in the two cases is given by

$$\frac{\tilde{Y}(\omega)}{Y(\omega)} = \frac{[ms^2(cs + k)]/(ms^2 + cs + k) + Ms^2 + Cs + K}{(M + m)s^2 + Cs + K} \quad (17.77)$$

with $s = j\omega$. Using the nondimensional parameters defined by the equations from Equation 17.71 to Equation 17.75, we obtain

$$\frac{\tilde{Y}(\omega)}{Y(\omega)} = \frac{(j\bar{\omega})^2 \alpha (2\zeta\beta j\bar{\omega} + \beta^2) + (j\bar{\omega})^2 + 2Zj\bar{\omega} + 1}{(1 + \alpha)(j\bar{\omega})^2 + 2Zj\bar{\omega} + 1} \quad (17.78)$$

in which ζ denotes the equipment damping ratio and Z denotes the cabinet damping ratio.

The ratio $\tilde{Y}(\omega)/Y(\omega)$ represents the amplification in the cabinet response when the equipment is replaced by a dummy weight for a harmonic excitation. Figure 17.17 shows eight curves obtained for the ζ , α , β , and Z combinations, as given in Table 17.2. Notice that the best response is obtained in Curve 6. It can be concluded that a dummy test procedure for cabinet-mounted equipment is satisfactory when

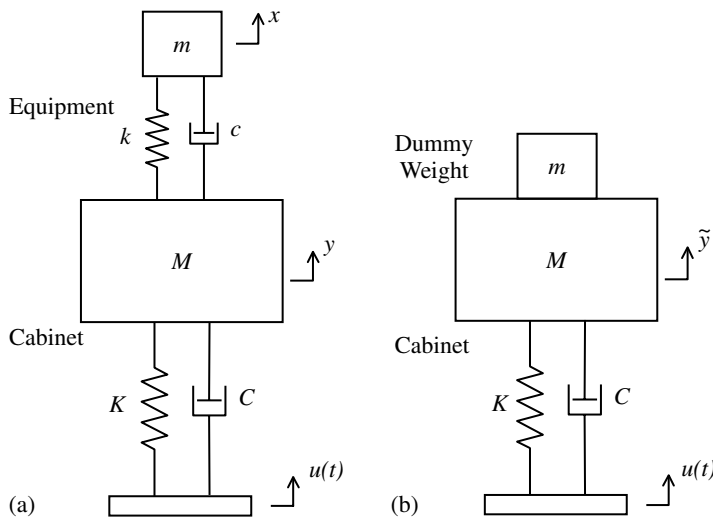

FIGURE 17.16 A simplified model for (a) an equipment cabinet test system; (b) a dummy-weight cabinet test system.

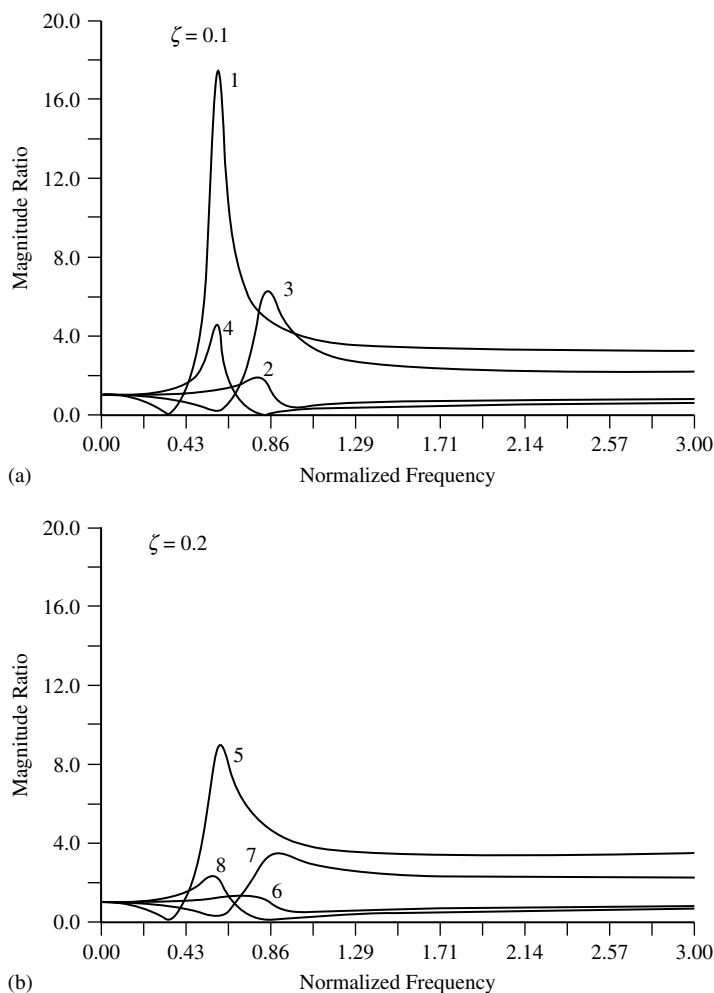

FIGURE 17.17 Cabinet response amplification in dummy-weight tests.

the equipment inertia and natural frequency are small in comparison to the values for the cabinet. Also, increasing the damping level has a favorable effect on test results.

17.3.5 Pretest Inspection

Pretest inspection of a test object is important at least for two major reasons. First, if the equipment supplied for testing is different from the piece of equipment or the group of equipment that is required to be qualified, then these differences must be carefully observed and recorded in sufficient detail. In particular, deviations in the model number, mounting features and other details of the mechanical interface, geometry, size, and significant dynamic features should be recorded. Second, before testing, the test object should be inspected for any damage, deficiencies, or malfunctions. Structural integrity usually can be determined by visual inspection alone. To determine malfunctions by operability monitoring, however, the test object must be actuated and the operating environment should be simulated.

If the equipment supplied for testing is not identical to that required to be tested, adequate justification must be provided for the differences to guarantee that the objectives of the test can be achieved by testing the equipment that is supplied. Otherwise, the test should be abandoned pending the arrival of the correct test object.

If any structural failure or operation malfunction is noted during pretest inspection, no corrective action should be taken by the test laboratory personnel unless those actions are notified to and fully authorized by the supplier of the test object. Otherwise, the test should be abandoned and the customer should be promptly notified of the anomalies.

It is important that the functional-operability pretest inspection is performed in the same functional environment as that is experienced under normal in-service conditions. When monitoring functional-operability parameters, it is necessary to guarantee that the monitoring instrumentation meets the required accuracy. Instrumentation data should be provided to the customer for review. This assures that the observed malfunction is real and not merely apparent, caused by a malfunction in the monitoring instrumentation and channels. The monitoring-equipment accuracy should be higher than that required for the operability parameter itself.

Justification is needed if some components in the test object are not actuated and monitored during pretest inspection. Also, the warm-up period and the total time of actuation should be justified. In particular, if the proper operation of the equipment is governed by the continuity of a parameter (such as an electrical signal), the time duration of monitoring should be noted. If, however, the proper function is governed by a change of state (such as the opening or closing of a valve, a switch, or a relay), the number of cycles of actuation is important.

17.4 Testing Procedures

Vibration testing may involve pretesting prior to the main tests. The objectives of pretesting may be (1) exploratory, in order to obtain dynamic information such as natural frequencies, mode shapes and damping about the test object; (2) preconditioning, in order to age or pass the “infant-mortality” stage so that the main test will be realistic and correspond to normal operating conditions. In the present section, we will describe both pretesting and main testing in an integrated manner.

17.4.1 Resonance Search

Vibration test programs usually require a resonance-search pretest. This is typically carried out at a lower excitation intensity than that used for the main test in order to minimize the damage potential (overtesting). The primary objective of a resonance-search test is to determine resonant frequencies of the test object. More elaborate tests are employed, however, to determine mode shapes and modal damping ratios in addition to resonant frequencies. Such frequency-response data on the test object are useful in planning and conducting the main test.

Frequency-response data usually are available as a set of complex frequency-response functions. There are tests that determine the frequency-response functions of a test object, and simpler tests are available to determine resonant frequencies alone. Some of the uses of frequency-response data are given below.

1. A knowledge of the resonant frequencies of the test object is important in conducting the main test. More attention should be given, for example, when performing a main test in the vicinity of resonant frequencies. In the resonance neighborhoods, lower sweep rates should be used if sine sweep is used in the main test, and larger dwell periods should be used if a sine dwell is part of the main test. Frequency-response data give the most desirable frequency range for conducting main tests.
2. From frequency-response data, it is possible to determine the most desirable test excitation directions and the corresponding input intensities.
3. The degree of nonlinearity and the time variance in the system parameters of the test object can be estimated by conducting more than one frequency-response test at different excitation levels. If the deviation in the frequency-response functions thus obtained is

sufficiently small, then a linear, time-invariant dynamic model is considered satisfactory in the analysis of the test object.

4. If no resonances are observed in the test object over the frequency range of interest, as determined by the operating environment for a given application, then a static analysis will be adequate to qualify the test object.
5. A set of frequency-response functions can be considered a dynamic model for the test specimen. This model can be employed in further studies of the test specimen by analytical means.

17.4.2 Methods of Determining Frequency-Response Functions

Three methods of determining frequency-response functions are outlined here.

17.4.2.1 Fourier Transform Method

If $y(t)$ is the response at location B of the test object, when a transient input, $u(t)$, is applied at location A , then the frequency-response function, $H(f)$, between locations A and B is given by the ratio of the Fourier integral transforms of the output, $y(t)$, and the input, $u(t)$:

$$H(f) = \frac{Y(f)}{U(f)} \quad (17.79)$$

In particular, if $u(t)$ is a unit impulse, then $U(f) = 1$ and, hence, $H(f) = Y(f)$.

17.4.2.2 Spectral Density Method

If the input excitation is a random signal, the frequency-response function between the input point and the output point can be determined as the ratio of the cross-spectral density, $\Phi_{uy}(f)$, of the input, $u(t)$, and the output, $y(t)$, and the PSD, $\Phi_{uu}(f)$, of the input:

$$H(f) = \frac{\Phi_{uy}(f)}{\Phi_{uu}(f)} \quad (17.80)$$

17.4.2.3 Harmonic Excitation Method

If the input signal is sinusoidal (harmonic) with frequency, f , the output also will be sinusoidal with frequency, f , at steady state but with a change in the phase angle. Then, the frequency-response function is obtained as a magnitude function and a phase-angle function. The magnitude, $|H(f)|$, is equal to the steady-state amplification of the output signal, and the phase angle, $\angle H(f)$, is equal to the steady-state phase lead of the output signal. This pair of curves, the magnitude plot and the phase angle plot, is called a *Bode plot* or Bode diagram.

17.4.3 Resonance-Search Test Methods

There are three basic types of resonance-search test methods. They are categorized according to the nature of the excitation used in the test; specifically, (1) impulsive excitation, (2) initial displacement, or (3) forced vibration. The first two categories are free-vibration tests; that is, response measurements are made on free decay of the test object following a momentary (initial) excitation. Typical tests belonging to each of these categories are described in the following sections.

17.4.3.1 Hammer (Bump) Test and Drop Test

In a resonance search using the impulsive-excitation method, an impulsive force (a large magnitude of force acting over a very short duration) is applied at a suitable location of the test object, and the resulting transient response of the object is observed, preferably at several locations. This is

FIGURE 17.18 Schematic diagram of a hammer test arrangement.

equivalent to applying an initial velocity to the test object and letting it vibrate freely. By Fourier analysis of the response data, it is possible to obtain the resonant frequencies, corresponding mode shapes, and modal damping.

Hammer tests and drop tests belong to the impulsive-excitation category. A schematic diagram of the hammer-test arrangement is shown in Figure 17.18. A schematic diagram of the drop-test arrangement is shown in Figure 17.19. The angle of swing of the hammer or the drop height of the object determines the intensity of the applied impulse. Alternatively, the impulse can be generated using explosive cartridges (for relatively large structures) located suitably in the test object, or by firing small projectiles at the test object. The response is monitored at several locations of the test object. The response at the point of application of the impulse is always monitored. Response analysis can be done in real time, or the response can be recorded for subsequent analysis. A major concern in these tests is making sure that all significant resonances in the required frequency range are excited under the given excitation. Several tests for different configurations of the test object might be necessary to achieve this.

Proper selection of the response-monitoring locations is also important in obtaining meaningful test results. By changing the impulsive-force intensity and repeating the test, any significant nonlinear (or time-variant-parameter) behavior of the test object can be determined. A common practice is to monitor the impulsive-force signal during impact. In this way, poor impacts (for example, low-intensity impacts

FIGURE 17.19 Schematic diagram of a drop test arrangement.

or multiple impacts caused by the bouncing back of a hammer) can be detected and the corresponding test results can be rejected.

17.4.3.2 Pluck Test

A resonance search on a test object can be performed by applying a displacement initial condition (rather than a velocity initial condition, as in impulsive tests) to a suitably mounted test object and measuring its subsequent response at various locations as it executes free vibrations. By properly selecting the locations and the magnitudes of the initial displacements, it is sometimes possible to excite various modes of vibration, provided that these modes are reasonably uncoupled.

The pluck test is the most common test that uses the initial-displacement method. A schematic diagram of the test set-up is shown in Figure 17.20. The test object is initially deflected by pulling it with a cable. When the cable is suddenly released, the test object will undergo free vibrations about its static-equilibrium position. The response is observed for several locations of the test object and analyzed to obtain the required parameters.

In Figure 17.18 to Figure 17.20, the frequency-response function between two locations (*A* and *B*, for example) is obtained by analyzing the corresponding two signals, using either the Fourier transform method (Equation 17.79) or the spectral-density method (Equation 17.80). These frequency-domain techniques will automatically provide the natural-frequency and modal-damping information. Alternatively, modal damping can be determined using time-domain methods, for example, by evaluating the logarithmic decrement of the response after passing it through a filter having a center frequency adjusted to the predetermined natural frequency of the test object for that mode. The accuracy of the estimated modal-damping value can be improved significantly by such filtering methods.

Often, the most difficult task in a natural-frequency search is the excitation of a single a mode. If two natural frequencies are close together, modal interactions of the two invariably will be present in the response measurements. Because of the closeness of the frequencies, the response curve will display a beat phenomenon, as shown in Figure 17.21, which makes it difficult to determine damping by the logarithmic-decrement method. It is difficult to distinguish between decay caused by damping and rapid drop-off caused by beating. In this case, one of the frequency components must be filtered out, using a very narrowband-pass filter, before computing damping.

The required testing time for the impulsive-excitation and initial-displacement test methods is relatively small in comparison with forced-vibration test durations. For this reason, these former (free-vibration) tests are often preferred in preliminary (exploratory) testing before the main tests. The directions and locations of impact or initial displacements should be properly chosen, however, so that as many significant modes as possible will be excited in the desired frequency range. If the

FIGURE 17.20 Diagram of a pluck test arrangement.

FIGURE 17.21 Beat phenomenon resulting from interaction of closely spaced modes.

impact is applied at a node point, (of a particular mode, for instance) it will be virtually impossible to detect that mode from the response data. Sometimes, a large number of monitoring locations are necessary to accurately determine mode shapes of the test object. This depends primarily on the size and dynamic complexity of the test object and the particular mode number. This, in turn, necessitates the use of more sensors (accelerometers and the like) and recorder channels. If a sufficient number of monitoring channels is not available, the test will have to be repeated, each time using a different set of monitoring locations. Under such circumstances, it is advisable to keep one channel (monitoring location) unchanged and to use it as the reference channel. In this manner, any deviations in the test-excitation input can be detected for different tests and properly adjusted or taken into account in subsequent analysis (for example, by normalizing the response data).

17.4.3.3 Shaker Tests

A convenient method of resonance search is by using a continuous excitation. A forced excitation, which typically is a sinusoidal signal or a random signal, is applied to the test object by means of a shaker, and the response is continuously monitored. The test set-up is shown schematically in Figure 17.22. For sinusoidal excitations, signal amplification and phase shift over a range of excitations will determine the frequency-response function. For random excitations, Equation 17.80 may be used to determine the frequency-response function.

One or several portable exciters (shakers) or a large shaker table similar to that used in the main vibration test can be employed to excite the test object. The number and the orientations of the shakers and the mounting configurations and monitoring locations of the test object should be chosen depending on the size and complexity of the test object, the required accuracy of the resonance-search results, and the modes of vibration that need to be excited. The shaker-test method has the advantage of being able to control the nature of the test-excitation input (for example, frequency content, intensity, and sweep rate), although it might be more complex and costly. The results from shaker tests are more accurate and more complete.

Test objects usually display a change in resonant frequencies when the shaker amplitude is increased. This is caused by inherent nonlinearities in complex structural systems. Usually, the

FIGURE 17.22 Schematic diagram of a shaker test for resonance search.

change appears as a spring-softening effect, which results in lower resonant frequencies at higher shaker amplitudes. If this nonlinear effect is significant, the resonant frequencies for the main test level cannot be accurately determined using a resonance search at low intensity. Some form of extrapolation of the test results, or analysis using an appropriate dynamic model, might be necessary in this case to determine the resonant-frequency information that might be required to perform the main test.

17.4.4 Mechanical Aging

Before performing a qualification test, it is usually necessary to age the test object to put it into a condition that represents its state following its operation for a predetermined period under in-service conditions. In this manner, it is possible to reduce the probability of burn-in failure (infant mortality) during testing. Some tests, such as design-development tests and quality-assurance tests, might not require prior aging.

The nature and degree of aging that is required depends on such factors as the intended function of the test object, the operating environment, and the purpose of the dynamic test. In qualification tests, it may be necessary to demonstrate that the test object still has adequate capability to withstand an extreme dynamic environment toward the end of its design life (that is, the period in which it can be safely operated without requiring corrective action). In such situations, it is necessary to age the test object to an extreme deterioration state, representing the end of the design life of the test object.

Test objects are aged by subjecting them to various environmental conditions (for example, high temperatures, radiation, humidity, and vibrations). Usually, it is not practical to age the equipment at the same rate as it would age under a normal service environment. Consequently, accelerated aging procedures are used to reduce the test duration and cost. Furthermore, the operating environment may not be fully known at the testing stage. This makes the simulation of the true operating environment virtually impossible. Usually, accelerated aging is done sequentially, by subjecting the test equipment to the various environmental conditions one at a time. Under in-service conditions, however, these effects occur simultaneously, with the possibility of interactions between different effects. Therefore, when sequential aging is employed, some conservatism should be added. The type of aging used should be consistent with the environmental conditions and operating procedures of the specific application of the test object. Often these conditions are not known in advance, in which case, standardized aging procedures should be used.

Our main concern in this section is mechanical aging, although other environmental conditions can significantly affect the dynamic characteristics of a test object. The two primary mechanisms of mechanical aging are material fatigue and mechanical wearout. The former mechanism plays a primary role if in-service operation consists of cyclic loading over relatively long periods of time. Wearout, however, is a long-term effect caused by any type of relative motion between components of the test object. It is very difficult to analyze component wearout, even if only the mechanical aspects are considered (that is the effects of corrosion, radiation, and the like are neglected). Some mechanical wearout processes resemble fatigue aging; however, they depend simultaneously on the number of cycles of load applications and the intensity of the applied load. Consequently, only the cumulative damage phenomenon, which is related to material fatigue, is usually treated in the literature.

Although mechanical aging is often considered a pretest procedure (for example, the resonance-search test), it actually is part of the main test. In a dynamic qualification program, if the test object malfunctions during mechanical aging, this amounts to failure in the qualification test. Furthermore, exploratory tests, such as resonance-search tests, are sometimes conducted at higher intensities than what is required to introduce mechanical aging into the test object.

17.4.4.1 Equivalence for Mechanical Aging

It is usually not practical to age a test object under its normal operating environment, primarily because of time limitations and the difficulty in simulating the actual operating environment. Therefore, it may

be necessary to subject the test object to an accelerated aging process in a dynamic environment of higher intensity than that present under normal operating conditions.

Two aging processes are said to be equivalent if the final aged condition attained by the two processes is identical. This is virtually impossible to realize in practice, particularly when the object and the environment are complex and the interactions of many dynamic causes have to be considered. In this case, a single most severe aging effect is used as the standard for comparison to establish the equivalence. The equivalence should be analyzed in terms of both the intensity and the nature of the dynamic excitations used for aging.

17.4.4.2 Excitation-Intensity Equivalence

A simplified relationship between the dynamic-excitation intensity, U , and the duration of aging, T , that is required to attain a certain level of aging, keeping the other environmental factors constant, may be given as

$$T = \frac{c}{U^r} \quad (17.81)$$

in which c is a proportionality constant and r is an exponent. These parameters depend on such factors as the nature and sequence of loading and characteristics of the test object. It follows from Equation 17.81 that, by increasing the excitation intensity by a factor n , the aging duration can be reduced by a factor of n^r . In practice, however, the intensity–time relationship is much more complex, and caution should be exercised when using Equation 17.81. This is particularly true if the aging is caused by multiple dynamic factors of varying characteristics that are acting simultaneously. Furthermore, there is usually an acceptable upper limit to n . It is unacceptable, for example, to use a value that will produce local yielding or any such irreversible damage to the equipment that is not present under normal operating conditions.

It is not necessary to monitor functional operability during mechanical aging. Furthermore, it can happen that, during accelerated aging, the equipment malfunctions but, when the excitation is removed, it operates properly. This type of reversible malfunction is acceptable in accelerated aging.

The time to attain a given level of aging is usually related to the stress level at a critical location of the test object. Since this critical stress can be related, in turn, to the excitation intensity, the relationship given by Equation 17.81 is justified.

17.4.4.3 Dynamic-Excitation Equivalence

The equivalence of two dynamic excitations that have different time histories can be represented using methods employed to represent dynamic excitations (for example, response spectrum, Fourier spectrum, and PSD). If the maximum (peak) excitation is the factor that primarily determines aging in a given system under a particular dynamic environment, then response-spectrum representation is well suited for establishing the equivalence of two excitations. If, however, the frequency characteristics of the excitation are the major determining factor for mechanical aging, then Fourier spectrum representation is favored for establishing the equivalence of two deterministic excitations, and PSD representation is suited for random excitations. When two excitation environments are represented by their respective PSD functions, $\Phi_1(\omega)$ and $\Phi_2(\omega)$, if the significant frequency range for the two excitations is (ω_1, ω_2) , then the degree of aging under the two excitations may be compared using the ratio

$$\frac{A_1}{A_2} = \frac{\int_{\omega_1}^{\omega_2} \Phi_1(\omega) d\omega}{\int_{\omega_1}^{\omega_2} \Phi_2(\omega) d\omega} \quad (17.82)$$

in which A denotes a measure of aging. If the two excitations have different frequency ranges of interest, a range consisting of both ranges might be selected for the integrations in Equation 17.82.

17.4.4.4 Cumulative Damage Theory

Miner's linear cumulative damage theory may be used to estimate the combined level of aging resulting from a set of excitation conditions. Consider m excitations acting separately on a system. Suppose that each of these excitations produces a unit level of aging in N_1, N_2, \dots, N_m loading cycles, respectively, when acting separately. If, in a given dynamic environment, n_1, n_2, \dots, n_m loading cycles, respectively, from the m excitations actually have been applied to the system (possibly all excitations were acting simultaneously), the level of aging attained can be given by

$$A = \sum_{i=1}^m \frac{n_i}{N_i} \quad (17.83)$$

The unit level of aging is achieved, theoretically, when $A = 1$. Equation 17.83 corresponds to Miner's linear cumulative damage theory.

Because of various interactive effects produced by different loading conditions, when some or all of the m excitations act simultaneously, it is usually not necessary to have $A = 1$ under the combined excitation to attain the unit level of aging. Furthermore, it is extremely difficult to estimate $N_i, i = 1, \dots, m$. For such reasons, the practical value of A in Equation 17.83 for using in attaining a unit level of aging could vary widely (typically, from 0.3 to 3.0).

17.4.5 Test-Response Spectrum Generation

A vibration test may be specified by a RRS. In this case, the response spectrum of the actual excitation signal, that is, the TRS, should envelop the RRS during testing. It is customary for the purchaser (the owner of the test object) to provide the test laboratory with a multichannel FM tape or some form of signal storage device containing the components of the excitation input signal that should be used in the test. Alternatively, the purchaser may request that the test laboratory generate the required signal components under the purchaser's supervision. If sine beats are combined to generate the test excitations, each FM tape should be supplemented by tabulated data giving the channel number, the beat frequencies (Hz) in that channel, and the amplitude (g) of each sine-beat component. The RRS curve that is enveloped by the particular input should also be specified.

The excitation signal that is applied to the shaker-table actuator is generated by combining the contents of each channel in an appropriate ratio so that the response spectrum of the excitation that is actually felt at the mounting locations of the test object (the TRS) satisfactorily matches the RRS supplied to the test laboratory. Matching is performed by passing the contents of each channel through a variable-gain amplifier and mixing the resulting components according to variable proportions. These operations are performed by a waveform mixer. The adjustment of the amplifier gains is done by trial and error. The phase of the individual signal components should be maintained during the mixing process.

Each channel may contain a single-frequency component (such as sine beat) or a multifrequency signal of fixed duration (for example, 20 sec). If the RRS is complex, each channel may have to carry a multifrequency signal to achieve close matching of the TRS with the RRS. Also, a large number of channels might be necessary. The test excitation signal is generated continuously by repetitively playing the FM tape loop of fixed duration.

In product qualification, response spectra are usually specified in units of acceleration due to gravity (g). Consequently, the contents in each channel of the test-input FM tape represent acceleration motions. For this reason, the signal from the waveform mixer must be integrated twice before it is used to drive the shaker table. The actuator of the exciter is driven by this displacement signal, and its control may be done by feedback from a displacement sensor. However, if the control sensor is an accelerometer, as is typical, double integration of that signal will be needed as well. In typical test facilities, a double integration unit is built into the shaker system. It is then possible to use any type of signal (displacement, velocity, acceleration) as the excitation input and to decide

simultaneously on the number of integrations that are necessary. If the input signal is a velocity time history, for example, one integration should be chosen and so on.

The tape speed should be specified (for example, 7.5, 15 in./s) when the signals recorded on tapes are provided to generate input signals for vibration testing. This is important to ensure that the frequency content of the signal is not distorted. The speeding up of the tape has the effect of scaling up of each frequency component in the signal. It has also the effect, however, of filtering out very high-frequency components in the signal. If the excitation signals are available as digital records, then a DAC is needed to convert them into analog signals.

17.4.6 Instrument Calibration

The test procedure normally stipulates accuracy requirements and tolerances for various critical instruments that are used in testing. It is desirable that these instruments have current calibration records that are agreeable to an accepted standard. Instrument manufacturers usually provide these calibration records. Accelerometers, for example, may have calibration records for several temperatures (for example, -65 , 75 , 350°F) and for a range of frequencies (such as 1 to 1000 Hz). Calibration records for accelerometers are given in both voltage sensitivity (mV/g) and charge sensitivity (pC/g), along with percentage-deviation values. These tolerances and peak deviations for various test instruments should be provided for the purchaser's review before they are used in the test apparatus.

From the tolerance data for each sensor or transducer, it is possible to estimate peak error percentages in various monitoring channels in the test set-up, particularly in the channels used for functional-operability monitoring. The accuracy associated with each channel should be adequate to measure expected deviations in the monitored operability parameter.

It is good practice to calibrate sensor or transducer units, such as accelerometers and associated auxiliary devices, daily or after each test. These calibration data should be recorded under different scales when a particular instrument has multiple scales, and for different instrument settings.

17.4.7 Test-Object Mounting

When a test object is being mounted on a shaker table, care should be taken to simulate all critical interface features under normal installed conditions for the intended operation. This should be done as accurately as is feasible. Critical interface requirements are those that could significantly affect the dynamics of the test object. If the mounting conditions in the test set-up significantly deviate from those under installed conditions for normal operation, adequate justification should be provided to show that the test is conservative (that is, the motions produced under the test mounting conditions are more severe than in in-service conditions). In particular, local mounting that would not be present under normal installation conditions should be avoided in the test set-up.

In simulating in-service interface features, the following details should be considered as a minimum:

1. Test orientation of the test object should be its in-service orientation, particularly with respect to the direction of gravity (vertical), available DoF, and mounting locations.
2. Mounting details at the interface of the test object and the mounting fixture should represent in-service conditions with respect to the number, size, and strength of welds, bolts, nuts, and other hold-down hardware.
3. Additional interface linkages, including wires cables, conduits, pipes, instrumentation (dials, meters, gauges, sensors, transducers, and so on), and the supporting brackets of these elements, should be simulated at least in terms of mass and stiffness, and preferably in terms of size as well.
4. Any dynamic effects of adjacent equipment cabinets and supporting structures under in-service conditions should be simulated or taken into account in analysis.
5. Operating loads, such as those resulting from fluid flow, pressure forces, and thermal effects, should be simulated if they appear to significantly affect test object dynamics. In particular, the nozzle loads (fluid) should be simulated in magnitude, direction, and location.

The required mechanical interface details of the test object are obtained by the test laboratory at the information-acquisition stage. Any critical interface details that are simulated during testing should be included in the test report.

At least three control accelerometers should be attached to the shaker table near the mounting location of the test object. One control accelerometer measures the excitation-acceleration component applied to the test object in the vertical direction. The other two measure the excitation-acceleration components in two horizontal directions at right angles. The two horizontal (control) directions are chosen to be along the two major freedom-of-motion directions (or dynamic principal axes) of the test object. Engineering judgment may be used in deciding these principal directions of high response in the test object. Often, geometric principal axes are used. The control accelerometer signals are passed through a response-spectrum analyzer (or a suitably programmed digital computer) to compute the TRS in the vertical and two horizontal directions that are perpendicular.

Vibration tests generally require monitoring of the dynamic response at several critical locations of the test object. In addition, the tests may call for the determining of mode shapes and natural frequencies of the test object. For this purpose, a sufficient number of accelerometers should be attached to various key locations in the test object. The test procedure (document) should contain a sketch of the test object, indicating the accelerometer locations. Also, the type of accelerometers employed, their magnitudes and directions of sensitivity, and the tolerances should be included in the final test report.

17.4.8 Test-Input Considerations

In vibration testing, a significant effort goes into the development of test excitation inputs. Not only the nature but also the number and the directions of the excitations can have a significant effect on the outcomes of a test. This is so because the excitation characteristics determine the nature of a test.

17.4.8.1 Test Nomenclature

We have noted that a common practice in vibration testing is to apply synthesized vibration excitation to a test object that is appropriately mounted on a shaker table. Customarily, only translatory excitations as generated by linear actuators, are employed. Nevertheless the resulting motion of the test object usually consists of rotational components as well. A typical vibration environment may consist of three-dimensional motions, however. The specification of a three-dimensional test environment is a complex task, even after omitting the rotational motions at the mounting locations of the test object. Furthermore, practical vibration environments are random and they can be represented with sufficient accuracy only in a probabilistic sense.

Very often the type of testing that is used is governed mainly by the capabilities of the test laboratory to which the contract is granted. Test laboratories conduct tests using their previous experience and engineering judgment. Making extensive improvements to existing tests can be very costly and time-consuming, and this is not warranted from the point of view of the customer or the vendor. Regulatory agencies usually allow simpler tests if sufficient justification can be provided indicating that a particular test is conservative with respect to regulatory requirements.

The complexity of a shaker-table apparatus is governed primarily by the number of actuators that are employed and the number of independent directions of simultaneous excitation that it is capable of producing. Terminology for various tests is based on the number of independent directions of excitation used in the test. It would be advantageous to standardize this terminology to be able to compare different test procedures. Unfortunately, the terminology used to denote different types of tests usually depends on the particular test laboratory and the specific application. Attempts to standardize various test methods have become tedious, partly because of the lack of a universal nomenclature for dynamic testing. A justifiable grouping of test configurations is presented in this section. [Figure 17.23](#) illustrates the various test types.

FIGURE 17.23 Vibration-test configurations.

In test nomenclature, the DoF refers to the number of directions of independent motions that can be generated simultaneously by means of independent actuators in the shaker table. According to this concept, three basic types of tests can be identified:

1. Single-DoF (or rectilinear) testing is that in which the shaker table employs only one exciter (actuator), producing test-table motions along the axis of that actuator. The actuator may not necessarily be in the vertical direction.
2. Two-DoF testing is that in which two independent actuators, oriented at right angles to each other, are employed. The most common configuration consists of a vertical actuator and a horizontal actuator. Theoretically, the motion of each actuator can be specified independently.
3. Three-DoF testing is that in which three actuators, oriented at mutually right angles, are employed. A desirable configuration consists of a vertical actuator and two horizontal actuators. At least theoretically, the motion of each actuator can be specified independently.

It is common practice to specify the directions of excitation with respect to the geometric principal axes of the test object. This practice is somewhat questionable, primarily because it does not take into account the flexibility and inertia distributions of the object. Flexibility and inertia elements in the test object have a significant influence on the level of dynamic coupling present in a given pair of directions. In this respect, it is more appropriate to consider *dynamic principal axes* rather than geometric principal axes of the test object. One useful definition is in terms of eigenvectors of an appropriate three-dimensional, frequency-response function matrix that takes into account the response at every critical location in the test object. The only difficulty in this method is that prior frequency-response testing or analysis is needed to determine the test input direction. For practical purposes, the vertical axis (the direction of gravity) is taken as one principal axis.

The single-DoF (rectilinear) test configuration has three subdivisions, based on the orientation of the vibration exciter (actuator) with respect to the principal axes of the test object. It is assumed that one principal axis of the test object is the vertical axis and that the three principal axes are

mutually perpendicular. The three subdivisions are as follows:

1. Rectilinear uniaxial testing, in which the single actuator is oriented along one of the principal axes of the test object
2. Rectilinear biaxial testing, in which the single actuator is oriented on the principal plane containing the vertical and one of the two horizontal principal axes (the actuator is inclined to both principal axes in the principal plane)
3. Rectilinear triaxial testing, in which the single actuator is inclined to all three orthogonal principal axes of the test object

The two-DoF test configuration has two subdivisions, based on the orientation of the two actuators with respect to the principal axes of the test object, as follows:

1. Two-DoF biaxial testing, in which one actuator is directed along the vertical principal axis and the other along one of the two horizontal principal axes of the test object
2. Two-DoF triaxial testing, in which one actuator is positioned along the vertical principal axis and the other actuator is horizontal but inclined to both horizontal principal axes of the test object

17.4.8.2 Testing with Uncorrelated Excitations

Simultaneous excitations in three orthogonal directions often produce responses (accelerations, stresses, etc.) that are very different from that which is obtained by vectorially summing the responses to separate excitations acting one at a time. This is primarily because of the nonlinear, time-variant nature of test specimens and test apparatus, their dynamic coupling, and the randomness of excitation signals. If these effects are significant, it is theoretically impossible to replace a three-DoF test, for example, with a sequence of three single-DoF tests. In practice, however, some conservatism can be incorporated into two-DoF and single-DoF tests to account for these effects. These tests with added conservatism may be employed when three-DoF testing is not feasible. It should be clear by now that rectilinear triaxial testing is generally not equivalent to three-degree-freedom testing, because the former merely applies an identical excitation in all three orthogonal directions, with scaling factors (direction cosines). One obvious drawback of rectilinear triaxial testing is that the input excitation in a direction at right angles to the actuator is theoretically zero, and the excitation is at its maximum along the actuator. In three-DoF testing using uncorrelated random excitations, however, no single direction has a zero excitation at all times, and also the probability is zero that the maximum excitation occurs in a fixed direction at all times.

Three-DoF testing is mentioned infrequently in the literature on vibration testing. A major reason for the lack of three-DoF testing might be the practical difficulty in building test tables that can generate truly uncorrelated input motions in three orthogonal directions. The actuator interactions caused by dynamic coupling through the test table and mechanical constraints at the table supports are primarily responsible for this. Another difficulty arises because it is virtually impossible to synthesize perfectly uncorrelated random signals to drive the actuators. Two-DoF testing is more common. In this case, the test must be repeated for a different orientation of the test object (for example, with a 90° rotation about the vertical axis), unless some form of dynamic-axial symmetry is present in the test object.

Test programs frequently specify uncorrelated excitations in two-DoF testing for the two actuators. This requirement lacks solid justification, because two uncorrelated excitations applied at right angles do not necessarily produce uncorrelated components in a different pair of orthogonal directions, unless the mean square values of the two excitations are equal. To demonstrate this, consider the two uncorrelated excitations, u and v , shown [Figure 17.24](#). The components u' and v' , in a different pair of orthogonal directions obtained by rotating the original coordinates through an angle θ in the counterclockwise direction, are given by

$$u' = u \cos \theta + v \sin \theta \quad (17.84)$$

$$v' = -u \sin \theta + v \cos \theta \quad (17.85)$$

Without loss of generality, we can assume that u and v have zero means. Then, u' and v' also will have zero means. Furthermore, since u and v are uncorrelated, we have

$$E(uv) = E(u)E(v) = 0 \quad (17.86)$$

From Equation 17.84 and Equation 17.85, we obtain

$$E(u'v') = E[(u \cos \theta + v \sin \theta) \times (-u \sin \theta + v \cos \theta)]$$

This, when expanded and substituted with Equation 17.86, becomes

$$E(u'v') = \sin \theta \cos \theta [E(v^2) - E(u^2)] \quad (17.87)$$

Since θ is any general angle, the excitation components u' and v' become uncorrelated if and only if

$$E(v^2) = E(u^2) \quad (17.88)$$

This is the required result. Nevertheless, a considerable effort, in the form of digital Fourier analysis, is expended by vibration-testing laboratories to determine the degree of correlation in test signals employed in two-DoF testing.

17.4.8.3 Symmetrical Rectilinear Testing

Single-DoF (rectilinear) testing that is performed with the test excitation applied along the line of symmetry with respect to an orthogonal system of three principal axes of the test object mainframe is termed symmetrical rectilinear testing. In product qualification literature, this test is often referred to as the 45° test. The direction cosines of the input orientation are $(1/\sqrt{3}, 1/\sqrt{3}, 1/\sqrt{3})$ for this test configuration. The single-actuator input intensity is amplified by a factor of $\sqrt{3}$ in order to obtain the required excitation intensity in the three principal directions. Note that symmetrical rectilinear testing falls into the category of rectilinear triaxial testing, as defined earlier. This is one of the widely used testing configurations in seismic qualification, for example.

17.4.8.4 Geometry vs. Dynamics

In vibration testing the emphasis is on the dynamic behavior rather than the geometry of the equipment. For a simple three-dimensional body that has homogeneous and isotropic characteristics, it is not difficult to correlate its geometry to its dynamics. A symmetrical rectilinear test makes sense for such systems. The equipment we come across is often much more complex, however. Furthermore, our interest is not merely in determining the dynamics of the mainframe of the equipment. We are more interested in the dynamic reliability of various critical components located within the mainframe. Unless we have some previous knowledge of the dynamic characteristics in various directions of the system components, it is not possible to draw a direct correlation between the geometry and the dynamics of the tested equipment.

17.4.8.5 Some Limitations

In a typical symmetrical rectilinear test, we deal with “black-box” equipment whose dynamics are completely unknown. The excitation is applied along the line of symmetry of the principal axes of the mainframe. A single test of this type does not guarantee excitation of all critical components located inside the equipment. Figure 17.25 illustrates this further. Consider the plane perpendicular to the direction of excitation. The dynamic effect caused by the excitation is minimal along any line on

FIGURE 17.24 Effect of coordinate transformation on correlation.

this plane. (Any dynamic effect on this plane is caused by dynamic coupling among different body axes.) Accordingly, if there is a component (or several components) inside the equipment whose direction of sensitivity lies on this perpendicular plane, the single excitation might not excite that component. Since we deal with a black box, we do not know the equipment dynamics beforehand. Hence, there is no way of identifying the existence of such unexcited components. When the equipment is put into service, a vibration of sufficient intensity may easily overstress this component along its direction of sensitivity and may bring about component failure. It is apparent that at least three tests, performed in three orthogonal directions, are necessary to guarantee excitation of all components, regardless of their direction of sensitivity.

A second example is given in Figure 17.26. Consider a dual-arm component with one arm sensitive in the $O-O$ direction and the second arm sensitive in the $P-P$ direction. If component failure occurs when the two arms are in contact, a single excitation in either the $O-O$ direction or the $P-P$ direction will not bring about component failure. If the component is located inside a black box, such that either the $O-O$ direction or the $P-P$ direction is very close to the line of symmetry of the principal axes of the mainframe, a single symmetrical rectilinear test will not result in system malfunction. This may be true, because we do not have a knowledge of component dynamics in such cases. Again, under service conditions, a vibration of sufficient intensity can produce an excitation along the $A-A$ direction, subsequently causing system malfunction.

A further consideration in using rectilinear testing is dynamic coupling between the directions of excitation. In the presence of dynamic coupling, the sum of individual responses of the test object resulting from four symmetrical rectilinear tests is not equal to the response obtained when the excitations are applied simultaneously in the four directions. Some conservatism should be introduced when employing rectilinear testing for objects having a high level of dynamic coupling between the test directions. If the test-object dynamics are restrained to only one direction under normal operating conditions, however, then rectilinear testing can be used without applying any conservatism.

17.4.8.6 Testing Black Boxes

When the equipment dynamics are unknown, a single rectilinear test does not guarantee proper testing of the equipment. To ensure excitation of every component within the test object that has directional intensities, three tests should be carried out along three independent directions. The first test may be carried out with a single horizontal excitation, for example. The second test could then be performed with the equipment rotated through 90° about its vertical axis, and using the same horizontal excitation. The last test would be performed with a vertical excitation.

FIGURE 17.25 Illustration of the limitation of a single rectilinear test.

FIGURE 17.26 Illustrative example of the limitation of several rectilinear tests.

Alternatively, if symmetrical rectilinear tests are preferred, four such tests should be performed for four equipment orientations (for example, an original test, a 90° rotation, a 180° rotation, and a 270° rotation about the vertical axis). These tests also ensure excitation of all components that have directional intensities. This procedure might not be very efficient, however. The shortcoming of this series of four tests is that some of the components will be overtested. It is clear from Figure 17.27, for example, that the vertical direction is excited by all four tests. The method has the advantage, however, of simplicity of performance.

FIGURE 17.27 Directions of excitation in a sequence of four rectilinear tests.

17.4.8.7 Phasing of Excitations

The main purpose of rotating the test orientation in rectilinear testing is to ensure that all components within the equipment are excited. Phasing of different excitations also plays an important role, however, when several excitations are used simultaneously. To explore this concept further, it should be noted that a random input applied in the $A-B$ direction or in the $B-A$ direction has the same frequency and amplitude (spectral) characteristics. This is clear because the PSD of $u = \text{PSD}$ of $(-u)$, and the autocorrelation of $u = \text{autocorrelation}$ of $(-u)$. Hence, it is seen that, if the test is performed along the $A-B$ direction, it is of no use to repeat the test in the $B-A$ direction. It should be understood, however, that the situation is different when several excitations are applied simultaneously.

FIGURE 17.28 Significance of excitation phasing in two-DoF testing.

The simultaneous action of u and v is not the same as the simultaneous action of $-u$ and v (see Figure 17.28). The simultaneous action of u and v is the same, however, as the simultaneous action of $-u$ and $-v$. Obviously, this type of situation does not arise when there are no simultaneous excitations, as in rectilinear testing.

17.4.8.8 Testing a Gray or White Box

When some information regarding the true dynamics of the test object is available, it is possible to reduce the number of necessary tests. In particular, if the equipment dynamics are completely known, then a single test would be adequate. The best direction for excitation of the system in Figure 17.26, for example, is $A-A$. (Note that $A-A$ may be lined up in any arbitrary direction inside the equipment housing. In such a situation, knowledge of the equipment dynamics is crucial.) This also indicates that it is very important to accumulate and use any past experience and data on the dynamic behavior of similar equipment. Any test that does not use some previously known information regarding the equipment is a blind test, and it cannot be optimal in any respect. As more information is available, better tests can be conducted.

17.4.8.9 Overtesting in Multitest Sequences

It is well known that increasing the test duration increases aging of the test object because of prolonged stressing and load cycling of various components. This is the case when a test is repeated one or more times at the same intensity as that prescribed for a single test. The symmetrical rectilinear test requires four separate tests at the same excitation intensity as that prescribed for a single test. As a result, the

equipment becomes subjected to overtesting, at least in certain directions. The degree of overtesting is small if the tests are performed in only three orthogonal directions. In any event, a certain amount of dynamic coupling is present in the test-object's structure and, to minimize overtesting in these sequential tests, a smaller intensity than that prescribed for a single test should be employed. The value of the intensity-reduction factor clearly depends on the characteristics of the test object, the degree of reliability expected, and the intensity value itself. More research is necessary to develop expressions for intensity-reduction factors for various test objects.

17.5 Some Practical Information

Some useful practical information on vibration testing of products is given here.

TABLE 17.3 Random Vibration Tests for a Product Development Application

Vibration Test	Root-Mean-Square Value of Excitation (g)	Peak Value of the Excitation PSD (g^2/Hz)	Minimum Times the Random Vibration is Applied	Minimum Duration of Vibration (min)	Vibration Axes
A	2.7	0.01	1	60	Major horizontal axis
B	6.0	0.05	2	30	Major horizontal axis
C	3.2	0.01	1	15	All three
D	5.8	0.02	1	15	All three
E	4.9	0.01	1	15	All three
F	6.3	0.04	2	5	All three

Summary

In experimental modal analysis (EMA), first the modal information (natural frequencies, modal damping ratios, and mode shapes) of a test object is determined through experimentation, and this information is then used to determine a model for the test object. Once an “experimental model” is obtained in this manner, it may be used in a variety of practical uses including system analysis, fault detection and diagnosis, design, and control. This chapter presents some standard techniques and procedures associated with EMA.

18.1 Introduction

Experimental modal analysis (EMA) is basically a procedure of “experimental modeling.” The primary purpose here is to develop a dynamic model for a mechanical system, using experimental data. In this sense, EMA is similar to “model identification” in control system practice, and may utilize somewhat related techniques of “parameter estimation.” It is the nature of the developed model, which may distinguish EMA from other conventional procedures of model identification. Specifically, EMA produces a *modal model* as the primary result, which consists of:

1. Natural frequencies
2. Modal damping ratios
3. Mode shape vectors

Once a modal model is known, standard results of modal analysis may be used to extract an *inertia (mass) matrix*, a *damping matrix*, and a *stiffness matrix*, which constitute a complete dynamic model for the experimental system, in the time domain. Since EMA produces a modal model (and in some cases a complete time-domain dynamic model) for a mechanical system from test data of the system, its uses can be

extensive. In particular, EMA is useful in mechanical systems, primarily with regard to vibration, in:

1. Design
2. Diagnosis
3. Control

In the area of design, the following three approaches that utilize EMA should be mentioned:

1. Component modification
2. Modal response specification
3. Substructuring

In component modification, we modify (i.e., add, remove, or vary) inertia (mass), stiffness, and damping parameters in a mechanical system and determine the resulting effect on the modal response (natural frequencies, damping ratios, and mode shapes) of the system. In modal response specification, we establish the best changes, from the design point of view, in system parameters (inertia, stiffness, and damping values and their degrees of freedom (DoF), in order to give a “specified” (prescribed) change in the modal response. In substructuring, two or more subsystem models are combined using dynamic interfacing components, and the overall model is determined. Some of the subsystem models used in this manner can be of analytical origin (e.g., finite element models).

Diagnosis of problems (faults, performance degradation, component deterioration, impending failure, etc.) of a mechanical system requires *condition monitoring* of the system, and analysis and evaluation of the monitored information. Often, analysis involves extraction of modal parameters using monitored data. Diagnosis may involve the establishment of changes (both gradual and sudden), patterns, and trends in these system parameters.

Control of a mechanical system may be based on modal analysis. Standard and well-developed techniques of modal control are widely used in mechanical system practice. In particular, vibration control, both active and passive, can use modal control. In this approach, the system is first expressed as a modal model, then control excitations, parameter adaptations, and so on are established that result in a specified (derived) behavior in various modes of the system. Of course, techniques of EMA are commonly used here, both in obtaining a modal model from test data and in establishing modal excitations and parameter changes that are needed to realize a prescribed behavior in the system.

The standard steps of EMA are as follows:

1. Obtain a suitable (admissible) set of test data, consisting of forcing excitations and motion responses for various pairs of DoF of the test object.
2. Compute the frequency transfer functions (the frequency response functions) of the pairs of test data, using Fourier analysis. Digital Fourier analysis using Fast Fourier Transform (FFT) is the standard way of accomplishing this. Either software-based (computer) equipment or hardware-based instrumentation may be used.
3. Curve fit analytical transfer functions to the computed transfer functions. Determine natural frequencies, damping ratios, and residues for various modes in each transfer function.
4. Compute mode shape vectors.
5. Compute inertia (mass) matrix \mathbf{M} , stiffness matrix \mathbf{K} , and damping matrix \mathbf{C} .

Some variations of these steps is possible in practice, and Step 5 is omitted in some situations. In the present chapter, we will study some standard techniques and procedures associated with the process of EMA.

18.2 Frequency-Domain Formulation

Frequency-domain analysis of vibrating systems is very useful in a wide variety of applications. The analytical convenience of frequency-domain methods results from the fact that differential equations in the time domain become algebraic equations in the frequency domain. Once the

necessary analysis is performed in the frequency domain, it is often possible to interpret the results without having to transform them back to the time domain through inverse Fourier transformation. In the context of the present chapter, frequency-domain representation is particularly important because it is the frequency transfer functions that are used for extracting the necessary modal parameters.

For the convenience of notation, we shall develop the frequency-domain results using the Laplace variable, s . As usual, the straightforward substitution of $s = j\omega$ or $s = j2\pi f$ gives the corresponding frequency-domain results.

18.2.1 Transfer-Function Matrix

Let us consider a linear mechanical system that is represented by

$$\mathbf{M}\ddot{\mathbf{y}} + \mathbf{C}\dot{\mathbf{y}} + \mathbf{K}\mathbf{y} = \mathbf{f}(t) \quad (18.1)$$

where

$\mathbf{f}(t)$ = forcing excitation vector (n th order column)
 \mathbf{y} = displacement response vector (n th order column)
 \mathbf{M} = mass (inertia) matrix ($n \times n$)
 \mathbf{C} = damping (linear viscous) matrix ($n \times n$)
 \mathbf{K} = stiffness matrix ($n \times n$)

If the assumption of *proportional damping* is made, the coordinate transformation

$$\mathbf{y} = \mathbf{\Psi}\mathbf{q} \quad (18.2)$$

decouples Equations 18.1 into the canonical form of modal equations

$$\bar{\mathbf{M}}\ddot{\mathbf{q}} + \bar{\mathbf{C}}\dot{\mathbf{q}} + \mathbf{K}\mathbf{q} = \mathbf{\Psi}^T\mathbf{f}(t) \quad (18.3)$$

where

$\mathbf{\Psi}$ = modal matrix ($n \times n$) of n independent modal vector vectors $[\boldsymbol{\psi}_1, \boldsymbol{\psi}_2, \dots, \boldsymbol{\psi}_n]$
 $\bar{\mathbf{M}}$ = diagonal matrix of modal masses M_i
 $\bar{\mathbf{C}}$ = diagonal matrix of modal damping constants C_i
 $\bar{\mathbf{K}}$ = diagonal matrix of modal stiffnesses K_i

Specifically, we have

$$\bar{\mathbf{M}} = \mathbf{\Psi}^T\mathbf{M}\mathbf{\Psi} \quad (18.4)$$

$$\bar{\mathbf{C}} = \mathbf{\Psi}^T\mathbf{C}\mathbf{\Psi} \quad (18.5)$$

$$\bar{\mathbf{K}} = \mathbf{\Psi}^T\mathbf{K}\mathbf{\Psi} \quad (18.6)$$

If the modal vectors are assumed to be \mathbf{M} -normal, then we have

$$M_i = 1$$

$$K_i = \omega_i^2$$

and furthermore, we can express C_i in the convenient form

$$C_i = 2\zeta_i\omega_i$$

where

ω_i = undamped natural frequency
 ζ_i = modal damping ratio

By Laplace transformation of the response canonical equations of modal motion (Equation 18.3), assuming zero initial conditions, we obtain

$$\begin{bmatrix} s^2 + 2\zeta\omega_1s + \omega_1^2 & & & 0 \\ & s^2 + 2\zeta\omega_2s + \omega_2^2 & & \\ & & \ddots & \\ 0 & & & s^2 + 2\zeta\omega_ns + \omega_n^2 \end{bmatrix} \mathbf{Q}(s) = \mathbf{\Psi}^T \mathbf{F}(s) \quad (18.7)$$

Laplace transforms of the modal response (or generalized coordinate) vector, $\mathbf{q}(t)$, and the forcing excitation vector, $\mathbf{f}(t)$, are denoted by the column vectors, $\mathbf{Q}(s)$ and $\mathbf{F}(s)$, respectively. The square matrix on the left-hand side of Equation 18.7 is a diagonal matrix. Its inverse is obtained by inverting the diagonal elements. Consequently, the following modal transfer relation results:

$$\mathbf{Q}(s) = \begin{bmatrix} G_1 & & & 0 \\ & G_2 & & \\ & & \ddots & \\ 0 & & & G_n \end{bmatrix} \mathbf{\Psi}^T \mathbf{F}(s) \quad (18.8)$$

in which the diagonal elements are the damped simple-oscillator transfer functions

$$G_i(s) = \frac{1}{[s^2 + 2\zeta_i\omega_i s + \omega_i^2]} \quad \text{for } i = 1, 2, \dots, n \quad (18.9)$$

Note that ω_i , the i th undamped natural frequency (in the time domain), is only approximately equal to the frequency of the i th *resonance* of the transfer function (in the frequency domain), as given by

$$\omega_{ri} = \sqrt{1 - 2\zeta_i^2} \omega_i \quad (18.10)$$

As we have discussed before, and as is clear from Equation 18.10, the approximation improves for decreasing modal damping. Consequently, in most applications of EMA, the resonant frequency is taken to be equal (approximately) to the natural frequency for a given mode.

From the time-domain coordinate transformation (Equation 18.2), the Laplace domain coordinate transformation relation is obtained as

$$\mathbf{Y}(s) = \mathbf{\Psi} \mathbf{Q}(s) \quad (18.11)$$

Substitute Equation 18.8 into Equation 18.11; thus

$$\mathbf{Y}(s) = \mathbf{\Psi} \begin{bmatrix} G_1 & & & 0 \\ & G_2 & & \\ & & \ddots & \\ 0 & & & G_n \end{bmatrix} \mathbf{\Psi}^T \mathbf{F}(s) \quad (18.12)$$

Equation 18.12 is the excitation–response (input–output) transfer relation. It is clear that the $n \times n$ *transfer function matrix*, \mathbf{G} , for the n -DoF system is given by

$$\mathbf{G}(s) = \mathbf{\Psi} \begin{bmatrix} G_1 & & & 0 \\ & G_2 & & \\ & & \ddots & \\ 0 & & & G_n \end{bmatrix} \mathbf{\Psi}^T \quad (18.13)$$

Notice in particular that $\mathbf{G}(s)$ is a symmetric matrix; specifically

$$\mathbf{G}^T(s) = \mathbf{G}(s) \quad (18.14)$$

which should be clear from the matrix transposition property, $(\mathbf{ABC})^T = \mathbf{C}^T \mathbf{B}^T \mathbf{A}^T$.

An alternative version of Equation 18.13 that is extensively used in EMA can be obtained by using the partitioned form (or assembled form) of the modal matrix in Equation 18.13. Specifically, we have

$$\mathbf{G}(s) = [\boldsymbol{\psi}_1, \boldsymbol{\psi}_2, \dots, \boldsymbol{\psi}_n] \begin{bmatrix} G_1 & & & \mathbf{0} \\ & G_2 & & \\ & & \ddots & \\ \mathbf{0} & & & G_n \end{bmatrix} \begin{bmatrix} \boldsymbol{\psi}_1^T \\ \boldsymbol{\psi}_2^T \\ \vdots \\ \boldsymbol{\psi}_n^T \end{bmatrix} \quad (18.15)$$

On multiplying out the last two matrices on the right-hand side of Equation 18.15 term by term, the following intermediate result is obtained:

$$\mathbf{G}(s) = [\boldsymbol{\psi}_1, \boldsymbol{\psi}_2, \dots, \boldsymbol{\psi}_n] \begin{bmatrix} G_1 \boldsymbol{\psi}_1^T \\ G_2 \boldsymbol{\psi}_2^T \\ \vdots \\ G_n \boldsymbol{\psi}_n^T \end{bmatrix}$$

Note that G_i are scalars while $\boldsymbol{\psi}_i$ are column vectors. The two matrices in this product can be multiplied out now to obtain the matrix sum

$$\mathbf{G}(s) = G_1 \boldsymbol{\psi}_1 \boldsymbol{\psi}_1^T + G_2 \boldsymbol{\psi}_2 \boldsymbol{\psi}_2^T + \dots + G_n \boldsymbol{\psi}_n \boldsymbol{\psi}_n^T = \sum_{r=1}^n G_r \boldsymbol{\psi}_r \boldsymbol{\psi}_r^T \quad (18.16)$$

in which $\boldsymbol{\psi}_r$ is the r th modal vector that is normalized with respect to the mass matrix. Notice that each term $\boldsymbol{\psi}_r \boldsymbol{\psi}_r^T$ in the summation (Equation 18.16) is an $n \times n$ matrix with the element corresponding to its i th row and k th column being $(\psi_i \psi_k)_r$. The ik th element of the transfer matrix $\mathbf{G}(s)$ is the transfer function $G_{ik}(s)$, which determines the transfer characteristics between the response location, i , and the excitation location, k . From Equation 18.16, this is given by

$$G_{ik}(s) = \sum_{r=1}^n G_r (\psi_i \psi_k)_r = \sum_{r=1}^n \frac{(\psi_i \psi_k)_r}{[s^2 + 2\zeta_r \omega_r s + \omega_r^2]} \quad (18.17)$$

with $s = j\omega = j2\pi f$ in the frequency domain. Note that $(\psi_i)_r$ is the i th element of the r th modal vector, and is a scalar quantity. Similarly, $(\psi_i \psi_k)_r$ is the product of the i th element and the k th element of the r th modal vector, and is also a scalar quantity. This is the numerator of each modal transfer function within the right-hand side summation of Equation 18.17, and is the *residue* of the pole (eigenvalue) of that mode.

Equation 18.17 is useful in EMA. Essentially, we start by determining the residues $(\psi_i \psi_k)_r$ of the poles in an admissible set of measured transfer functions. We can determine the modal vectors in this manner. In addition, by analyzing the measured transfer functions, the *modal damping ratios*, ζ_i , and the *natural frequencies*, ω_i , can be estimated. From these results, an estimate for the time-domain model (i.e., the matrices \mathbf{M} , \mathbf{K} , and \mathbf{C}) can be determined.

18.2.2 Principle of Reciprocity

By the symmetry of transfer matrix, as given by Equation 18.14, it follows that

$$G_{ik}(s) = G_{ki}(s) \quad (18.18)$$

This fact is further supported by Equation 18.17. This symmetry can be interpreted as *Maxwell's principle of reciprocity*. To understand this further, consider the complete set of transfer relations given by Equation 18.12 and Equation 18.13:

$$\begin{aligned} Y_1(s) &= G_{11}(s)F_1(s) + G_{12}(s)F_2(s) + \cdots + G_{1n}(s)F_n(s) \\ Y_2(s) &= G_{21}(s)F_1(s) + G_{22}(s)F_2(s) + \cdots + G_{2n}(s)F_n(s) \\ &\vdots \\ Y_n(s) &= G_{n1}(s)F_1(s) + G_{n2}(s)F_2(s) + \cdots + G_{nn}(s)F_n(s) \end{aligned} \quad (18.19)$$

Note that the diagonal elements, $G_{11}, G_{22}, \dots, G_{nn}$, are *driving-point transfer functions* (or autotransfer functions) and the rest are *cross-transfer functions*. Suppose that a single excitation, $F_k(s)$, is applied at the k th DoF with all the other excitations set to zero. The resulting response at the i th DoF is given by

$$Y_i(s) = G_{ik}(s)F_k(s) \quad (18.20)$$

Similarly, when a single excitation, $F_i(s)$, is applied at the i th DoF, the resulting response at the k th DoF is given by

$$Y_k(s) = G_{ki}(s)F_i(s) \quad (18.21)$$

In view of the symmetry that is indicated by Equation 18.18, it follows from Equation 18.20 and Equation 18.21 that if the two separate excitations, $F_k(s)$ and $F_i(s)$, are identical then the corresponding responses, $Y_i(s)$ and $Y_k(s)$, are also identical. In other words, the response at the i th DoF due to a single force at the k th DoF is equal to the response at the k th DoF when the same single force is applied at the i th DoF. This is the frequency-domain version of the principle of reciprocity.

Example 18.1

Consider the two-DoF system shown in Figure 18.1. Assume that the excitation forces, $f_1(t)$ and $f_2(t)$, act at the y_1 and y_2 DoFs, respectively. The equations of motion are given by

$$\begin{bmatrix} m & 0 \\ 0 & m \end{bmatrix} \ddot{\mathbf{y}} + \begin{bmatrix} c & 0 \\ 0 & c \end{bmatrix} \dot{\mathbf{y}} + \begin{bmatrix} 2k & -k \\ -k & 2k \end{bmatrix} \mathbf{y} = \mathbf{f}(t) \quad (i)$$

This system has proportional damping (specifically, it is clear that \mathbf{C} is proportional to \mathbf{M}) and hence possesses the same real modal vectors as does the undamped system. Let us first obtain the transfer matrix in the direct manner. By taking the Laplace transform (with zero initial conditions) of the equations of motion (i), we have

$$\begin{bmatrix} ms^2 + cs + 2k & -k \\ -k & ms^2 + cs + 2k \end{bmatrix} \mathbf{Y}(s) = \mathbf{F}(s) \quad (ii)$$

FIGURE 18.1 A vibrating system with proportional damping.

Hence, in the relation $\mathbf{Y}(s) = \mathbf{G}(s)\mathbf{F}(s)$, the transfer matrix \mathbf{G} is given by

$$\begin{aligned}\mathbf{G}(s) &= \begin{bmatrix} ms^2 + cs + 2k & -k \\ -k & ms^2 + cs + 2k \end{bmatrix}^{-1} \\ &= \frac{1}{[(ms^2 + cs + 2k)^2 - k^2]} \begin{bmatrix} ms^2 + cs + 2k & k \\ k & ms^2 + cs + 2k \end{bmatrix}\end{aligned}\quad (\text{iii})$$

The characteristic polynomial $\Delta(s)$ of the system is

$$\Delta(s) = (ms^2 + cs + 2k)^2 - k^2 = (ms^2 + cs + k)(ms^2 + cs + 3k) \quad (\text{iv})$$

and is common to the denominator of all four transfer functions in the matrix. Specifically,

$$G_{11}(s) = G_{22}(s) = \frac{ms^2 + cs + 2k}{\Delta(s)} \quad (\text{v})$$

$$G_{12}(s) = G_{21}(s) = \frac{k}{\Delta(s)} \quad (\text{vi})$$

This result implies that the characteristic equation characterizes the entire system (particularly, the natural frequencies and damping ratios) and, no matter what transfer function is measured (or analyzed), the same natural frequencies and modal damping are obtained.

We can put these transfer functions into the partial fraction form. For example,

$$\frac{ms^2 + cs + 2k}{(ms^2 + cs + k)(ms^2 + cs + 3k)} = \frac{A_1s + A_2}{(ms^2 + cs + k)} + \frac{A_3s + A_4}{(ms^2 + cs + 3k)} \quad (\text{vii})$$

By comparing the numerator coefficients, we find that $A_1 = A_3 = 0$ (this is the case when the modes are *real*; with complex modes, $A_1 \neq 0$ and $A_3 \neq 0$ in general) and $A_2 = A_4 = 1/2$. These results are summarized below:

$$G_{11}(s) = G_{22}(s) = \frac{1/(2m)}{[s^2 + 2\zeta_1\omega_1s + \omega_1^2]} + \frac{1/(2m)}{[s^2 + 2\zeta_2\omega_2s + \omega_2^2]} \quad (\text{viii})$$

$$G_{12}(s) = G_{21}(s) = \frac{1/(2m)}{[s^2 + 2\zeta_1\omega_1s + \omega_1^2]} - \frac{1/(2m)}{[s^2 + 2\zeta_2\omega_2s + \omega_2^2]} \quad (\text{ix})$$

with

$$\omega_1 = \sqrt{k/m}, \quad \omega_2 = \sqrt{3k/m}, \quad \zeta_1 = c/\sqrt{4mk}, \quad \text{and} \quad \zeta_2 = c/\sqrt{12mk}$$

By comparing the *residues* (numerators) of these expressions with the relation expressed in Equation 18.17, we can determine the \mathbf{M} -normal modal vectors. Specifically, by examining G_{11} :

$$(\psi_1^2)_1 = \frac{1}{2m}, \quad (\psi_1^2)_2 = \frac{1}{2m}$$

and by examining at G_{12} :

$$(\psi_1\psi_2)_1 = \frac{1}{2m}, \quad (\psi_1\psi_2)_2 = -\frac{1}{2m}$$

We need consider only two admissible transfer functions (e.g., G_{11} and G_{12} , or G_{11} and G_{21} , or G_{12} and G_{22} , or G_{21} and G_{22}) in order to completely determine the modal vectors. Specifically, we obtain

$$\begin{bmatrix} \psi_1 \\ \psi_2 \end{bmatrix}_1 = \begin{bmatrix} 1/\sqrt{2m} \\ 1/\sqrt{2m} \end{bmatrix} \quad \text{and} \quad \begin{bmatrix} \psi_1 \\ \psi_2 \end{bmatrix}_2 = \begin{bmatrix} 1/\sqrt{2m} \\ -1/\sqrt{2m} \end{bmatrix}$$

Note that the modal masses are unity for these modal vectors. Also, there is an arbitrariness in the sign. As usual, we have overcome this problem by making the first element of each modal vector positive.

18.3 Experimental Model Development

We have noted that the process of extracting modal data (natural frequencies, modal damping, and mode shapes) from measured excitation–response data is termed experimental modal analysis. Modal testing and the analysis of test data are the two main steps of EMA. Information obtained through EMA is useful in many applications, including the validation of analytical models for dynamic systems, fault diagnosis in machinery and equipment, *in situ* testing for requalification to revised regulatory specifications, and design development of mechanical systems.

In the present development, it is assumed that the test data are available in the frequency domain as a set of transfer functions. In particular, suppose that an *admissible* set of transfer functions is available. The actual process of constructing or computing these frequency transfer functions from measured excitation–response (input–output) test data (in the time domain) is known as *model identification* in the frequency domain. This step should precede the actual modal analysis in practice. Numerical analysis (or curve fitting) is the basic tool used for this purpose, and it will be discussed in a later section.

The basic result used in EMA is Equation 18.17 with $s = j\omega$ or $s = j2\pi f$ for the frequency-transfer functions. For convenience, however, the following notation is used:

$$G_{ik}(\omega) = \sum_{r=1}^n \frac{(\psi_i \psi_k)_r}{[\omega_r^2 - \omega^2 + 2j\zeta_r \omega_r \omega]} \quad (18.22)$$

$$G_{ik}(f) = \sum_{r=1}^n \frac{(\psi_i \psi_k)_r}{4\pi^2[f_1^2 - f^2 + 2j\zeta_r f_r f]} \quad (18.23)$$

where ω and f are used in place of $j\omega$ and $j2\pi f$ in the function notation $G(\cdot)$. As already observed in Example 18.1, it is not necessary to measure all n^2 transfer functions in the $n \times n$ transfer function matrix, \mathbf{G} , in order to determine the complete modal information. Owing to the symmetry of \mathbf{G} it follows that at most only $1/2n(n+1)$ transfer functions are needed. In fact, it can be “shown by construction” (i.e., in the process of developing the method itself) that only n transfer functions are needed. These n transfer functions cannot be chosen arbitrarily, however, even though there is a wide choice for the admissible set of n transfer functions. A convenient choice is to measure any one *row* or any one *column* of the transfer function matrix. It should be clear from the following development that any set of transfer functions that spans all n DoF of the system would be an admissible set provided that only one autotransfer function is included in the minimal set. Hence, for example, all the transfer functions on the main diagonals or on the main cross diagonal of \mathbf{G} , do not form an admissible set.

Suppose that the k th column (G_{ik} , $i = 1, 2, \dots, n$) of the transfer function matrix is measured by applying a single forcing excitation at the k th DoF and measuring the corresponding responses at all n DoF in the system. The main steps in extracting the modal information from this data are given below:

1. Curve fit the (measured) n transfer functions to expressions of the form given by Equation 18.22. In this manner determine the natural frequencies ω_r , the damping ratios ζ_r , and the residues $(\psi_i \psi_k)_r$, for the set of modes $r = 1, 2$, and so on.
2. The residues of a diagonal transfer function (i.e., point transfer functions or autotransfer function), G_{kk} , are $(\psi_k^2)_1, (\psi_k^2)_2, \dots, (\psi_k^2)_n$. From these, determine the k th row of the modal matrix; $(\psi_k)_1, (\psi_k)_2, \dots, (\psi_k)_n$. Note that \mathbf{M} -normality is assumed. However, the modal vectors are arbitrary up to a multiplier of -1 . Hence, we may choose this row to have all positive elements.
3. The residues of a nondiagonal transfer function, that is, a cross-transfer function, $G_{k+i,k}$ are $(\psi_{k+i} \psi_k)_1, (\psi_{k+i} \psi_k)_2, \dots, (\psi_{k+i} \psi_k)_n$. By substituting the values obtained in Step 2 into these values, determine the $k+i$ th row of the modal matrix; $(\psi_{k+i})_1, (\psi_{k+i})_2, \dots, (\psi_{k+i})_n$. The complete modal matrix Ψ is obtained by repeating this step for $i = 1, 2, \dots, n-k$ and $i = -1, -2, \dots, -k+1$. Note that the associated modal vectors are \mathbf{M} -normal.

The procedure just outlined for determining the modal matrix verifies, by construction, that only n transfer functions are needed to extract the complete modal information. It further reveals that it is not

essential to perform the transfer function measurements in a row fashion or column fashion. A diagonal element (i.e., a *point transfer function*, or an *autotransfer function*) should always be measured. The remaining $n - 1$ transfer functions must be off diagonal but otherwise can be chosen arbitrarily, provided that all n DoF are spanned either as an excitation point or as a measurement location (or both). This guarantees that no symmetric transfer function elements are included. This defines a minimal set of transfer function measurements. An *admissible set* of more than n transfer functions can be measured in practice so that redundant measurements are available in addition to the minimal set that is required. Such redundant data are useful for checking the accuracy of the modal estimates. Examples for an admissible (nonminimal) set, a minimal set, and an inadmissible set of transfer functions matrix elements are shown schematically in Figure 18.2. Note that the inadmissible set in this example contains 11 transfer function measurements but the sixth DoF is not covered by this set. On the other hand, a minimal set requires only six transfer functions.

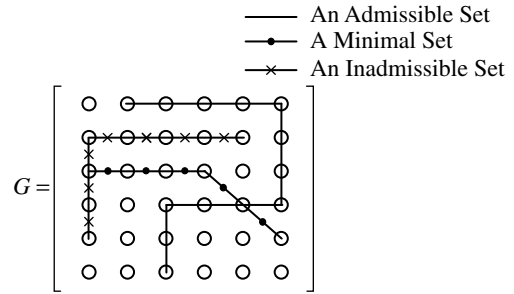

FIGURE 18.2 A nonminimal admissible set, a minimal set, and inadmissible set of possible transfer function measurements.

18.3.1 Extraction of the Time-Domain Model

Once the complete modal information is extracted by modal analysis, it is possible, at least in theory, to determine a time-domain model (\mathbf{M} , \mathbf{K} , and \mathbf{C} matrices) for the system. To obtain the necessary equations, first premultiply by $(\Psi^T)^{-1}$ and postmultiply by Ψ Equation 18.4, Equation 18.5, and Equation 18.6 to obtain

$$\mathbf{M} = (\Psi^T)^{-1} \bar{\mathbf{M}} \Psi^{-1} \quad (18.24)$$

where $\bar{\mathbf{M}} = \mathbf{I}$ = identity matrix

$$\mathbf{K} = (\Psi^T)^{-1} \bar{\mathbf{K}} \Psi^{-1} \quad (18.25)$$

$$\mathbf{C} = (\Psi^T)^{-1} \bar{\mathbf{C}} \Psi^{-1} \quad (18.26)$$

Since the modal matrix Ψ is nonsingular because \mathbf{M} is assumed nonsingular in the dynamic models that we use (i.e., each DoF has an associated mass, or the system does not possess static modes), the inverse transformations given by the equations from Equation 18.24 to Equation 18.26 are feasible. It appears, however, that two matrix inversions are needed for each result. Since \mathbf{M} , \mathbf{K} , and \mathbf{C} matrices are diagonal, their inverse is given by inverting the diagonal elements. This fact can be used to obtain each result through just one matrix inversion.

Equation 18.24, Equation 18.25, and Equation 18.26 are written as

$$\mathbf{M} = (\Psi \bar{\mathbf{M}}^{-1} \Psi^T)^{-1} \quad (18.27)$$

$$\mathbf{K} = (\Psi \bar{\mathbf{K}}^{-1} \Psi^T)^{-1} \quad (18.28)$$

$$\mathbf{C} = (\Psi \bar{\mathbf{C}}^{-1} \Psi^T)^{-1} \quad (18.29)$$

Note that for the present \mathbf{M} -normal case

$$\bar{\mathbf{M}}^{-1} = \mathbf{I} \quad (18.30)$$

$$\bar{\mathbf{K}}^{-1} = \text{diag}[1/\omega_1^2, 1/\omega_2^2, \dots, 1/\omega_n^2] \quad (18.31)$$

$$\bar{\mathbf{C}}^{-1} = \text{diag}[1/(2\zeta_1 \omega_1), 1/(2\zeta_2 \omega_2), \dots, 1/(2\zeta_n \omega_n)] \quad (18.32)$$

By substituting the equations from Equation 18.30 to Equation 18.32 into the equations from Equation 18.27 to Equation 18.29, we obtain the relations that can be used in computing the time-domain model:

$$\mathbf{M} = (\mathbf{\Psi}\mathbf{\Psi}^T)^{-1} \quad (18.33)$$

$$\mathbf{K} = \left(\mathbf{\Psi} \begin{bmatrix} 1/\omega_1^2 & & & \mathbf{0} \\ & 1/\omega_2^2 & & \\ & & \ddots & \\ \mathbf{0} & & & 1/\omega_n^2 \end{bmatrix} \mathbf{\Psi}^T \right)^{-1} \quad (18.34)$$

$$\mathbf{C} = \left(\mathbf{\Psi} \begin{bmatrix} 1/(2\zeta_1\omega_1) & & & \mathbf{0} \\ & 1/(2\zeta_2\omega_2) & & \\ & & \ddots & \\ \mathbf{0} & & & 1/(2\zeta_n\omega_n) \end{bmatrix} \mathbf{\Psi}^T \right)^{-1} \quad (18.35)$$

Alternatively, only one matrix inversion (that of $\mathbf{\Psi}$) is needed if we use the fact that

$$(\mathbf{\Psi}^T)^{-1} = (\mathbf{\Psi}^{-1})^T$$

Then,

$$\mathbf{M} = (\mathbf{\Psi}^{-1})^T \tilde{\mathbf{M}} \mathbf{\Psi}^{-1} \quad (18.36)$$

$$\mathbf{K} = (\mathbf{\Psi}^{-1})^T \tilde{\mathbf{K}} \mathbf{\Psi}^{-1} \quad (18.37)$$

$$\mathbf{C} = (\mathbf{\Psi}^{-1})^T \tilde{\mathbf{C}} \mathbf{\Psi}^{-1} \quad (18.38)$$

The main steps of EMA are summarized in Box 18.1. In practice, frequency-response data are less accurate at higher resonances. Some of the main sources of error are as follows:

- (1) Aliasing distortion in the frequency domain, due to finite sampling rate of data, will distort high-frequency results during digital computation.
- (2) Inadequate spectral-line resolution (or frequency resolution) and frequency coverage (bandwidth) can introduce errors at high-frequency resonances. The frequency resolution is fixed both by the signal record length (T) and the type of time window used in digital Fourier analysis, but the resonant peaks are sharper for higher frequencies. Frequency coverage depends on the data sampling rate.
- (3) Low signal-to-noise ratio (SNR) at high frequencies, in part due to noise and poor dynamic range of equipment and in part due to low signal levels, will result in data measurement errors. Signal levels are usually low at high frequencies because inertia in a mechanical system acts as a low-pass filter $1/(m\omega^2)$.
- (4) Computations involving high order matrices (multiplication, inversion, etc.) will lead to numerical errors in complex systems with many DoF.

It is customary, therefore, to extract modal information only for the first several modes. In that case, it is not possible to recover the mass, stiffness, and damping matrices. Even if these matrices are computed, their accuracy is questionable due to their sensitivity to the factors listed above.

18.4 Curve Fitting of Transfer Functions

Parameter estimation in vibrating systems can be interpreted as a technique of *experimental modeling*. This process requires experimental data in a suitable form, preferably excitation–response data, and is often represented as a set of transfer functions in the frequency domain. Parameter estimation using

Box 18.1

MAIN STEPS OF EXPERIMENTAL MODAL ANALYSIS

1. Measure an admissible set of excitation (u) and response (y) signals. (Cover all DoF; one response measurement should be for the excitation location.)
2. Group the signals, assign windows, and filter the signals.
3. Compute transfer functions using FFT and the spectral density method:

$$G_{uy} = \Phi_{uy} / \Phi_{uu}$$

4. Compute ordinary coherence functions

$$\gamma_{uy}^2 = \frac{|\Phi_{uy}|^2}{\Phi_{uu} \Phi_{yy}}$$

and choose the accurate transfer functions on this basis (γ_{uy} close to 1 \Rightarrow accept; γ_{uy} close to 0 \Rightarrow reject).

5. Curve fit n admissible transfer functions to expressions:

$$G_{ik} = \sum_{r=1}^n \frac{(\psi_i \psi_k)_r}{[\omega_r^2 - \omega^2 + 2j\zeta_r \omega_r \omega]}$$

Hence, extract:

Residues $(\psi_i \psi_k)_r \Rightarrow$ mode shapes vectors ψ_r which are \mathbf{M} -normal;

Natural frequencies (undamped), ω_r ;

Modal damping ratios (viscous), ζ_r .

6. Form the modal matrix $\Psi = [\psi_1, \psi_2, \dots, \psi_n]$;
Compute Ψ^{-1} .

7. Modal mass matrix $\bar{\mathbf{M}} = \mathbf{I}$;

Modal stiffness matrix $\bar{\mathbf{K}} = \text{diag}[\omega_1^2, \omega_2^2, \dots, \omega_n^2]$;

Modal damping matrix $\bar{\mathbf{C}} = \text{diag}[2\zeta_1 \omega_1, 2\zeta_2 \omega_2, \dots, 2\zeta_n \omega_n]$;

8. Compute the system model:

Mass matrix $\mathbf{M} = (\Psi^{-1})\Psi^{-1}$;

Stiffness matrix $\mathbf{K} = (\Psi^{-1})^T \bar{\mathbf{K}} \Psi^{-1}$;

Damping matrix $\mathbf{C} = (\Psi^{-1})\bar{\mathbf{C}}\Psi^{-1}$.

measured response data is termed *model identification* or, simply, identification in the literature on systems and control. We shall present a parameter estimation procedure that involves frequency transfer functions, which is particularly useful in EMA.

18.4.1 Problem Identification

Transfer functions that are computed from measured time histories using digital Fourier analysis (e.g., FFT) cannot be directly used in the modal analysis computations. The data must be available as analytical transfer functions. Therefore, it is important to represent the computed transfer functions with suitable analytical expressions. This is done, in practice, either by curve fitting

a suitable transfer function model into the computed data or by simplified methods such as “peak picking.” Accordingly, this conversion of data is an experimental modeling technique.

Identification of transfer function models from measured data is an essential step in EMA. Apart from that, it has other important advantages. In particular, analytical transfer function plots clearly identify system resonances and generate numerical values for the corresponding parameters (resonant frequencies, damping, phase angles, and magnitudes) in a convenient manner. This form represents a significant improvement over the crude transfer function plots, which are normally far less presentable and rather difficult to interpret.

18.4.2 Single- and Multi-Degree-of-Freedom Techniques

Several single-DoF techniques exist for extracting analytical parameters from experimental transfer functions. In particular, the methods of curve fitting (circle fitting) and peak picking are considered here. In a single-DoF method, only one resonance is considered at a time.

Single-DoF curve fitting, or more correctly, *single-resonance curve fitting* is the term used to denote any curve fitting procedure that fits a quadratic (second-order) transfer function into each resonance in the measured transfer function, one at a time. In the case of closely spaced modes (or closely spaced resonances), the associated error can be very large. The accuracy is improved if expressions of a higher order than quadratic are used for this purpose, but unacceptable errors can still exist. In peak picking, each resonance of experimental transfer function data is examined individually; the resonant frequency and the damping constant corresponding to that resonance are determined by comparing with an analytical single-DoF transfer function.

In multi-DoF curve fitting, or more appropriately, *multiresonance curve fitting*, all resonances (or modes) of importance are considered simultaneously and fitted into an analytical transfer function of suitable order. This method is generally more accurate but computationally more demanding than the single-resonance method. In choosing between the single-resonance and multiresonance methods, the required accuracy should be weighted against the cost and speed of computation.

18.4.3 Single-Degree-of-Freedom Parameter Extraction in the Frequency Domain

The theory of curve fitting by a circle (i.e., circle fitting) for each resonance of an experimentally determined transfer function is presented first. Next, the peak picking method will be described.

18.4.3.1 Circle-Fit Method

It can be shown that the *mobility* transfer function (velocity/force) of a single-DoF system with linear *viscous damping*, when plotted on the *Nyquist plane* of real axis and imaginary axis for the frequency transfer function, is a circle. Similarly, it can be shown that the *receptance* or *dynamic flexibility* or compliance transfer function (displacement/force) of a single-DoF system with *hysteretic damping*, when plotted on the Nyquist plane, is also a circle. Note that, for hysteretic damping, the damping constant (in the time domain) is not actually a constant but is inversely proportional to the frequency of motion. However, in this case, in the frequency domain, the damping term will be independent of frequency. The fact that such circle representations are possible for transfer functions of a single-DoF system may be used in fitting a circle to a transfer function that is computed from experimental data. This will lead to determining the analytical parameters for the transfer function. This approach is illustrated now through analytical development.

Case of Viscous Damping

Consider a single-DoF system with linear, viscous damping, as given by

$$m\ddot{y} + c\dot{y} + ky = f(t) \quad (18.39)$$

where m , k , and c are the mass, stiffness, and damping constants of the system elements, respectively, $f(t)$ is the excitation force, and y is the displacement response. Equation 18.39 may be expressed in the standard form:

$$\ddot{y} + 2\zeta\omega_n\dot{y} + \omega_n^2 y = \frac{1}{m}f(t) \quad (18.40)$$

Receptance

$$\frac{Y(s)}{F(s)} = \frac{1}{m[s^2 + 2\zeta\omega_n s + \omega_n^2]} \quad \text{with } s = j\omega \quad (18.41)$$

Mobility

$$\frac{V(s)}{F(s)} = \frac{sY(s)}{F(s)} = \frac{s}{m[s^2 + 2\zeta\omega_n s + \omega_n^2]} \quad \text{with } s = j\omega \quad (18.42)$$

Consider the mobility (velocity/force) transfer function given by

$$G(s) = \frac{s}{s^2 + 2\zeta\omega_n s + \omega_n^2} \quad (18.43)$$

where the constant parameter, m , in Equation 18.42 has been omitted, without loss of generality. In the frequency domain ($s = j\omega$), we have

$$G(j\omega) = \frac{j\omega}{\omega_n^2 - \omega^2 + 2j\zeta\omega_n\omega} \quad (18.44)$$

Multiply the numerator and the denominator of $G(j\omega)$ in Equation 18.44 by the complex conjugate of the denominator (i.e., $\omega_n^2 - \omega^2 - 2j\zeta\omega_n\omega$). Then, the denominator is converted to the square of its original magnitude, as given by

$$\Delta = (\omega_n^2 - \omega^2)^2 + (2\zeta\omega_n\omega)^2 \quad (18.45)$$

and the frequency transfer function (Equation 18.44) is converted into the form

$$G(j\omega) = \frac{j\omega}{\Delta} [\omega_n^2 - \omega^2 - 2j\zeta\omega_n\omega] \quad (18.46)$$

$$G(j\omega) = \text{Re} + j \text{Im} \quad \text{where} \quad \text{Re} = \frac{2\zeta\omega_n\omega^2}{\Delta} \quad \text{and} \quad \text{Im} = \frac{\omega}{\Delta}(\omega_n^2 - \omega^2) \quad (18.47)$$

Now, we can write

$$\text{Re} - \frac{1}{4\zeta\omega_n} = \frac{8\zeta^2\omega_n^2\omega^2 - 4\zeta^2\omega_n^2\omega^2 - (\omega_n^2 - \omega^2)^2}{4\zeta\omega_n\Delta} = \frac{4\zeta^2\omega_n^2\omega^2 - (\omega_n^2 - \omega^2)^2}{4\zeta\omega_n\Delta}$$

Hence, in view of Equation 18.47 we have

$$\begin{aligned} \left[\text{Re} - \frac{1}{4\zeta\omega_n} \right]^2 + \text{Im}^2 &= \left[\frac{4\zeta^2\omega_n^2\omega^2 - (\omega_n^2 - \omega^2)^2}{4\zeta\omega_n\Delta} \right]^2 + \frac{\omega^2(\omega_n^2 - \omega^2)^2}{\Delta^2} \\ &= \frac{16\zeta^4\omega_n^4\omega^4 - 8\zeta^2\omega_n^2\omega^2(\omega_n^2 - \omega^2)^2 + (\omega_n^2 - \omega^2)^4 + 16\zeta^2\omega_n^2\omega^2(\omega_n^2 - \omega^2)^2}{16\zeta^2\omega_n^2\Delta^2} \\ &= \frac{[4\zeta^2\omega_n^2\omega^2 + (\omega_n^2 - \omega^2)^2]^2}{16\zeta^2\omega_n^2\Delta^2} = \frac{\Delta^2}{16\zeta^2\omega_n^2\Delta^2} = \frac{1}{16\zeta^2\omega_n^2} = R^2 \end{aligned}$$

It follows that the transfer function, $G(j\omega)$, represents a circle in the real–imaginary plane, with the following properties:

$$\text{Circle radius } R = \frac{1}{4\zeta\omega_n} \quad (18.48)$$

$$\text{Circle center} = \left(\frac{1}{4\zeta\omega_n}, 0 \right) \quad (18.49)$$

Now, we may reintroduce the constant parameter, m , back into the transfer function, as in Equation 18.42. Then, we have

$$\begin{aligned} \text{Circle radius } R &= \frac{1}{4\zeta\omega_n m}, \\ \text{Center} &= \left(\frac{1}{4\zeta\omega_n m}, 0 \right) \end{aligned} \quad (18.50)$$

A sketch of this circle is shown in Figure 18.3(a). As mentioned before, the plane formed by the real and imaginary parts of $G(j\omega)$ as the Cartesian x and y axes, respectively, is the *Nyquist plane*. The plot of $G(j\omega)$ on this plane is the *Nyquist diagram*. It follows that the *Nyquist diagram* of the mobility function (Equation 18.42 or Equation 18.44) is a circle.

Case of Hysteretic Damping

Consider a single-DoF system with *hysteretic damping*. The equation motion is given by

$$\begin{aligned} m\ddot{y} + \frac{h}{\omega}\dot{y} + ky &= f(t) \\ \text{with } f(t) &= f_0 \sin \omega t \end{aligned} \quad (18.51)$$

Note the frequency dependent damping constant, with the hysteretic damping parameter, h , in the time domain. The receptance function, $G(j\omega)$, is given by

$$G(j\omega) = \frac{1}{(k - m\omega^2) + jh}$$

Note that the damping term, jh , is independent of frequency in the frequency domain for this case. As for the case of viscous damping, we can easily show that the Nyquist plot of this transfer function is a circle with

$$\text{Radius} = \frac{1}{2h} \quad \text{and} \quad \text{Center} = \left(0, -\frac{1}{2h} \right) \quad (18.52)$$

A sketch of the resulting circle is shown in Figure 18.3(b).

In general, for a multi-DoF viscous-damped system we have the “mobility” function

$$G_{ik}(j\omega) = j\omega \sum_{r=1}^n \frac{(\psi_i \psi_k)_r}{[\omega_r^2 - \omega^2 + 2j\zeta_r \omega_r \omega]} \quad (18.53)$$

If the resonances are not closely spaced we can assume that, near each resonance (r)

$$\begin{aligned} G_{ik} &= \text{constant offset (complex)} + \text{single DoF mobility function} \\ &= \text{constant offset} + \left[\frac{j\omega(\psi_i \psi_k)_r}{\omega_r^2 - \omega^2 + 2j\zeta_r \omega_r \omega} \right] \end{aligned} \quad (18.54)$$

We can curve fit each resonance r to a circle this way and thereby extract the $(\psi_i \psi_k)_r$ value (the residue) from the radius of the circle fit.

Note: This method cannot be used if the resonances are closely spaced and consequently if significant modal interactions are present.

FIGURE 18.3 (a) Circle fit of a mobility function with viscous damping; (b) circle fit of a receptance function with hysteretic damping.

18.4.3.2 Peak-Picking Method

The peak-picking method is also a single-DoF method in view of the fact that each resonance of an experimentally determined transfer function is considered separately. The approach is to compare the resonance region with an analytical transfer function of a damped single-DoF system. One of three types of transfer functions, receptance, mobility, and accelerance as listed in Table 18.1, can be used for this purpose. Note that, when the level of damping is small, it can be assumed (approximately) that the resonance is at the undamped natural frequency $\omega_n = \sqrt{k/m}$. Substituting this value for ω in each of the frequency transfer functions, we can determine the transfer function value at resonance, denoted by $G_{\text{peak}}(j\omega)$. It is noted from Table 18.1 that this function value in general depends on the damping constant and the natural frequency. Since ω_n is known directly from the peak location of the transfer function, it is possible to compute c (or the damping ratio, ζ) by first determining the corresponding peak magnitude.

Specifically, from Table 18.1, it is clear that we should pick the imaginary part of the frequency transfer function for receptance or accelerance data and the real part of the transfer function for mobility data. Then, we pick the peak value of the chosen part of the transfer function and the frequency at the peak.

Table 18.2 gives normalized expressions for the three frequency transfer functions, receptance = displacement/force; mobility = velocity/force; accelerance = acceleration/force, in the frequency domain, in the case of a single-DoF mechanical system with (1) viscous damping and (2) hysteretic damping. It may be verified that their Nyquist diagrams are circles (either exactly or approximately), thereby enabling one to use the circle-fit method.

Note that $r = \omega/\omega_n$, where ω is the excitation frequency and ω_n is the undamped natural frequency; ζ is the damping ratio in the case of viscous damping; and $d = h/k$ where h is the hysteretic damping parameter and k is the system stiffness.

Peak picking is good in cases where modes are well separated and lightly damped. It does not work when the system is highly damped (or overdamped) or when the damping is zero (infinite peak). It is a quick approach that is appropriate for initial evaluations and trouble shooting.

TABLE 18.1 Some Frequency Transfer Functions Used in Peak Picking

Single-DoF system	$m\ddot{y} + c\dot{y} + ky = f(t)$
Receptance (dynamic flexibility, compliance) $G^r(j\omega) = \frac{\text{Displacement } y}{\text{Force } f}$	$\frac{1}{ms^2 + cs + k}$ with $s = j\omega$
Mobility $G^m(j\omega) = \frac{\text{Velocity } v}{\text{Force } f}$	$\frac{s}{ms^2 + cs + k}$ with $s = j\omega$
Accelerance $G^a(j\omega) = \frac{\text{Acceleration } a}{\text{Force } f}$	$\frac{s^2}{ms^2 + cs + k}$ with $s = j\omega$
Resonant peaks $G_{\text{peak}}(j\omega)$ (occur approximately at $\omega = \omega_n$ for light damping)	$G_{\text{peak}}^r = -\frac{j}{c\omega_n}$ $G_{\text{peak}}^m = \frac{1}{c}$ $G_{\text{peak}}^a = \frac{j\omega_n}{c}$

TABLE 18.2 Normalized Frequency Response Functions for Single-DoF Curve Fitting

Frequency Response Function	With Viscous Damping	With Hysteretic Damping
Receptance	$\frac{1}{1 - r^2 + 2j\zeta r}$	$\frac{1}{1 - r^2 + jd}$
Mobility	$\frac{j r}{1 - r^2 + 2j\zeta r}$	$\frac{j r}{1 - r^2 + jd}$
Accelerance	$\frac{-r^2}{1 - r^2 + 2j\zeta r}$	$\frac{-r^2}{1 - r^2 + jd}$

18.4.4 Multi-Degree of Freedom Curve Fitting

We shall now discuss a general multiresonance curve fitting method. The corresponding single-resonance method should also be clear from this general procedure. Note that many different versions of problem formulation and algorithm development are possible for least squares curve fitting, but the results should be essentially the same. The method presented here is a frequency-domain method as we are dealing with experimentally determined frequency transfer functions. In a comparable time-domain method, a suitable analytical expression of the complex exponential form is fitted into the experimental impulse response function obtained by the inverse Fourier transformation of measured transfer function. That method acquires additional error due to truncation (*leakage*) and finite sampling rate (*aliasing*) during the inverse FFT.

18.4.4.1 Formulation of the Method

The objective of the present multiresonance (multi-DoF) curve fitting procedure is to fit the computed (measured) transfer function data into an analytical expression of the form

$$G(s) = \frac{[b_0 + b_1s + \cdots + b_ms^m]}{[a_0 + a_1s + \cdots + a_{p-1}s^{p-1} + s^p]} \quad \text{for } m \leq p \quad (18.55)$$

The data for curve fitting are the N complex transfer function values $[G_1, G_2, \dots, G_N]$ computed at discrete frequencies $[\omega_1, \omega_2, \dots, \omega_N]$. Typically, if 1024 samples of time history were used in the FFT computations to determine the transfer function, we would have 512 valid spectral lines of transfer function data. However, near the high-frequency end, these data values become excessively distorted due to the aliasing error; only a part of the 512 spectral lines will be usable, typically the first 400 lines. In that case, we have $N = 400$. This value can be doubled by doubling the FFT block size (to 2048 words in the buffer), thereby doubling the record length or the sampling rate. It is acceptable to leave out part of the computed transfer function, not for poor accuracy but because that part falls outside the frequency band of interest in that particular modal analysis problem. A less wasteful practice is to pick the sampling rate of the measured time-history data to reflect the highest frequency of interest in the modal analysis.

The (complex) error in the estimated value at each frequency point (spectral line), ω_i , is given by

$$\tilde{e}_i = G(\omega_i) - G_i = \frac{[b_0 + b_1s_i + \cdots + b_ms_i^m]}{[a_0 + a_1s_i + \cdots + a_{p-1}s_i^{p-1} + s_i^p]} - G_i \quad (18.56)$$

with $s = j\omega$.

The characteristic equation of the dynamic model is given by

$$\Delta(s) = a_0 + a_1s + \cdots + a_{p-1}s^{p-1} + s^p = 0 \quad (18.57)$$

Its roots are the eigenvalues of the system. For damped systems, they occur in complex conjugates with negative real parts (*note*: $p = 2 \times \text{number of DoFs}$, in typical cases). For systems with *rigid-body modes*, zero eigenvalues will also be present. However, since there is some damping in the system and since the lowest frequency that is tested and analyzed is normally greater than zero even for systems with rigid-body modes, we have

$$\Delta(j\omega) \neq 0 \quad (18.58)$$

in the frequency range of interest. Hence, the estimation error given by Equation 18.56 can be expressed as

$$e_i = [b_0 + b_1s_i + \cdots + b_ms_i^m] - G_i[a_0 + a_1s_i + \cdots + a_{p-1}s_i^{p-1} + s_i^p] \quad (18.59)$$

with $s = j\omega$.

The quadratic error function is given by the sum of the squares of magnitude error for all discrete frequency points used in modal analysis; thus

$$J = \sum_{i=1}^N |e_i|^2 = \sum_{i=1}^N e_i^* e_i \quad (18.60)$$

FIGURE 18.4 An example of multi-DoF curve fitting on experimental data.

Note that $[\]^*$ denotes the complex conjugate. Complex conjugation is achieved by simply replacing $(j\omega)$ with $(-j\omega)$ in Equation 18.59. It follows that Equation 18.60 can be written as

$$J = \sum_{i=1}^N \left\langle \left[b_0 + b_1(-j\omega_i) + \cdots + b_m(-j\omega_i)^m - G_i^* \{ a_0 + a_1(-j\omega_i) + \cdots + a_{p-1}(-j\omega_i)^{p-1} + (-j\omega_i)^p \} \right] \left[b_0 + b_1(j\omega_i) + \cdots + b_m(j\omega_i)^m - G_i \{ a_0 + a_1(j\omega_i) + \cdots + a_{p-1}(j\omega_i)^{p-1} + (j\omega_i)^p \} \right] \right\rangle \quad (18.61)$$

The basis of the least squares curve fitting method of parameter estimation is to pick the transfer function parameters b_i ; $i = 0, 1, \dots, m$ and a_i ; $i = 0, \dots, p - 1$, such that the quadratic error function, J , is a minimum. Analytically, this requires

$$\frac{\partial J}{\partial b_k} = 0 \quad k = 0, 1, \dots, m \quad (18.62)$$

$$\frac{\partial J}{\partial a_k} = 0 \quad k = 0, 1, \dots, p - 1 \quad (18.63)$$

Note that Equation 18.62 and Equation 18.63 correspond to $m + p + 1$ linear equations in the $m + p + 1$ unknowns b_i , $i = 0, 1, \dots, m$ and a_i , $i = 0, 1, \dots, p - 1$. A well-defined solution exists to this set of *nonhomogeneous equations* provided that the equations are *linearly independent*, which is guaranteed if the determinant of the coefficients of the unknown parameters does not vanish. It is a good practice to check for linear independence of the set of $m + p + 1$ equations using this determinant condition prior to performing further computations to solve the equations. The solution approach itself is primarily computational in nature and is not presented here. Figure 18.4 shows a result of multi-DoF curve fitting on an experimental frequency transfer function, as collected from a civil engineering structure. Note the close match of the magnitude but not the phase angle. This analysis resulted in the resonant frequency and damping ratio values that are given in Table 18.3.

18.4.5 A Comment on Static Modes and Rigid-Body Modes

Some test systems may possess static modes, and rigid-body modes under rare circumstances. Static modes arise in analytical models if we fail to assign an inertia (mass) element for each DoF. Rigid-body modes arise in analytical models if proper restraints are not provided for the inertia elements. In practice,

TABLE 18.3 Extracted Parameters in an Example of Experimental Modal Analysis

Mode No.	Resonant Frequency (Hz)	Damping Ratio (viscous)
1	1.773×10^2	1.170×10^{-2}
2	3.829×10^2	8.149×10^{-3}
3	6.145×10^2	6.033×10^{-3}
4	7.018×10^2	5.931×10^{-3}
5	9.839×10^2	4.580×10^{-3}
6	1.190×10^3	3.676×10^{-3}

however, static modes arise if a coordinate is assigned to a DoF that actually does not exist, or if some parts of the physical system are relatively light with stiff restraints (i.e., very high natural frequencies), and rigid-body modes arise in the presence of relatively heavy components restrained by very flexible elements (i.e., very low natural frequencies). Note that the assumed transfer function (Equation 18.55) allows for both these extremes. Specifically, if static modes are present it is necessary that the transfer function can be expressed as a sum of a constant term (static mode) and an ordinary transfer function (without a static mode). Hence, it will approach a nonzero constant value as the frequency, ω , increases. This requires $m = p$. If rigid-body modes are present, the characteristic polynomial $\Delta(s)$ of the model should have a factor s^2 . This corresponds to $a_0 = a_1 = 0$.

18.4.6 Residue Extraction

The estimated transfer functions as given by Equation 18.55 is in the form of the ratio of two polynomials; *the rational fraction form*. This has to be converted into the partial fraction form given by Equation 18.17 in order to extract the residues $(\psi_i \psi_k)_r$ that are needed for determining the mode shapes. For this, the natural frequencies, ω_r , and the modal damping ratios, ζ_r , should be computed first. These are given by the roots of the characteristic Equation 18.57 as

$$\lambda_r, \lambda_r^* = \zeta_r \omega_r \pm j \sqrt{1 - \zeta_r^2} \omega_r; \quad r = 1, 2, \dots, n \tag{18.64}$$

Once these eigenvalues are known, by solving Equation 18.57 using the estimated values for a_0, a_1, \dots, a_{p-1} , it is a straightforward task to compute the quadratic factors

$$\Delta_r(s) = s^2 + 2\zeta_r \omega_r s + \omega_r^2 \quad r = 1, 2, \dots, n \tag{18.65}$$

Note that, from Equation 18.17

$$(\psi_i \psi_k)_r = [G_{ik}(s) \Delta_r(s)]_{s=\lambda_r} \tag{18.66}$$

assuming distinct eigenvalues. This is true because, when the partial fraction form is multiplied by $\Delta_r(s)$, it will cancel out with the denominator of the partial fraction corresponding to the r th mode, leaving its residue. Then, when s is set equal to Δ_r , all the remaining partial fraction terms will vanish due to the fact that $\Delta_r(\lambda_r) = 0$, provided that the eigenvalues are distinct. Since $G_{ik}(s)$ are known from the estimated transfer functions, the residues can be computed using Equation 18.66. Finally, the mode shapes are determined using the procedure outlined earlier. Some curve fitting approaches are summarized in Box 18.2.

18.5 Laboratory Experiments

Testing and analysis are important in the practice of mechanical vibration and are integral in EMA. In this section, we will describe two experiments in the category of modal testing. One experiment deals with a lumped-parameter system and the other with a distributed-parameter (or continuous) system.

Box 18.2

CURVE FITTING OF TRANSFER FUNCTION DATA

Single-resonance curve fitting:

- (a) Viscous damping:
 - 1. Compute mobility (velocity/force) function near resonance.
 - 2. Scale the data.
 - 3. Curve fit to circle in the Nyquist plane (Argand diagram).
- (b) Hysteretic damping:
 - 1. Compute receptance (displacement/force) function near resonance.
 - 2. Scale the data.
 - 3. Curve fit to circle in the Nyquist plane (Argand diagram).

Multiresonance curve fitting:

- 1. Compute transfer function over the entire frequency range.
- 2. Scale the data.
- 3. Curve fit to a general polynomial ratio with static and rigid-body modes.

Both experiments have direct practical implications and have been used in an established undergraduate course in mechanical vibrations.

18.5.1 Lumped-Parameter System

A schematic representation of a prototype unit that is used in laboratory for modal testing is shown in [Figure 18.5](#). A view of the experimental system is shown in [Figure 18.6](#). The system is a crude representation of an engine unit that is supported on flexible mounts and subjected to unbalance forces and moments.

The test object is assumed to consist of lumped elements of inertia, stiffness, and damping. The rectangular metal box, which represents the engine housing, is mounted on four springs and damping elements at the four corners. Inside the box are two pairs of identical and meshed gears, which are driven by a single DC motor. Each gear has two slots at diametrically opposite locations in order to place the eccentric masses. Various types of unbalance excitations can be generated by placing the four eccentric masses at different combinations of locations on the gear wheels.

The drive motor is operated by a DC power supply with a speed control knob. The motor speed (and hence the gear speed) is measured using an optical encoder that is mounted on the drive shaft. It generates pulses as the encoder disk rotates with the shaft, in proportion to the angle of rotation. The pulse frequency of the encoder determines the shaft speed. A pair of accelerometers with magnetic bases is mounted on the top of the engine box. The locations that are used for this purpose are indicated in [Figure 18.5](#).

[Figure 18.6](#) shows, from left to right, the following components of the experimental system:

- 1. Digital spectrum analyzer
- 2. A combined instrument panel consisting of a vibration meter, a tunable band-pass filter, and a unit consisting of a conditioning amplifier and a phase meter

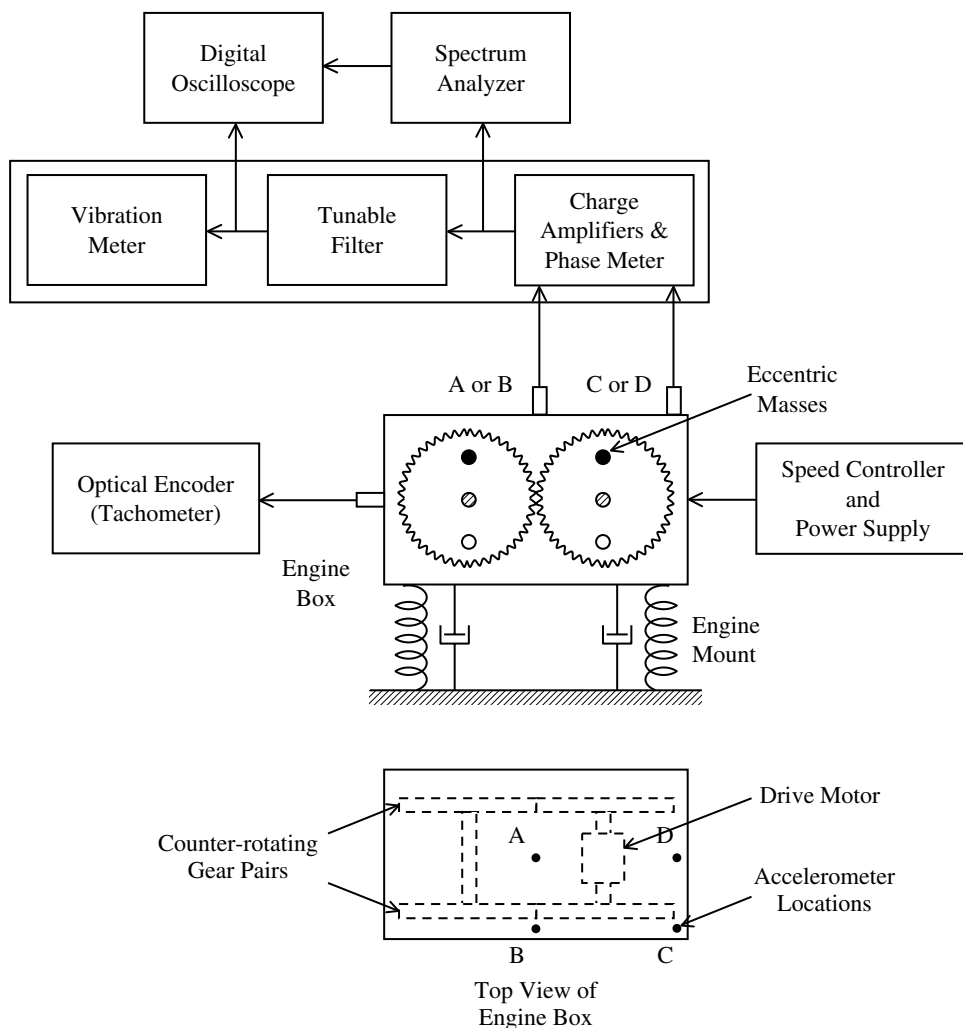

FIGURE 18.5 Schematic diagram of an experimental setup for modal testing in laboratory.

3. Power supply for the instrument panel, placed on top of the panel
4. Engine unit with two accelerometers mounted on top surface of the housing
5. Digital oscilloscope placed on a shelf top immediately above the engine unit
6. DC power supply and speed controller combination for the drive motor

The phase meter measures the phase difference between two input signals. The tunable filter is a band-pass filter and it can be tuned by a fine-adjustment dial so that a signal in a very narrow band (i.e., harmonic signal) can be filtered and measured. The vibration meter measures the magnitude (peak or rms value) of a signal. The choice of a displacement value (i.e., double integration), a velocity value (a single integration), or an acceleration value (no integration) is available, and can be selected using a knob.

By placing the eccentric masses at various locations on the gear wheels, different modes can be excited. For example, the placement of all four eccentric masses at the vertical radius location above the rotating axis will generate a net harmonic force in the vertical direction, as the motor is driven. This will excite the heave (up and down) mode of the engine box. If the two masses on a meshed pair are placed at the vertical radius location below the rotating axis while the masses on the other meshed

FIGURE 18.6 A view of an experimental setup for modal testing at the University of British Columbia.

pair are placed vertically above the rotating axis, then it will result a net moment (pitch) about a central horizontal axis of the engine box. This will excite the pitch mode, and so on. For a given arrangement of eccentric masses, two tests can be carried out, one in the frequency domain and the other in the time domain.

18.5.1.1 Frequency-Domain Test

Choose the “displacement” setting of the vibration meter. Start the motor and maintain the speed at a low value, say 4 Hz. Tune the filter, using its dial, until the vibration meter reading becomes the largest. The tuned frequency will be, in the ideal case, equal to the motor speed. Record the motor speed (i.e., the excitation frequency) and the magnitude of the displacement response. Increase the motor speed in 1-Hz steps and repeat the measurements, until reaching a reasonably high frequency, covering at least one resonance, say 25 Hz. Reduce the speed in steps of 1 Hz and repeat the measurements. Take some more measurements in the neighborhood of each resonance using smaller frequency steps. Plot the data as a frequency spectrum after compensating for the fact that the amplitude of the excitation force increases with the square of the drive speed (hence, divide the vibration magnitudes by square of the frequency). This experiment can be used, for example, to measure mode shapes, resonant frequencies, and damping ratios (by the half-power bandwidth method).

18.5.1.2 Time-Domain Tests

A test can be conducted to determine the damping ratio corresponding to a particular mode by the logarithmic decrement method. Here, first pick the eccentric mass arrangement so as to excite the desired mode. Next increase the motor speed and then fine-tune the operation at the desired resonance. Maintain the speed steady at this condition and observe the accelerometer signal using the oscilloscope, while making sure that at least ten complete cycles can be viewed on the screen. Suddenly, turn off the motor and record the decay of the acceleration signal using the oscilloscope. Another test that can be carried out is an impact (hammer) test. Here, use the spectrum analyzer to record and analyze a vibration response of the engine box through an accelerometer. Gently tap the engine box in different critical directions (e.g., at points A, B, C, and D in the vertical direction, in [Figure 18.5](#), or in the horizontal direction on the side of the engine box in the neighborhood of these points) and acquire the vibration signal using the spectrum analyzer. Process the signal using the spectrum analyzer, obtain the resonant frequencies, and compare them with those obtained from sine testing.

18.5.2 Distributed-Parameter System

All real vibrating systems have continuous components. Often, however, we make distributed-parameter assumptions depending on the properties and the operating frequency range of the vibrating system. When a lumped-parameter approximation is not adequate, a distributed-parameter analysis will be needed. Modal testing and comparison with analytic results can validate an analytical model.

The response of a distributed-parameter system will depend on the boundary conditions (the supporting conditions) as well as the initial conditions. For forced excitations, the response will depend on the nature of the excitation as well. Natural frequencies and mode shapes are system characteristics and depend on the boundary conditions, but not on the initial conditions and forcing excitations.

Consider the experimental setup schematically represented in Figure 18.7. A view of the setup is shown in Figure 18.8. The device that is tested is a ski. For analytical purposes, it may be approximated as a thin beam. The objective of the test is to determine the natural frequencies and mode shapes of the ski. Since the significant frequency range of the excitation forces on a ski, during use, is below 15 Hz, it is advisable to determine the modal information in the frequency range of about double the operating range (i.e., 0 to 30 Hz). In particular, in the design of a ski, natural frequencies below 15 Hz should be avoided, while keeping the unit as light and strong as possible. These are conflicting design requirements. It follows that modal testing can play an important role in the design development of a ski.

Consider the experimental setup that is sketched in Figure 18.7. The ski is firmly supported at its middle on the electrodynamic shaker. Two accelerometers are mounted on either side of the support and are movable along the ski. The accelerometer signals are acquired and conditioned using charge amplifiers. The two signals are observed in the x - y mode of the digital oscilloscope so that both the amplitudes and the phase difference can be measured. The sine-random signal generator is set to the sine mode so that a harmonic excitation is generated at the shaker head. The shape of the motion can be observed in slow motion by illuminating the ski with the hand-held stroboscope, with the strobe frequency set to within about ± 1 Hz of the excitation frequency.

In the experimental system shown in Figure 18.8, we observe, from left to right, the following components:

1. Electrodynamic shaker with the ski mounted on its exciter head (two accelerometers are mounted on the ski)
2. Hand-held stroboscope, placed beside the shaker

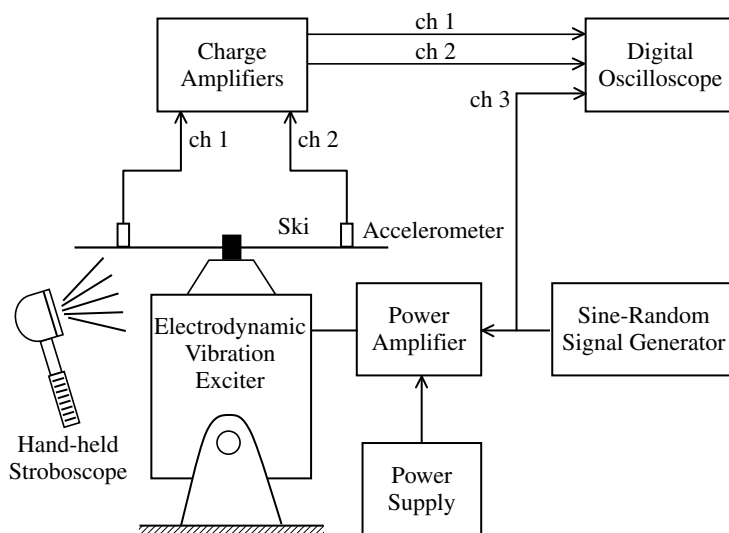

FIGURE 18.7 Schematic diagram of a laboratory setup for modal testing of a ski.

FIGURE 18.8 A view of the experimental system for modal testing of a ski at the University of British Columbia.

3. Power amplifier for driving the shaker, placed on top of the side table
4. Two charge amplifiers placed on top of the power amplifier and connected to the accelerometers
5. Sine-random signal generator, placed on the table top, next to the amplifier
6. Power supply for the shaker
7. Static load–deflection measurement device for determining the modulus of rigidity (EI) of the ski

Prior to modal testing, the modulus of rigidity of the ski is determined by supporting it on the two smooth end pegs of the loading structure, and loading at the midspan using incremental steps of 500-gm weights up to 4.0 kg, placed on a scale pan that is suspended at the midspan of the ski. The midspan deflection of the ski is measured using a spring-loaded dial gage that is mounted on the loading structure. If the midspan stiffness (force/deflection) as measured in this manner is k , it is known that the modulus of rigidity is

$$EI = \frac{k l^3}{48} \quad (18.67)$$

where l is the length of the ski. Note that this formula is for a simply supported ski, which is the case in view of the smooth supporting pegs. Also, weigh the ski and then compute m = mass per unit length. With this information, the natural frequencies and mode shapes can be computed for various end conditions. In particular, compute this modal information for the following supporting conditions:

1. Free–free
2. Clamped at the center

Next, perform modal testing using the experimental setup and compare the results with those computed using the analytical formulation.

The natural frequencies (actually, the resonant frequencies, which are almost equal to the natural frequencies in the present case of light damping) can be determined by increasing the frequency of excitation in small steps using the sine generator and noting the frequency values at which the amplitudes of the accelerometer signals reach local maxima, as observed on the oscilloscope screen. A mode shape is measured as follows. First, detect the corresponding natural frequency as above. While maintaining the shaker excitation at this frequency, place the accelerometer near the shaker head, and then move the other accelerometer from one end of the ski to the other in small steps of displacement and observe the amplitude ratio and the phase difference of the two accelerometer signals using the oscilloscope. Note that in-phase signals mean the motions of the two points are in the same direction,

and the out-of-phase signals mean the motions are in the opposite directions. The mode shapes can be verified by observing the modal vibrations in slow motion using the stroboscope, as indicated before. Node points are the vibration-free points. They can be detected from the mode shapes. In particular, a tiny piece of paper will remain stationary at a node while making large jumps on either side of the node. Also, the phase angle of the vibration signal, as measured by an accelerometer, will jump by 180° if the accelerometer is carefully moved across the node point.

18.6 Commercial EMA Systems

Commercially available EMA systems typically consist of an FFT analyzer, a modal analysis processor, a graphics terminal, and a storage device. Digital plotters, channel selectors, hard copy units, and other accessories can be interfaced, and the operation of the overall system can be coordinated through a host computer to enhance its capability. The selection of hardware for a particular application should address specific objectives as well as hardware capabilities. Software selection is equally important. Proper selection of an EMA system is difficult unless the underlying theory is understood. In particular, the determination of transfer functions via FFT analysis; extraction of natural frequencies, modal damping ratios, and mode shapes from transfer function data; and the construction of mass, stiffness, and damping matrices from modal data should be considered. We have already presented the underlying theory. In the present section, we will describe the features of a typical EMA system.

18.6.1 System Configuration

The extraction of modal parameters from dynamic test data is essentially a two-step procedure consisting of:

1. FFT analysis
2. Modal analysis

In the first step, appropriate frequency transfer functions are computed and stored. These raw transfer functions form the input data for the subsequent modal analysis, yielding modal parameters (natural frequencies, damping ratios, and mode shapes) and a linear differential equation model for the dynamic system (test object).

18.6.1.1 FFT Analysis Options

The basic hardware configuration of a commercial modal analysis system is shown in [Figure 18.9](#). Notice that the FFT analyzer forms the front end of the system. The excitation signal and the response measurements can be transmitted on line to the FFT analyzer (through charge amplifiers for piezoelectric sensors); many signals can be transmitted simultaneously in the multiple-channel case. Alternatively, all measurements may first be recorded on a multiple-track FM tape and subsequently fed into the analyzer through a multiplexer. In the first case, it is necessary to take the FFT analyzer to the test site; an FM tape recorder is needed at the test site in the second case.

Through advances in microelectronics and LSI technology, the FFT analyzer has rapidly evolved into a powerful yet compact instrument that is often smaller in size than the conventional tape recorder used in vibration data acquisition; either device can be used in the field with equal convenience. On-site FFT analysis, however, allows one to identify and reject unacceptable measurements (e.g., low signal levels and high noise components) during data acquisition, so that alternative data that might be needed for a complete modal identification can be collected without having to repeat the test at another time. The main advantage of the FM tape method is that data are available in analog form, free of quantization error (digital word-size dependent), aliasing distortion (data sampling-rate dependent), and signal truncation error (data block-size dependent). Sophisticated analog filtering is often necessary, however,

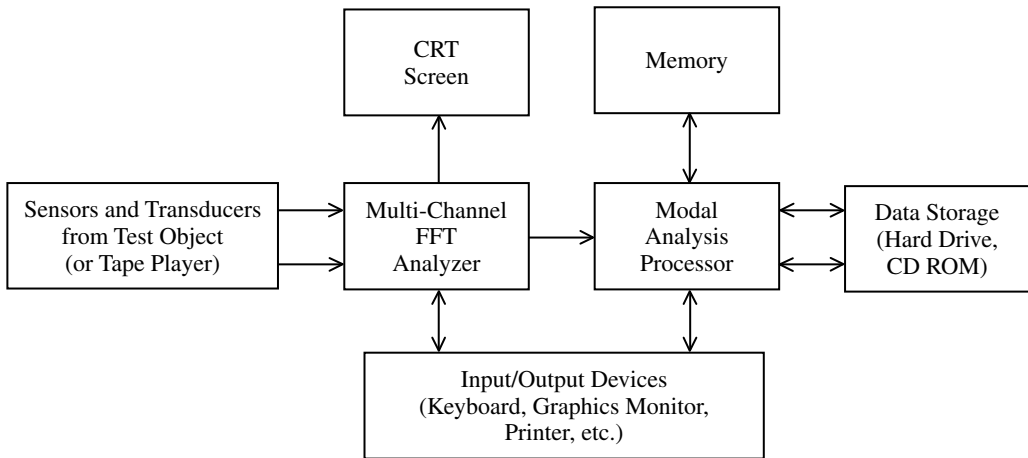

FIGURE 18.9 The configuration of a commercial experimental modal analysis system.

to remove extraneous noise entering from the recording process (e.g., line noise and tape noise), as well as from the measurement process (e.g., sensor and amplifier noise).

The analog-to-digital converter (ADC) is normally an integral part of the analyzer. The raw transfer functions, once computed, are stored on a floppy disk or hard disk as the “transfer function file.” This constitutes the input data file for modal extraction. Some analyzers, instead, compute power spectral densities with respect to the excitation signal and store these in the data file. From these data, it is possible instantly to compute coherence functions, transfer functions, and other spectral information using keyboard commands. Another procedure has been to compute Fourier spectra of all signals and store them as raw data, from which other spectral functions can be conveniently computed. Most analyzers have small CRT screens to display spectral results. Low-coherent transfer functions are detected by analytical or visual monitoring and are automatically discarded.

In principle, the same processor can be used for both FFT analysis and modal analysis. Some commercial modal analysis systems use a plug-in programmable FFT card in a common processor cage. Historically, however, the digital FFT analyzer was developed as a stand-alone hardware unit to be used as a powerful measuring instrument in a wide variety of applications, rather than just as a data processor. Uses include measurement of resonant frequencies and damping in vibration isolation applications, measurement of phase lag between two signals, estimation of signal noise levels, identification of the sources of noise in measured signals, and measurement of correlation in a pair of signals. Because of this versatility, most modal analysis systems do come with a standard FFT analyzer unit as the front end and a separate computer for modal analysis.

18.6.1.2 Modal Analysis Components

In addition to the transfer function file, the modal analysis processor needs geometric information about the test object, typically coordinates of the mass points and directions of the DoF. This information is stored in a “geometry file.” The results of modal analysis are usually stored in two separate files: the “parameter file” containing natural frequencies, modal damping ratios, mass matrix, stiffness matrix, and damping matrix; and the “mode shape file,” containing mode shape vectors that are used for graphics display and printout. Individual modes can be displayed on the CRT screen of the graphics monitor either as a static traces or in animated (dynamic) form. The graphics monitor and printer are standard components of the system. The entire system may be interfaced with other peripheral I/O devices using an IEEE-488 interface bus or the somewhat slower serial RS-232 interface. For example, the overall operation can be coordinated, and further processing done, using a host computer. A desktop (personal) computer may substitute for the modal analysis processor, graphics monitor, and storage devices in the standard system, resulting in a reasonable reduction of the overall cost. An alternative configuration that

TABLE 18.4 Comparative Data for Four Modal Analysis Systems

Description	System A	System B	System C	System D
Number of weighting window options available	3	10	5	4
Analyzer data channels	2	2	2	2
Maximum DoFs per analysis	750 @ 20 modes	450	725 @ 5 modes	750
Maximum number of modes analyzed	50 @ 250 DoF	20	10 (typical)	64
Multi-DoFs curve fitting	Yes	Yes	No	Yes
FFT Resolution (usable spectral lines/512)	400	400	400	400
Zoom analysis capability in FFT	Yes	Yes	Yes	Optional
Statistical error-band analysis	No	No	No	No
Static mode-shape extremes	Yes	Yes	Yes	Yes
Animated graphics capability	Yes	Yes	Yes	Yes
Color graphics capability	No	Yes	No	No
Hidden-line display	No	No	No	No
Color printing	No	No	Yes	No
Structural mass and stiffness matrices	No	No	No	Yes
Approximate cost	\$30,000	\$20,000	\$25,000	\$50,000

is particularly useful in data transfer and communication from remote test sites uses a voice-grade telephone line and a modem coupler to link the FFT analyzer to the main processor.

The first step in selecting a modal analysis system for a particular application is to understand the specific needs of that application. For industrial applications of modal testing, the following requirements are typically adequate:

1. Acceptance of a wide range of measured signals having a variety of transient and frequency band characteristics
2. Capability to handle up to 300 DoF of measured data in a single analysis
3. FFT with frequency resolution of at least 400 spectral lines per 512
4. Zoom analysis capability
5. Capability to perform statistical error-band analysis
6. Static display and plot of mode-shape extremes
7. Animated (dynamic) display of mode shapes
8. Color graphics
9. Hidden-line display
10. Color printing with high line resolution
11. Capability to generate an accurate time-domain model (mass, stiffness, and damping matrices)

The capabilities of four representative modal analysis systems are summarized in Table 18.4.

Summary

Damping in vibrating systems occurs through the dissipation of mechanical energy. This chapter presents modeling, analysis, and measurement of mechanical damping. The types of damping covered include material internal damping (including viscoelastic damping and hysteretic damping), structural damping, fluid damping, interface damping, viscous damping, Coulomb friction, and Stribeck damping. Representations of various types of damping using equivalent viscous damping models are analyzed. Damping in rotating devices is also studied.

19.1 Introduction

Damping is the phenomenon by which mechanical energy is dissipated (usually by conversion into internal thermal energy) in dynamic systems. Knowledge of the level of damping in a dynamic system is important in the utilization, analysis, and testing of the system. For example, a device with natural frequencies within the seismic range (that is, less than 33 Hz) and which has relatively low damping, could produce damaging motions under resonance conditions when subjected to a seismic disturbance. This effect could be further magnified by low-frequency support structures and panels with low damping. This example shows that knowledge of damping in constituent devices, components, and support structures is important in the design and operation of complex mechanical systems. The nature and the level of component damping should be known in order to develop a dynamic model of the system and its peripherals. Knowledge of damping in a system is also important in imposing dynamic environmental limitations on the system (that is, the maximum dynamic excitation the system can withstand) under in-service conditions. Furthermore, knowledge of a system's damping can be useful in order to make design modifications in a system that has failed the acceptance test.

However, the significance of knowledge of damping levels in a test object for the development of test excitation (input) is often overemphasized. Specifically, if the response spectrum method is used to represent the required excitation in a vibration test, then there is no need for the damping value used in the development of the required response spectrum specification to be equal to the actual damping in the

test object. The only requirement is that the damping used in the specified response spectrum be equal to that used in the test response spectrum. The degree of dynamic interaction between the test object and the shaker table, however, will depend on the actual level of damping in these systems. Furthermore, when testing near the resonant frequency of a test object, it is desirable to know about the damping in the test object.

In characterizing damping in a dynamic system it is important, first, to understand the major mechanisms associated with mechanical energy dissipation in the system. Then a suitable damping model should be chosen to represent the associated energy dissipation. Finally, damping values (model parameters) should be determined, for example, by testing the system or a representative physical model, by monitoring system response under transient conditions during normal operation or by employing already available data.

19.2 Types of Damping

There is some form of mechanical energy dissipation in any dynamic system. In the modeling of systems, damping can be neglected if the mechanical energy that is dissipated during the time duration of interest is small in comparison to the initial total mechanical energy of excitation in the system. Even for highly damped systems, it is useful to perform an analysis with the damping terms neglected, in order to study several crucial dynamic characteristics, e.g., modal characteristics (undamped natural frequencies and mode shapes).

Several types of damping are inherently present in a mechanical system. If the level of damping that is available in this manner is not adequate for proper functioning of the system then external damping devices may be added either during the original design or during subsequent design modifications of the system. Three primary mechanisms of damping are important in the study of mechanical systems. They are:

1. Internal damping (of material)
2. Structural damping (at joints and interfaces)
3. Fluid damping (through fluid–structure interactions)

Internal (material) damping results from mechanical energy dissipation within the material due to various microscopic and macroscopic processes. Structural damping is caused by mechanical energy dissipation resulting from relative motions between components in a mechanical structure that has common points of contact, joints or supports. Fluid damping arises from the mechanical energy dissipation resulting from drag forces and associated dynamic interactions when a mechanical system or its components move in a fluid.

Two general types of external dampers may be added to a mechanical system in order to improve its energy dissipation characteristics. They are:

1. Passive dampers
2. Active dampers

Passive dampers are devices that dissipate energy through some kind of motion, without needing an external power source or actuators. Active dampers have actuators that need external sources of power. They operate by actively controlling the motion of the system that needs damping. Dampers may be considered as vibration controllers. In the present chapter, the emphasis will be on damping that is inherently present in a mechanical system.

19.2.1 Material (Internal) Damping

Internal damping of materials originates from the energy dissipation associated with microstructure defects, such as grain boundaries and impurities; thermoelastic effects caused by local temperature gradients resulting from nonuniform stresses, as in vibrating beams; eddy current effects in ferromagnetic

materials; dislocation motion in metals; and chain motion in polymers. Several models have been employed to represent energy dissipation caused by internal damping. This variety of models is primarily a result of the vast range of engineering materials; no single model can satisfactorily represent the internal damping characteristics of all materials. Nevertheless, two general types of internal damping can be identified: viscoelastic damping and hysteretic damping. The latter term is actually a misnomer, because all types of internal damping are associated with hysteresis loop effects. The stress (σ) and strain (ϵ) relations at a point in a vibrating continuum possess a hysteresis loop, such as the one shown in Figure 19.1. The area of the hysteresis loop gives the energy dissipation per unit volume of the material, per stress cycle. This is termed the per-unit-volume damping capacity, and is denoted by d . It is clear that d is given by the cyclic integral

$$d = \oint \sigma d\epsilon \quad (19.1)$$

In fact, for any damped device, there is a corresponding hysteresis loop in the displacement–force plane as well. In this case, the cyclic integral of force with respect to the displacement, which is the area of the hysteresis loop, is equal to the work done against the damping force. It follows that this integral (loop area) is the energy dissipated per cycle of motion. This is the *damping capacity* which, when divided by the material volume, gives the per-unit-volume damping capacity as before.

It should be clear that, unlike a pure elastic force (e.g., a spring force), a damping force cannot be a function of displacement (q) alone. The reason is straightforward. Consider a force $f(q)$ which depends on q alone. Then, for a particular displacement point, q , of the component the force will be the same regardless of the direction of motion (i.e., the sign of \dot{q}). It follows that, in a loading and unloading cycle, the same path will be followed in both directions of motion. Hence, a hysteresis loop will not be formed. In other words, the net work done in a complete cycle of motion will be zero. Next consider a force $f(q, \dot{q})$ which depends on both q and \dot{q} . Then, at a given displacement point, q , the force will depend on \dot{q} as well. Hence, force in one direction of motion will be different from that in the opposite direction. As a result, a hysteresis loop will be formed, which corresponds to work done against the damping force (i.e., energy dissipation). We can conclude then that the damping force has to depend on a relative velocity, \dot{q} , in some manner. In particular, Coulomb friction, which does not depend on the magnitude of \dot{q} , does depend on the sign (direction) of \dot{q} .

19.2.1.1 Viscoelastic Damping

For a linear viscoelastic material, the stress–strain relationship is given by a linear differential equation with respect to time, having constant coefficients. A commonly employed relationship is

$$\sigma = E\epsilon + E^* \frac{d\epsilon}{dt} \quad (19.2)$$

which is known as the Kelvin–Voigt model. In Equation 19.2, E is Young's modulus and E^* is a viscoelastic parameter that is assumed to be time independent. The elastic term $E\epsilon$ does not contribute to damping, and, as noted before, mathematically, its cyclic integral vanishes. Consequently, for the Kelvin–Voigt model, damping capacity per unit volume is

$$d_v = E^* \oint \frac{d\epsilon}{dt} d\epsilon \pi \quad (19.3)$$

FIGURE 19.1 A typical hysteresis loop for mechanical damping.

For a material that is subjected to a harmonic (sinusoidal) excitation, at steady state, we have

$$\varepsilon = \varepsilon_{\max} \cos \omega t \quad (19.4)$$

When Equation 19.4 is substituted in Equation 19.3, we obtain

$$d_v = \pi \omega E^* \varepsilon_{\max}^2 \quad (19.5)$$

Now, $\varepsilon = \varepsilon_{\max}$ when $t = 0$ in Equation 19.4, or when $d\varepsilon/dt = 0$. The corresponding stress, according to Equation 19.2, is $\sigma_{\max} = E\varepsilon_{\max}$. It follows that

$$d_v = \frac{\pi \omega E^* \sigma_{\max}^2}{E^2} \quad (19.6)$$

These expressions for d_v depend on the frequency of excitation, ω .

Apart from the Kelvin–Voigt model, two other models of viscoelastic damping are also commonly used. They are, the Maxwell model given by

$$\sigma + c_s \frac{d\sigma}{dt} = E^* \frac{d\varepsilon}{dt} \quad (19.7)$$

and the standard linear solid model given by

$$\sigma + c_s \frac{d\sigma}{dt} = E\varepsilon + E^* \frac{d\varepsilon}{dt} \quad (19.8)$$

It is clear that the standard linear solid model represents a combination of the Kelvin–Voigt model and the Maxwell model, and is the most accurate of the three. But, for most practical purposes, the Kelvin–Voigt model is adequate.

19.2.1.2 Hysteretic Damping

It was noted above that the stress, and hence the internal damping force, of a viscoelastic damping material depends on the frequency of variation of the strain (and consequently the frequency of motion). For some types of material, it has been observed that the damping force does not significantly depend on the frequency of oscillation of strain (or frequency of harmonic motion). This type of internal damping is known as hysteretic damping.

Damping capacity per unit volume (d_h) for hysteretic damping is also independent of the frequency of motion and can be represented by

$$d_h = J \sigma_{\max}^n \quad (19.9)$$

A simple model that satisfies Equation 19.9, for the case of $n = 2$, is given by

$$\sigma = E\varepsilon + \frac{\tilde{E}}{\omega} \frac{d\varepsilon}{dt} \quad (19.10)$$

which is equivalent to using a viscoelastic parameter, E^* , that depends on the frequency of motion in Equation 19.2 according to $E^* = \tilde{E}/\omega$.

Consider the case of harmonic motion at frequency ω , with the material strain given by

$$\varepsilon = \varepsilon_0 \cos \omega t \quad (19.11)$$

Then, Equation 19.10 becomes

$$\sigma = E\varepsilon_0 \cos \omega t - \tilde{E}\varepsilon_0 \sin \omega t = E\varepsilon \cos \omega t + \tilde{E}\varepsilon_0 \cos\left(\omega t + \frac{\pi}{2}\right) \quad (19.12)$$

Note that the material stress has two components, as given by the right-hand side of Equation 19.12. The first component corresponds to the linear elastic behavior of a material and is in phase with the strain. The second component of stress, which corresponds to hysteretic damping, is 90° out of phase. (This stress component leads the strain by 90° .) A convenient mathematical representation is possible, by using the usual complex form of the response according to

$$\varepsilon = \varepsilon_0 e^{j\omega t} \quad (19.13)$$

Then, Equation 19.10 becomes

$$\sigma = (E + j\tilde{E})\varepsilon \quad (19.14)$$

It follows that this form of simplified hysteretic damping may be represented by using a complex modulus of elasticity, consisting of a real part which corresponds to the usual linear elastic (energy storage) modulus (or Young's modulus) and an imaginary part which corresponds to the hysteretic loss (energy dissipation) modulus.

By combining Equation 19.2 and Equation 19.10, a simple model for combined viscoelastic and hysteretic damping may be given by

$$\sigma = E\varepsilon + \left(E^* + \frac{\tilde{E}}{\omega}\right) \frac{d\varepsilon}{dt} \quad (19.15)$$

The equation of motion for a system whose damping is represented by Equation 19.15 can be deduced from the pure elastic equation of motion by simply substituting E by the operator

$$E + \left(E^* + \frac{\tilde{E}}{\omega}\right) \frac{\partial}{\partial t}$$

in the time domain.

Example 19.1

Determine the equation of flexural motion of a nonuniform slender beam whose material has both viscoelastic and hysteretic damping.

Solution

The Bernoulli–Euler equation of bending motion on an undamped beam subjected to a dynamic load of $f(x, t)$ per unit length, is given by

$$\frac{\partial^2}{\partial x^2} EI \frac{\partial^2 q}{\partial x^2} + \rho A \frac{\partial^2 q}{\partial t^2} = f(x, t) \quad (19.16)$$

Here, q is the transverse motion at a distance, x , along the beam. Then, for a beam with material damping (both viscoelastic and hysteretic) we can write

$$\frac{\partial^2}{\partial x^2} EI \frac{\partial^2 q}{\partial x^2} + \frac{\partial^2}{\partial x^2} \left(E^* + \frac{\tilde{E}}{\omega}\right) I \frac{\partial^3 q}{\partial t \partial x^2} + \rho A \frac{\partial^2 q}{\partial t^2} = f(x, t) \quad (19.17)$$

in which ω is the frequency of the external excitation $f(x, t)$ in the case of steady forced vibrations. In the case of free vibration, however, ω represents the frequency of free vibration decay. Consequently, when analyzing the modal decay of free vibrations, ω in Equation 19.17 should be replaced by the appropriate frequency (ω_i) of modal vibration in each modal equation. Hence, the resulting damped vibratory system possesses the same normal mode shapes as the undamped system. The analysis of the damped case is very similar to that for the undamped system.

19.2.2 Structural Damping

Structural damping is a result of mechanical energy dissipation caused by friction due to the relative motion between components and by impacting or intermittent contact at the joints in a mechanical system or structure. Energy dissipation behavior depends on the details of the particular mechanical system. Consequently, it is extremely difficult to develop a generalized analytical model that would satisfactorily describe structural damping. Energy dissipation caused by rubbing is usually represented by a Coulomb friction model. Energy dissipation caused by impacting, however, should be determined from the coefficient of restitution of the two members that are in contact.

The most common method of estimating structural damping is by measurement. The measured values, however, represent the overall damping in the mechanical system. The structural damping component is obtained by subtracting the values corresponding to other types of damping, such as material damping, present in the system (estimated by environment-controlled experiments, previous data, and so forth) from the overall damping value.

Usually, internal damping is negligible compared to structural damping. A large proportion of mechanical energy dissipation in tall buildings, bridges, vehicle guideways, and many other civil engineering structures and in machinery, such as robots and vehicles, takes place through the structural damping mechanism. A major form of structural damping is the slip damping that results from energy dissipation by interface shear at a structural joint. The degree of slip damping that is directly caused by Coulomb (dry) friction depends on such factors as joint forces (for example, bolt tensions), surface properties and the nature of the materials of the mating surfaces. This is associated with wear, corrosion, and general deterioration of the structural joint. In this sense, slip damping is time-dependent. It is a common practice to place damping layers at joints to reduce undesirable deterioration of the joints. Sliding causes shear distortions in the damping layers, causing energy dissipation by material damping and also through Coulomb friction. In this way, a high level of equivalent structural damping can be maintained without causing excessive joint deterioration. These damping layers should have a high stiffness (as well as a high specific-damping capacity) in order to take the structural loads at the joint.

For structural damping at a joint, the damping force varies as slip occurs at the joint. This is primarily caused by local deformations at the joint, which occur with slipping. A typical hysteresis loop for this case is shown in Figure 19.2(a). The arrows on the hysteresis loop indicate the direction of relative velocity. For idealized Coulomb friction, the frictional force (F) remains constant in each direction of relative motion. An idealized hysteresis loop for structural Coulomb damping is shown in Figure 19.2(b). The corresponding constitutive relation is

$$f = c \operatorname{sgn}(\dot{q}) \quad (19.18)$$

in which f is the damping force, q is the relative displacement at the joint and c is a friction parameter. A simplified model for structural damping caused by local deformation may be given by

$$f = c|q|\operatorname{sgn}(\dot{q}) \quad (19.19)$$

The corresponding hysteresis loop is shown in Figure 19.2(c). Note that the *signum function* is defined by

$$\operatorname{sgn}(v) = \begin{cases} 1 & \text{for } v \geq 0 \\ -1 & \text{for } v < 0 \end{cases} \quad (19.20)$$

19.2.3 Fluid Damping

Consider a mechanical component moving in a fluid medium. The direction of relative motion is shown parallel to the y -axis in Figure 19.3. Local displacement of the element relative to the surrounding fluid is denoted by $q(x, y, t)$.

FIGURE 19.2 Some representative hysteresis loops: (a) typical structural damping; (b) Coulomb friction model; and (c) simplified structural damping model.

FIGURE 19.3 A body moving in a fluid medium.

The resulting drag force per unit area of projection on the x - z plane is denoted by f_d . This resistance is the cause of mechanical energy dissipation in fluid damping. It is usually expressed as

$$f_d = \frac{1}{2} c_d \rho \dot{q}^2 \text{sgn}(\dot{q}) \quad (19.21)$$

in which $\dot{q} = \partial q(x, z, t) / \partial t$ is the relative velocity. The drag coefficient, c_d , is a function of the Reynold's number and the geometry of the structural cross section. A net damping effect is

generated by viscous drag produced by the boundary layer effects at the fluid–structure interface, and by pressure drag produced by the turbulent effects resulting from flow separation at the wake. The two effects are illustrated in Figure 19.4. Fluid density is ρ . For fluid damping, the damping capacity per unit volume associated with the configuration shown in Figure 19.3 is given by

FIGURE 19.4 Mechanics of fluid damping.

$$d_f = \frac{\oint \int_0^{L_x} \int_0^{L_z} f_d \, dz \, dx \, dq(x, z, t)}{L_x L_z q_0} \quad (19.22)$$

in which, L_x and L_z are cross-sectional dimensions of the element in the x and y -directions, respectively, and q_0 is a normalizing amplitude parameter for relative displacement.

Example 19.2

Consider a beam of length L and uniform rectangular cross section that is undergoing transverse vibration in a stationary fluid. Determine an expression for the damping capacity per unit volume for this fluid–structure interaction.

Solution

Suppose that the beam axis is along the x -direction and the transverse motion is in the z -direction. There is no variation in the y -direction, and hence, the length parameters in this direction cancel out.

$$d_f = \frac{\oint \int_0^L f_d \, dx \, dq(x, t)}{L q_0}$$

or

$$d_f = \frac{\int_0^T \int_0^L f_d \dot{q}(x, t) \, dx \, dt}{L q_0} \quad (19.23)$$

in which T is the period of the oscillations. Assuming constant c_d , we substitute Equation 19.21 into Equation 19.23:

$$d_f = \frac{1}{2} \frac{c_d \rho}{L q_0} \int_0^L \int_0^T |\dot{q}|^3 dt dx \tag{19.24}$$

For steady-excited harmonic vibration at frequency ω and shape function $Q(x)$ (or for free-modal vibration at natural frequency ω and mode shape $Q(x)$) we have

$$q(x, t) = q_{\max} Q(x) \sin \omega t \tag{19.25}$$

In this case, with the change of variable $\theta = \omega t$, Equation 19.24 becomes

$$d_f = 2 c_d \rho \frac{q_{\max}^3}{L q_0} \int_0^L |Q(x)|^3 dx \omega^2 \int_0^{\pi/2} \cos^3 \theta d\theta$$

or

$$d_f = \frac{4}{3} c_d \rho q_{\max}^3 \omega^2 \frac{\int_0^L |Q(x)|^3 dx}{L q_0}$$

Note. The integration interval of $t = 0$ to T becomes $\theta = 0$ to 2π or four times that from $\theta = 0$ to $\pi/2$. If the normalizing parameter is defined as

$$q_0 = \frac{1}{L} q_{\max} \int_0^L |Q(x)|^3 dx$$

then, we get

$$d_f = \frac{4}{3} c_d \rho q_{\max}^2 \omega^2 \tag{19.26}$$

A useful classification of damping is given in Box 19.1.

Box 19.1

DAMPING CLASSIFICATION

Type of Damping	Origin	Typical Constitutive Relation
Internal damping	Material properties	Viscoelastic $\sigma = E\varepsilon + E^* \frac{d\varepsilon}{dt}$
		Hysteretic $\sigma = E\varepsilon + \frac{\tilde{E}}{\omega} \frac{d\varepsilon}{dt}$
Structural damping	Structural joints and interfaces	Structural deformation $f = c q \operatorname{sgn}(\dot{q})$
		Coulomb $f = c \operatorname{sgn}(\dot{q})$
		General interface $f = \begin{cases} f_s & \text{for } v = 0 \\ f_{sb}(v) \operatorname{sgn}(v) & \text{for } v \neq 0 \end{cases}$
Fluid damping	Fluid–structure interactions	$f_d = \frac{1}{2} c_d \rho \dot{q}^2 \operatorname{sgn}(\dot{q})$

19.3 Representation of Damping in Vibration Analysis

It is not practical to incorporate detailed microscopic representations of damping in the dynamic analysis of systems. Instead, simplified models of damping that are representative of various types of energy dissipation are typically used. Consider a general n -degree-of-freedom mechanical system. Its motion can be represented by the vector \mathbf{x} of n generalized coordinates, x_i , representing the independent motions of the inertia elements. For small displacements, linear spring elements can be assumed. The corresponding equations of motion may be expressed in the vector matrix form

$$\mathbf{M}\ddot{\mathbf{x}} + \mathbf{d} + \mathbf{K}\mathbf{x} = \mathbf{f}(t) \tag{19.27}$$

in which \mathbf{M} is the mass (inertia) matrix and \mathbf{K} is the stiffness matrix. The forcing-function vector is $\mathbf{f}(t)$. The damping force vector $\mathbf{d}(\mathbf{x}, \dot{\mathbf{x}})$ is generally a nonlinear function of \mathbf{x} and $\dot{\mathbf{x}}$. The type of damping used in the system model may be represented by the nature of \mathbf{d} that is employed in the system equations. The various damping models that may be used, as discussed in the previous section, are listed in Table 19.1. Only the linear viscous damping term given in Table 19.1 is amenable to simplified mathematical analysis. In simplified dynamic models, other types of damping terms are usually replaced by an equivalent viscous damping term. Equivalent viscous damping is chosen so that its energy dissipation per cycle of oscillation is equal to that for the original damping. The resulting equations of motion are expressed by

$$\mathbf{M}\ddot{\mathbf{x}} + \mathbf{C}\dot{\mathbf{x}} + \mathbf{K}\mathbf{x} = \mathbf{f}(t) \tag{19.28}$$

In modal analysis of vibratory systems, the most commonly used model is proportional damping, where the damping matrix satisfies

$$\mathbf{C} = c_m\mathbf{M} + c_k\mathbf{K} \tag{19.29}$$

The first term on the right-hand side of Equation 19.29 is known as the inertial damping matrix. The corresponding damping force on each concentrated mass is proportional to its momentum. It represents the energy loss associated with a change in momentum (for example, during an impact). The second term is known as the stiffness damping matrix. The corresponding damping force is proportional to the rate of change of the local deformation forces at joints near the concentrated mass elements. Consequently, it represents a simplified form of linear structural damping. If damping is of the proportional type, it follows that the damped motion can be uncoupled into individual modes. This means that, if the damping model is of the proportional type, the damped system (as well as the undamped system) will possess real modes.

TABLE 19.1 Some Common Damping Models Used in Dynamic System Equations

Damping Type	Simplified Model d_i
Viscous	$\sum_j c_{ij}\dot{x}_j$
Hysteretic	$\sum_j \frac{1}{\omega} c_{ij}\dot{x}_j$
Structural	$\sum_j c_{ij} x_j \operatorname{sgn}(\dot{x}_j)$
Structural Coulomb	$\sum_j c_{ij} \operatorname{sgn}(\dot{x}_j)$
Fluid	$\sum_j c_{ij} \dot{x}_j \dot{x}_j$

19.3.1 Equivalent Viscous Damping

Consider a linear, single-DoF system with viscous damping, subjected to an external excitation. The equation of motion, for a unit mass, is given by

$$\ddot{x} + 2\zeta\omega_n\dot{x} + \omega_n^2x = \omega_n^2u(t) \quad (19.30)$$

If the excitation force is harmonic, with frequency ω , we have

$$u(t) = u_0 \cos \omega t \quad (19.31)$$

Then, the response of the system at steady state is given by

$$x = x_0 \cos(\omega t + \phi) \quad (19.32)$$

in which the response amplitude is

$$x_0 = u_0 \frac{\omega_n^2}{[(\omega_n^2 - \omega^2) + 4\zeta^2\omega_n^2\omega^2]^{1/2}} \quad (19.33)$$

and the response phase lead is

$$\phi = -\tan^{-1} \frac{2\zeta\omega_n\omega}{(\omega_n^2 - \omega^2)} \quad (19.34)$$

The energy dissipation (i.e., damping capacity), ΔU , per unit mass in one cycle is given by the net work done by the damping force, f_d ; thus,

$$\Delta U = \oint f_d dx = \int_{-\phi/\omega}^{(2\pi-\phi)/\omega} f_d \dot{x} dt \quad (19.35)$$

Since the viscous damping force, normalized with respect to mass (see Equation 19.30), is given by

$$f_d = 2\zeta\omega_n\dot{x} \quad (19.36)$$

the damping capacity, ΔU_v , for viscous damping, can be obtained as

$$\Delta U_v = 2\zeta\omega_n \int_0^{2\pi/\omega} \dot{x}^2 dt \quad (19.37)$$

Finally, using Equation 19.32 in Equation 19.37 we get

$$\Delta U_v = 2\pi x_0^2 \omega_n \omega \zeta \quad (19.38)$$

For any general type of damping (see Table 19.1), the equation of motion becomes

$$\ddot{x} + \mathbf{d}(x, \dot{x}) + \omega_n^2x = \omega_n^2u(t) \quad (19.39)$$

The energy dissipation in one cycle (Equation 19.35) is given by

$$\Delta U = \int_{-\phi/\omega}^{(2\pi-\phi)/\omega} d(x, \dot{x}) \dot{x} dt \quad (19.40)$$

Various damping force expressions, $d(x, \dot{x})$, normalized with respect to mass, are given in Table 19.2. For fluid damping, for example, the damping capacity is

$$\Delta U_f = \int_{-\phi/\omega}^{(2\pi-\phi)/\omega} c|\dot{x}|\dot{x}^2 dt \quad (19.41)$$

By substituting Equation 19.32 in Equation 19.41 for steady, harmonic motion we obtain

$$\Delta U_f = \frac{8}{3} c x_0^3 \omega^2 \quad (19.42)$$

TABLE 19.2 Equivalent Damping Ratio Expressions for Some Common Types of Damping

Damping Type	Damping Force, $d(x, \dot{x})$, per Unit Mass	Equivalent Damping Ratio, ζ_{eq}
Viscous	$2\zeta\omega_n\dot{x}$	ζ
Hysteretic	$\frac{c}{\omega}\dot{x}$	$\frac{c}{2\omega_n\omega}$
Structural	$c x \operatorname{sgn}(\dot{x})$	$\frac{c}{\pi\omega_n\omega}$
Structural Coulomb	$c\operatorname{sgn}(\dot{x})$	$\frac{2c}{\pi x_0\omega_n\omega}$
Fluid	$c \dot{x} \dot{x}$	$\frac{4}{3\pi}\left(\frac{\omega}{\omega_n}\right)x_0c$

By comparing Equation 19.42 with Equation 19.38, the equivalent damping ratio for fluid damping is obtained as

$$\zeta_f = \frac{4}{3\pi}\left(\frac{\omega}{\omega_n}\right)x_0c \quad (19.43)$$

in which x_0 is the amplitude of steady-state vibrations, as given by Equation 19.33. For the other types of damping listed in Table 19.1, expressions for the equivalent damping ratio can be obtained in a similar manner. The corresponding equivalent damping ratio expressions are given in Table 19.2. It should be noted that, for nonviscous damping types, ζ is generally a function of the frequency of oscillation, ω , and the amplitude of excitation, u_0 . It should be noted that the expressions given in Table 19.2 are derived assuming harmonic excitation. Engineering judgment should be exercised when employing these expressions for nonharmonic excitations.

For multi-DoF systems that incorporate proportional damping, the equations of motion can be transformed into a set of one-DoF equations (modal equations) of the type given in Equation 19.30. In this case, the damping ratio and natural frequency correspond to the respective modal values and, in particular, $\omega = \omega_n$.

19.3.2 Complex Stiffness

Consider a linear spring of stiffness k connected in parallel with a linear viscous damper of damping constant c , as shown in Figure 19.5(a). Suppose that a force, f , is applied to the system, moving it through distance x from the relaxed position of the spring. Then we have

$$f = kx + c\dot{x} \quad (19.44)$$

Suppose that the motion is harmonic, as given by

$$x = x_0 \cos \omega t \quad (19.45)$$

It is clear that the spring force, kx , is in phase with the displacement, but the damping force, $c\dot{x}$, has a 90° phase lead with respect to the displacement. This is because the velocity, $\dot{x} = -x_0\omega \sin \omega t = x_0\omega \cos(\omega t + \pi/2)$, has a 90° phase lead with respect to x . Specifically, we have

$$f = kx_0 \cos \omega t + cx_0\omega \cos\left(\omega t + \frac{\pi}{2}\right) \quad (19.46)$$

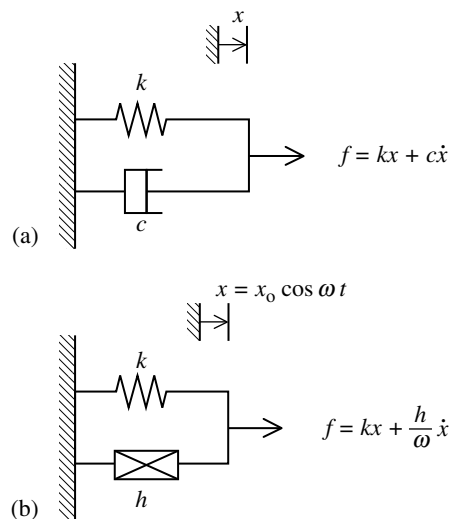

FIGURE 19.5 Spring element in parallel with (a) a viscous damper and (b) a hysteretic damper.

This same fact may be represented by using complex numbers, where the in-phase component is considered as the real part and the 90° phase lead component is considered as the imaginary part with each component oscillating at the same frequency ω . Then, we can write Equation 19.46 in the equivalent form

$$f = kx + j\omega cx \quad (19.47)$$

This is exactly what we get by starting with the complex representation of the displacement

$$x = x_0 e^{j\omega t} \quad (19.48)$$

and substituting it in Equation 19.44. We note that Equation 19.47 may be written as

$$f = k^* x \quad (19.49)$$

where k^* is a “complex” stiffness, given by

$$k^* = k + j\omega c \quad (19.50)$$

Clearly, the system itself and its two components (spring and damper) are real. Their individual forces are also real. The complex stiffness is simply a mathematical representation of the two force components (spring force and damping force), which are 90° out of phase, when subjected to harmonic motion. It follows that the linear damper may be “mathematically” represented by an “imaginary” stiffness. In the case of viscous damping this imaginary stiffness (and hence, the damping force magnitude) increases linearly with the frequency, ω , of the harmonic motion. The concept of complex stiffness when dealing with discrete dampers is analogous to the use of complex elastic modulus in material damping, as discussed earlier in this chapter.

We have noted that, for hysteretic damping, the damping force (or damping stress) is independent of the frequency in harmonic motion. It follows that a hysteretic damper may be represented by an equivalent damping constant of

$$c = \frac{h}{\omega} \quad (19.51)$$

which is valid for a harmonic motion (e.g., modal motion or forced motion) of frequency ω . This situation is shown in [Figure 19.5\(b\)](#). It can be seen that the corresponding complex stiffness is

$$k^* = k + jh \quad (19.52)$$

Example 19.3

A flexible system consists of a mass, m , attached to the hysteretic damper and spring combination shown in Figure 19.5(b). What is the frequency response function of the system relating an excitation force, f , applied to the mass and the resulting displacement response, x ? Obtain the resonant frequency of the system. Compare the results with the case for viscous damping.

Solution

For a harmonic motion of frequency ω , the equation of motion of the system is

$$m\ddot{x} + \frac{h}{\omega}\dot{x} + kx = f \quad (19.53)$$

With a forcing excitation of $f = f_0 e^{j\omega t}$ and the resulting steady-state response, $x = x_0 e^{j\omega t}$, where x_0 has a phase difference (i.e., it is a complex function) with respect to f_0 . Then, in the frequency domain, substituting the harmonic response $x = x_0 e^{j\omega t}$ into Equation 19.53 we get

$$\left[-\omega^2 m + \frac{h}{\omega} j\omega + k \right] x = f$$

resulting in the frequency transfer function

$$\frac{x}{f} = \frac{1}{[k - \omega^2 m + jh]} \quad (19.54)$$

Note that, as usual, this result is obtained simply by substituting $j\omega$ for d/dt . The magnitude of transfer function is at a maximum at resonance. This corresponds to a minimum value of

$$p(\omega) = (k - \omega^2 m)^2 + h^2$$

If we set $dp/d\omega = 0$, we get,

$$2(k - \omega^2 m)(-2\omega) = 0$$

Hence, the resonant frequency corresponds to the root of

$$k - \omega^2 m = 0$$

This gives the resonant frequency

$$\omega_r = \sqrt{\frac{k}{m}} \quad (19.55)$$

Note that, in the case of hysteretic damping, the resonant frequency is equal to the undamped natural frequency, ω_n , and, unlike in the case of viscous damping, does not depend on the level of damping itself. For convenience consider the system response as the spring force

$$f_s = kx \quad (19.56)$$

Then, a normalized transfer function is obtained, as given by

$$\frac{f_s}{f} = G(j\omega) = \frac{1}{\left[1 - \omega^2 \frac{m}{k} + j \frac{h}{k}\right]} \quad (19.57)$$

or,

$$\frac{f_s}{f} = \frac{1}{[1 - r^2 + j\alpha]} \quad (19.58)$$

where

$$r = \frac{\omega}{\omega_n} \quad \text{and} \quad \alpha = \frac{h}{k} \quad (19.59)$$

which are the normalized frequency and the normalized hysteretic damping, respectively. The magnitude of the transfer function is

$$\left| \frac{f_s}{f} \right| = \frac{1}{\sqrt{(1 - r^2)^2 + \alpha^2}} \quad (19.60)$$

and the phase angle (phase lead) is

$$\angle f_s/f = -\tan^{-1} \frac{\alpha}{(1 - r^2)} \quad (19.61)$$

These results are sketched in [Figure 19.6](#).

19.3.3 Loss Factor

We define the *damping capacity* of a device (damper) as the energy dissipated in a complete cycle of motion; specifically

$$\Delta U = \oint f_d dx \quad (19.62)$$

FIGURE 19.6 Frequency transfer function of a simple oscillator with hysteretic damping.

This is given by the area of the hysteresis loop in the displacement force plane. If the initial (total) energy of the system is denoted by U_{\max} , then the *specific damping capacity*, D , is given by the ratio

$$D = \frac{\Delta U}{U_{\max}} \quad (19.63)$$

The *loss factor*, η , is the specific damping capacity per radian of the damping cycle. Hence,

$$\eta = \frac{\Delta U}{2\pi U_{\max}} \quad (19.64)$$

Note that U_{\max} is approximately equal to the maximum kinetic energy and also to the maximum potential energy of the device when the damping is low.

Equation 19.38 gives the damping capacity per unit mass of a device with viscous damping as

$$\Delta U = 2\pi x_0^2 \omega_n \omega \zeta \quad (19.65)$$

Here, x_0 is the amplitude and ω is the frequency of harmonic motion of the device, ω_n is the undamped natural frequency and ζ is the damping ratio. The maximum potential energy per unit mass of the system is

$$U_{\max} = \frac{1}{2} \frac{k}{m} x_0^2 = \frac{1}{2} \omega_n^2 x_0^2 \quad (19.66)$$

Hence, from Equation 19.64, the loss factor for a viscous damped simple oscillator is given by

$$\eta = \frac{2\pi x_0^2 \omega_n \omega \zeta}{2\pi \times \frac{1}{2} \omega_n^2 x_0^2} = \frac{2\omega \zeta}{\omega_n} \quad (19.67)$$

For free decay of the system, we have $\omega = \omega_d \cong \omega_n$, where the latter approximation holds for low damping. For forced oscillation, the worst response conditions occur when $\omega = \omega_d \cong \omega_n$, which is what one must consider with regard to energy dissipation. In either case, the loss factor is approximately

given by

$$\eta = 2\zeta$$

(19.68)

For other types of damping, Equation 19.68 will still hold when the equivalent damping ratio, ζ_{eq} , (see Table 19.2) is used in place of ζ .

The loss factors of some common materials are given in Table 19.3. Definitions of useful damping parameters, as defined here, are summarized in Table 19.4. Expressions of loss factors for some useful damping models are given in Table 19.5.

TABLE 19.3 Loss Factors of Some Useful Materials

Material	Loss Factor $\eta \cong 2\zeta$
Aluminum	2×10^{-5} to 2×10^{-3}
Concrete	0.02 to 0.06
Glass	0.001 to 0.002
Rubber	0.1 to 1.0
Steel	0.002 to 0.01
Wood	0.005 to 0.01

TABLE 19.4 Definitions of Damping Parameters

Parameter	Definition	Mathematical Formula
Damping capacity (ΔU)	Energy dissipated per cycle of motion (area of displacement–force hysteresis loop)	$\oint f_d \, dx$
Damping capacity per volume (d)	Energy dissipated per cycle per unit material volume (area of strain–stress hysteresis loop)	$\oint \sigma \, d\varepsilon$
Specific damping capacity (D)	Ratio of energy dissipated per cycle (ΔU) to the initial maximum energy (U_{\max}) <i>Note:</i> for low damping, U_{\max} = maximum potential energy = maximum kinetic energy	$\frac{\Delta U}{U_{\max}}$
Loss factor (η)	Specific damping capacity per unit angle of cycle. <i>Note:</i> for low damping, $\eta = 2 \times$ damping ratio	$\frac{\Delta U}{2\pi U_{\max}}$

TABLE 19.5 Loss Factors for Several Material Damping Models

Material Damping Model	Stress–Strain Constitute Relation	Loss Factor (η)
Viscoelastic Kelvin–Voigt	$\sigma = E\varepsilon + E^* \frac{d\varepsilon}{dt}$	$\frac{\omega E^*}{E}$
Hysteretic Kelvin–Voigt	$\sigma = E\varepsilon + \frac{\tilde{E}}{\omega} \frac{d\varepsilon}{dt}$	$\frac{\tilde{E}}{E}$
Viscoelastic standard linear solid	$\sigma + c_s \frac{d\sigma}{dt} = E\varepsilon + E^* \frac{d\varepsilon}{dt}$	$\frac{\omega E^*}{E} \frac{(1 - c_s E/E^*)}{(1 + \omega^2 c_s^2)}$
Hysteretic standard linear solid	$\sigma + c_s \frac{d\sigma}{dt} = E\varepsilon + \frac{\tilde{E}}{\omega} \frac{d\varepsilon}{dt}$	$\frac{\tilde{E}}{E} \frac{(1 - \omega c_s E/\tilde{E})}{(1 + \omega^2 c_s^2)}$

19.4 Measurement of Damping

Damping may be represented by various parameters (such as specific damping capacity, loss factor, Q-factor, and damping ratio) and models (such as viscous, hysteretic, structural, and fluid). Before attempting to measure damping in a system, we need to decide on a representation (model) that will adequately characterize the nature of mechanical energy dissipation in the system. Next, we should decide on the parameter or parameters of the model that need to be measured.

It is extremely difficult to develop a realistic yet tractable model for damping in a complex piece of equipment operating under various conditions of mechanical interaction. Even if a satisfactory damping model is developed, experimental determination of its parameters could be tedious. A major difficulty arises because it usually is not possible to isolate various types of damping (for example, material, structural, and fluid) from an overall measurement. Furthermore, damping measurements must be conducted under actual operating conditions for them to be realistic.

If one type of damping (say, fluid damping) is eliminated during the actual measurement then it would not represent the true operating conditions. This would also eliminate possible interacting effects of the eliminated damping type with the other types. In particular, overall damping in a system is not generally equal to the sum of the individual damping values when they are acting independently. Another limitation of computing equivalent damping values using experimental data arises because it is assumed for analytical simplicity that the dynamic system behavior is linear. If the system is highly nonlinear, a significant error could be introduced into the damping estimate. Nevertheless, it is customary to assume linear viscous behavior when estimating damping parameters using experimental data.

There are two general ways by which damping measurements can be made: using a time–response record and using a frequency–response function of the system to estimate damping.

19.4.1 Logarithmic Decrement Method

This is perhaps the most popular time–response method that is used to measure damping. When a single-DoF oscillatory system with viscous damping (see Equation 19.30) is excited by an impulse input (or an initial condition excitation), its response takes the form of a time decay (see Figure 19.7), given by

$$y(t) = y_0 \exp(-\zeta \omega_n t) \sin \omega_d t \quad (19.69)$$

in which the damped natural frequency is given by

$$\omega_d = \sqrt{1 - \zeta^2} \omega_n \quad (19.70)$$

FIGURE 19.7 Impulse response of a simple oscillator.

If the response at $t = t_i$ is denoted by y_i , and the response at $t = t_i + 2\pi r/\omega_d$ is denoted by y_{i+r} , then, from Equation 19.69, we have

$$\frac{y_{i+r}}{y_i} = \exp\left(-\zeta \frac{\omega_n}{\omega_d} 2\pi r\right), \quad i = 1, 2, \dots, n$$

In particular, suppose that y_i corresponds to a peak point in the time decay function, having magnitude A_i , and that y_{i+r} corresponds to the peak point r cycles later in the time history, and its magnitude is denoted by A_{i+r} (see Figure 19.7). Even though the above equation holds for any pair of points that are r periods apart in the time history, the peak points seem to be the appropriate choice for measurement in the present procedure, as these values would be more prominent than any arbitrary points in a response–time history. Then,

$$\frac{A_{i+r}}{A_i} = \exp\left(-\zeta \frac{\omega_n}{\omega_d} 2\pi r\right) = \exp\left[-\frac{\zeta}{\sqrt{1-\zeta^2}} 2\pi r\right]$$

where Equation 19.70 has been used. Then, the logarithmic decrement δ is given by (per unit cycle)

$$\delta = \frac{1}{r} \ln\left(\frac{A_i}{A_{i+r}}\right) = \frac{2\pi\zeta}{\sqrt{1-\zeta^2}} \quad (19.71)$$

or the damping ratio may be expressed as

$$\zeta = \frac{1}{\sqrt{1 + (2\pi/\delta)^2}} \quad (19.72)$$

For low damping (typically, $\zeta < 0.1$), $\omega_d \cong \omega_n$ and Equation 19.71 become

$$\frac{A_{i+r}}{A_i} \cong \exp(-\zeta 2\pi r) \quad (19.73)$$

or

$$\zeta = \frac{1}{2\pi r} \ln\left(\frac{A_i}{A_{i+r}}\right) = \frac{\delta}{2\pi} \quad \text{for } \zeta < 0.1 \quad (19.74)$$

This is in fact the “per-radian” logarithmic decrement.

The damping ratio can be estimated from a free-decay record, using Equation 19.74. Specifically, the ratio of the extreme amplitudes in prominent r cycles of decay is determined and substituted into Equation 19.74 to get the equivalent damping ratio.

Alternatively, if n cycles of damped oscillation are needed for the amplitude to decay by a factor of two, for example, then, from Equation 19.74, we get

$$\zeta = \frac{1}{2\pi n} \ln(2) = \frac{0.11}{n} \quad \text{for } \zeta < 0.1 \quad (19.75)$$

For slow decays (low damping), we have

$$\ln\left(\frac{A_i}{A_{i+1}}\right) \cong \frac{2(A_i - A_{i+1})}{(A_i + A_{i+1})} \quad (19.76)$$

Then, from Equation 19.74, we get

$$\zeta = \frac{A_i - A_{i+1}}{\pi(A_i + A_{i+1})} \quad \text{for } \zeta < 0.1 \quad (19.77)$$

Any one of Equation 19.72, Equation 19.74, Equation 19.75, and Equation 19.77 could be employed in computing ζ from test data. It should be noted that the results assume single-DoF system behavior. For multi-DoF systems, the modal damping ratio for each mode can be determined using this method if the initial excitation is such that the decay takes place primarily in one mode of vibration.

In other words, substantial modal separation and the presence of “real” modes (not “complex” modes with nonproportional damping) are assumed.

19.4.2 Step–Response Method

This is also a time–response method. If a unit-step excitation is applied to the single-DoF oscillatory system given by Equation 19.30, its time–response is given by

$$y(t) = 1 - \frac{1}{\sqrt{1 - \zeta^2}} \exp(-\zeta \omega_n t) \sin(\omega_d t + \phi) \quad (19.78)$$

in which $\phi = \cos \zeta$. A typical step–response curve is shown in Figure 19.8. The time at the first peak (peak time), T_p , is given by

$$T_p = \frac{\pi}{\omega_d} = \frac{\pi}{\sqrt{1 - \zeta^2} \omega_n} \quad (19.79)$$

The response at peak time (peak value), M_p , is given by

$$M_p = 1 + \exp(-\zeta \omega_n T_p) = 1 + \exp\left(\frac{-\pi \zeta}{\sqrt{1 - \zeta^2}}\right) \quad (19.80)$$

The percentage overshoot, PO, is given by

$$PO = (M_p - 1) \times 100\% = 100 \exp\left(\frac{-\pi \zeta}{\sqrt{1 - \zeta^2}}\right) \quad (19.81)$$

It follows that, if any one parameter of T_p , M_p or PO is known from a step–response record, the corresponding damping ratio, ζ , can be computed by using the appropriate relationship from the following:

$$\zeta = \sqrt{1 - \left(\frac{\pi}{T_p \omega_n}\right)^2} \quad (19.82)$$

$$\zeta = \frac{1}{\sqrt{1 + \frac{1}{\left[\frac{\ln(M_p - 1)}{\pi}\right]^2}}} \quad (19.83)$$

$$\zeta = \frac{1}{\sqrt{1 + \frac{1}{\left[\frac{\ln(PO/100)}{\pi}\right]^2}}} \quad (19.84)$$

It should be noted that when determining M_p the response curve should be normalized to unit steady-state value. Furthermore, the results are valid only for single-DoF systems and modal excitations in multi-DoF systems.

19.4.3 Hysteresis Loop Method

For a damped system, the force versus displacement cycle produces a hysteresis loop. Depending on the inertial and elastic characteristics and other conservative loading conditions (e.g., gravity) in the system,

FIGURE 19.8 A typical step–response of a simple oscillator.

the shape of the hysteresis loop will change. But the work done by conservative forces (e.g., inertial, elastic, and gravitational) in a complete cycle of motion will be zero. Consequently, the net work done will be equal to the energy dissipated due to damping only. Accordingly, the area of the displacement–force hysteresis loop will give the damping capacity, ΔU (see Equation 19.62). The maximum energy in the system can also be determined from the displacement–force curve. Then, the loss factor, η , can be computed using Equation 19.64, and the damping ratio from Equation 19.68. This method of damping measurement may also be considered basically as a time domain method.

Note that Equation 19.65 is the work done against (i.e., energy dissipation in) a single loading–unloading cycle per unit mass. It should be recalled that $2\zeta\omega_n = c/m$, where c = viscous damping constant and m = mass. Accordingly, from Equation 19.65, the energy dissipation per unit mass and per hysteresis loop is $\Delta U = \pi x_0^2 \omega c/m$. Hence, without normalizing with respect to mass, the energy dissipation per hysteresis loop of viscous damping is

$$\Delta U_v = \pi x_0^2 \omega c \quad (19.85)$$

Equation 19.85 can be derived by performing the cyclic integration indicated in Equation 19.62 with the damping force $f_d = c\dot{x}$, harmonic motion $x = x_0 e^{j\omega t}$ and the integration interval $t = 0$ to $2\pi/\omega$.

Similarly, in view of Equation 19.51, the energy dissipation per hysteresis loop of hysteretic damping is

$$\Delta U_h = \pi x_0^2 h \quad (19.86)$$

Now, since the initial maximum energy may be represented by the initial maximum potential energy, we have

$$U_{\max} = \frac{1}{2} k x_0^2 \quad (19.87)$$

Note that the stiffness, k , may be measured as the average slope of the displacement–force hysteresis loop. Hence, in view of Equation 19.64, the loss factor for hysteretic damping is given by

$$\eta = \frac{h}{k} \quad (19.88)$$

Then, from Equation 19.68, the equivalent damping ratio for hysteretic damping is

$$\zeta = \frac{h}{2k} \quad (19.89)$$

Example 19.4

A damping material was tested by applying a loading cycle of -900 to 900 N and back to -900 N to a thin bar made of the material and measuring the corresponding deflection. The smoothed load vs. deflection curve obtained in this experiment is shown in [Figure 19.9](#). Assuming that the damping is predominantly of the hysteretic type, estimate

1. The hysteretic damping constant
2. The equivalent damping ratio

Solution

Approximating the top and the bottom segments of the hysteresis loop by triangles, we estimate the area of the loop as

$$\Delta U_h = 2 \times \frac{1}{2} \times 2.5 \times 900 \text{ N mm}$$

Alternatively, we may obtain this result by counting the squares within the hysteresis loop. The deflection amplitude is

$$x_0 = 8.5 \text{ mm}$$

FIGURE 19.9 An experimental hysteresis loop of a damping material.

Hence, from Equation 19.86 we have

$$h = \frac{2 \times \frac{1}{2} \times 2.5 \times 900}{\pi \times 8.5^2} \text{ N/mm} = 9.9 \text{ N/mm}$$

The stiffness of the damping element is estimated as the average slope of the hysteresis loop; thus

$$k = \frac{600}{4.5} \text{ N/mm} = 133.3 \text{ N/mm}$$

Hence, from Equation 19.89, the equivalent damping ratio is

$$\zeta = \frac{9.9}{2 \times 133.3} \approx 0.04$$

19.4.4 Magnification Factor Method

This is a frequency–response method. Consider a single-DoF oscillatory system with viscous damping. The magnitude of its frequency–response function is

$$|H(\omega)| = \frac{\omega_n^2}{\left[(\omega_n^2 - \omega^2)^2 + 4\zeta^2 \omega_n^2 \omega^2 \right]^{1/2}} \quad (19.90)$$

A plot of this expression with respect to ω , the frequency of excitation, is given in Figure 19.10. The peak value of magnitude occurs when the denominator of the expression is at its minimum. This corresponds to

$$\frac{d}{d\omega} \left[(\omega_n^2 - \omega^2)^2 + 4\zeta^2 \omega_n^2 \omega^2 \right] = 0 \quad (19.91)$$

FIGURE 19.10 The magnification factor method of damping measurement applied to a single-DoF system.

The resulting solution for ω is termed the resonant frequency, ω_r

$$\omega_r = \sqrt{1 - 2\zeta^2} \omega_n \quad (19.92)$$

It is noted that $\omega_r < \omega_d$ (see Equation 19.70), but for low damping ($\zeta < 0.1$), the values of ω_n , ω_d , and ω_r are nearly equal. The amplification factor, Q , which is the magnitude of the frequency–response function at resonant frequency, is obtained by substituting Equation 19.92 in Equation 19.90:

$$Q = \frac{1}{2\zeta\sqrt{1 - \zeta^2}} \quad (19.93)$$

For low damping ($\zeta < 0.1$), we have

$$Q = \frac{1}{2\zeta} \quad (19.94)$$

In fact, Equation 19.94 corresponds to the magnitude of the frequency–response function at $\omega = \omega_n$.

It follows that, if the magnitude curve of the frequency–response function (or a Bode plot) is available, then the system damping ratio, ζ , can be estimated using Equation 19.94. When using this method, the frequency–response curve must be normalized so that its magnitude at zero frequency (termed *static gain*) is unity.

For a multi-DoF system modal damping values may be estimated from the magnitude of the Bode plot of its frequency–response function, provided that the modal frequencies are not too closely spaced and the system is lightly damped. Consider the logarithmic (to the base ten) magnitude plot shown in Figure 19.11. The magnitude is expressed in decibels (dB), which is calculated by multiplying the $\log_{10}(\text{magnitude})$ by a factor of 20. At the i th resonant frequency, ω_i , the amplification factor, q_i (in dB), is obtained by drawing an asymptote to the preceding segment of the curve and measuring the peak value from the asymptote. Then,

$$Q_i = (10)^{q_i/20} \quad (19.95)$$

FIGURE 19.11 Magnification factor method applied to a multi-DoF system.

and the modal damping ratio

$$\zeta = \frac{1}{2Q_i}, \quad i = 1, 2, \dots, n \tag{19.96}$$

If the significant resonances are closely spaced, curve-fitting to a suitable function may be necessary in order to determine the corresponding modal damping values. The Nyquist plot may also be used in computing damping using frequency domain data.

19.4.5 Bandwidth Method

The bandwidth method of damping measurement is also based on frequency–response. Consider the frequency–response function magnitude given by Equation 19.90 for a single-DoF, oscillatory system with viscous damping. The peak magnitude is given by Equation 19.94 for low damping. Bandwidth (half-power) is defined as the width of the frequency–response magnitude curve when the magnitude is $(1/\sqrt{2})$ times the peak value. This is denoted by $\Delta\omega$ (see Figure 19.12). An expression

FIGURE 19.12 Bandwidth method of damping measurement in a single-DoF system.

for $\Delta\omega = \omega_2 - \omega_1$ is obtained below using Equation 19.90. By definition, ω_1 and ω_2 are the roots of the equation

$$\frac{\omega_n^2}{\left[(\omega_n^2 - \omega^2)^2 + 4\zeta^2 \omega_n^2 \omega^2\right]^{1/2}} = \frac{1}{\sqrt{2} \times 2\zeta} \quad (19.97)$$

for ω . Equation 19.97 can be expressed in the form

$$\omega^4 - 2(1 - 2\zeta^2)\omega_n^2 \omega^2 + (1 - 8\zeta^2)\omega_n^4 = 0 \quad (19.98)$$

This is a quadratic equation in ω^2 , having roots ω_1^2 and ω_2^2 , which satisfy

$$(\omega^2 - \omega_1^2)(\omega^2 - \omega_2^2) = \omega^4 - (\omega_1^2 + \omega_2^2)\omega^2 + \omega_1^2 \omega_2^2 = 0$$

Consequently,

$$\omega_1^2 + \omega_2^2 = 2(1 - 2\zeta^2)\omega_n^2 \quad (19.99)$$

and

$$\omega_1^2 \omega_2^2 = (1 - 8\zeta^2)\omega_n^4 \quad (19.100)$$

It follows that

$$(\omega_2 - \omega_1)^2 = \omega_1^2 + \omega_2^2 - 2\omega_1 \omega_2 = 2(1 - 2\zeta^2)\omega_n^2 - 2\sqrt{1 - 8\zeta^2}\omega_n^2$$

For small ζ (in comparison to 1), we have

$$\sqrt{1 - 8\zeta^2} \cong 1 - 4\zeta^2$$

Hence,

$$(\omega_2 - \omega_1)^2 \cong 4\zeta^2 \omega_n^2$$

or, for low damping

$$\Delta\omega = 2\zeta\omega_n = 2\zeta\omega_r \quad (19.101)$$

From Equation 19.101 it follows that the damping ratio can be estimated from the bandwidth using the relation

$$\zeta = \frac{1}{2} \frac{\Delta\omega}{\omega_r} \quad (19.102)$$

For a multi-DoF system with widely spaced resonances, the foregoing method can be extended to estimate modal damping. Consider the frequency–response magnitude plot (in dB) shown in [Figure 19.13](#).

Since a factor of $\sqrt{2}$ corresponds to 3 dB, the bandwidth corresponding to a resonance is given by the width of the magnitude plot at 3 dB below that resonant peak. For the i th mode, the damping ratio is given by

$$\zeta_i = \frac{1}{2} \frac{\Delta\omega_i}{\omega_i} \quad (19.103)$$

The bandwidth method of damping measurement indicates that the bandwidth at a resonance is a measure of the energy dissipation in the system in the neighborhood of that resonance. The simplified

FIGURE 19.13 Bandwidth method of damping measurement in a multi-DoF system.

relationship given by Equation 19.103 is valid for low damping, however, and is based on linear system analysis. Several methods of damping measurement are summarized in Box 19.2.

19.4.6 General Remarks

There are limitations to the use of damping values that are experimentally determined. For example, consider time–response methods for determining the modal damping of a device for higher modes. The customary procedure is to first excite the system at the desired resonant frequency, using a harmonic exciter, and then to release the excitation mechanism. In the resulting transient vibration, however, there invariably will be modal interactions, except in the case of proportional damping. In this type of test, it is tacitly assumed that the device can be excited in the particular mode. In essence, proportional damping is assumed in modal damping measurements. This introduces a certain amount of error into the measured damping values.

Expressions used in computing damping parameters from test measurements are usually based on linear system theory. However, all practical devices exhibit some nonlinear behavior. If the degree of nonlinearity is high, the measured damping values will not be representative of the actual behavior of the system. Furthermore, testing to determine damping is usually performed at low amplitudes of vibration. The corresponding responses could be an order of magnitude lower than, for instance, the amplitudes exhibited under extreme operating conditions. Damping in practical devices increases with the amplitude of motion, except for relatively low amplitudes (see Figure 19.14 illustrating nonlinear behavior). Consequently, the damping values determined from experiments should be extrapolated when they are used to study the behavior of the system under various operating conditions. Alternatively, damping could be associated with a stress level in the device. Different components in a device are subjected to varying levels of stress, however, and it might be difficult to obtain a representative stress value for the entire device. One of the methods recommended for estimating damping in structures under seismic disturbances, for example, is by analyzing earthquake response records for structures that are similar to the one being considered. Some typical damping ratios that are applicable under operating basis earthquake (OBE) and safe-shutdown earthquake (SSE) conditions for a range of items are given in Table 19.6.

When damping values are estimated using frequency–response magnitude curves, accuracy becomes poor at very low damping ratios ($< 1\%$). The main reason for this is the difficulty in obtaining a sufficient number of points in the magnitude curve near a poorly damped resonance when the frequency–response function is determined experimentally. As a result, the magnitude curve is poorly defined in the neighborhood of a weakly damped resonance. For low damping ($< 2\%$), time–response methods are particularly useful. At high damping values, the rate of decay can be so fast that the measurements contain large errors. Modal interference in closely spaced modes can also affect measured damping results.

Logarithmic decrement method	A_i = first significant amplitude; A_{i+r} = amplitude after r cycles	Logarithmic decrement $\delta = \frac{1}{r} \ln \frac{A_i}{A_{i+r}} \text{ (per cycle)}$ $\frac{\delta}{2\pi} = \frac{\zeta}{\sqrt{1-\zeta^2}} \text{ (per radian)}$ <p>or,</p> $\zeta = \frac{1}{\sqrt{1+(2\pi/\delta)^2}}$ <p>For low damping</p> $\zeta = \frac{\delta}{2\pi}$ $\zeta = \frac{A_i - A_{i+1}}{\pi(A_i + A_{i+1})}$
Step response method	M_p = first peak value normalized r.t. steady-state value; PO = percentage overshoot (over steady-state value)	$M_p = 1 + \exp\left[\frac{-\pi\zeta}{\sqrt{1-\zeta^2}}\right]$ $\text{PO} = 100 \exp\left[\frac{-\pi\zeta}{\sqrt{1-\zeta^2}}\right]$
Hysteresis loop method	ΔU = area of displacement–force hysteresis loop; x_0 = maximum displacement of the hysteresis loop; k = average slope of the hysteresis loop	Hysteretic damping constant $h = \frac{\Delta U}{\pi x_0^2}$ <p>Loss factor</p> $\eta = \frac{h}{k}$ <p>Equivalent damping ratio</p> $\zeta = \frac{h}{2k}$
Magnification factor method	Q = amplification at resonance, w.r.t. zero-frequency value	$Q = \frac{1}{2\zeta\sqrt{1-\zeta^2}}$ <p>For low damping</p> $\zeta = \frac{1}{2Q}$
Bandwidth method	$\Delta\omega$ = bandwidth at $1/\sqrt{2}$ of resonant peak (i.e., half-power bandwidth); ω_r = resonant frequency	$\zeta = \frac{\Delta\omega}{2\omega_r}$

Reinforced concrete structures	4	7

19.5 Interface Damping

In many practical applications damping is generated at the interface of two sliding surfaces. This is the case, for example, in bearings, gears, screws, and guideways. Even though this type of damping is commonly treated under structural damping, due to its significance we will consider it again here in more detail, as a category of its own.

Interface damping was formally considered by DaVinci in the early 1500s and again by Coulomb in the 1700s. The simplified model used by them is the well-known Coulomb friction model as given by

$$f = \mu R \operatorname{sgn}(v) \tag{19.104}$$

where

- f = the frictional force that opposes the motion
- R = the normal reaction force between the sliding surfaces
- v = the relative velocity between the sliding surfaces
- μ = the coefficient of friction

Note that the signum function “sgn” is used to emphasize that f is in the opposite direction of v . This simple model is not expected to provide accurate results in all cases of interface damping. It is known that, apart from the loading conditions, interface damping depends on a variety of factors such as material properties, surface characteristics, nature of lubrication, geometry of the moving parts, and the magnitude of the relative velocity.

A somewhat more complete model for interface damping, incorporating the following characteristics, is shown in Figure 19.15:

1. Static and dynamic friction, with stiction and stick–slip behavior.
2. Conventional Coulomb friction (Region 1).
3. A drop in dynamic friction, with a negative slope, before increasing again. This is known as the “Stribeck effect” (Region 2).
4. Conventional viscous damping (Region 3).

These characteristics cover the behavior of interface damping that is commonly observed in practice. In particular, suppose that a force is exerted to generate a relative motion between two surfaces. For small values of the force, there will not be a relative motion, in view of friction. The minimum force, f_s , that is needed for the motion to start is the static frictional force. The force that is needed to maintain the motion will drop instantaneously to f_d , as the motion begins. It is as though initially the two surfaces were “stuck” and f_s is the necessary breakaway force. Hence, this characteristic is known as stiction. The minimum force f_d that is needed to maintain the relative motion between the two surfaces is called dynamic friction. In fact, under dynamic conditions, it is possible for “stick–slip” to occur where repeated sticking and breaking away cycles of intermittent motion take place. Clearly, such “chattering” motion corresponds to instability (for example, in machine tools). It is an undesirable effect and should be avoided.

After the relative motion begins, conventional Coulomb type damping behavior may dominate for small relative velocities, as represented in Region 1. For lubricated surfaces, at low relative velocities, there will be some solid-to-solid contact that generates a Coulomb-type damping force. As the relative speed increases, the degree of this solid-to-solid contact will decrease and the damping force will drop, as in Region 2 of Figure 19.15. This characteristic is known as the Stribeck effect. Since the slope of the friction curve is negative in Regions 1 and 2, this corresponds to the unstable region. As the relative velocity is further increased, in fully lubricated surfaces, viscous-type damping will dominate, as shown in Region 3 of Figure 19.15. This is the stable region. It follows that a combined model of interface damping may be expressed as

$$f = \begin{cases} f_s & \text{for } v = 0 \\ f_{sb}(v)\text{sgn}(v) + bv & \text{for } v \neq 0 \end{cases} \quad (19.105)$$

FIGURE 19.15 Main characteristics of interface damping.

Note that $f_{sb}(v)$ is a nonlinear function of velocity that will represent both dynamic friction (for $v > 0$) and the Stribeck effect. Models that have been used to represent this effect include the following

$$f_{sb} = \frac{f_d}{1 + (v/v_c)^2} \quad (19.106)$$

$$f_{sb} = f_d e^{-(v/v_c)^2} \quad (19.107)$$

and

$$f_{sb} = (f_d + \alpha|v|^{1/2})\text{sgn}(v) \quad (19.108)$$

Note that f_d represents dynamic Coulomb friction and v_c and α are modal parameters.

Example 19.5

An object of mass m rests on a horizontal surface and is attached to a spring of stiffness k , as shown in Figure 19.16. The mass is pulled so that the extension of the spring is x_0 , and is moved from rest from that position. Determine the subsequent sliding motion of the object. The coefficient of friction between the object at the horizontal surface is μ .

FIGURE 19.16 An object sliding against Coulomb friction.

Solution

Note that, when the object moves to the left, the frictional force, μmg acts to the right, and *vice versa*. Now, consider the first cycle of motion, starting from rest with $x = x_0$ moving to the left, coming to rest with the spring compressed and then moving to the right.

First Half Cycle (Moving to Left)

The equation of motion is

$$m\ddot{x} = -kx + \mu mg \quad (i)$$

or

$$\ddot{x} + \omega_n^2 x = \mu g \quad (ii)$$

where $\omega_n = \sqrt{k/m}$ is the undamped material frequency. Equation ii has a homogeneous solution of

$$x_h = A_1 \sin(\omega_n t) + A_2 \cos(\omega_n t) \quad (iii)$$

and a particular solution of

$$x_p = \frac{\mu g}{\omega_n^2} \quad (iv)$$

Hence, the total solution is

$$x = A_1 \sin(\omega_n t) + A_2 \cos(\omega_n t) + \frac{\mu g}{\omega_n^2} \quad (v)$$

Using the initial conditions $x = x_0$ and $\dot{x} = 0$ at $t = 0$, we get $A_1 = 0$ and $A_2 = x_0 - (\mu g/\omega_n^2)$. Hence, Equation v becomes

$$x = \left(x_0 - \frac{\mu g}{\omega_n^2}\right) \cos(\omega_n t) + \frac{\mu g}{\omega_n^2} \quad (vi)$$

At the end of this half cycle we have $\dot{x} = 0$ or $\sin \omega_n t = 0$. Hence the corresponding time is $t = \pi/\omega_n$. Substituting this in Equation vi, the corresponding position of the object

is (note: $\cos \pi = -1$)

$$x_{l1} = -\left(x_0 - \frac{2\mu g}{\omega_n^2}\right) \quad (\text{vii})$$

Second Half Cycle (Moving to Right)

The equation of motion is

$$m\ddot{x} = -kx - \mu mg \quad (\text{viii})$$

or

$$\ddot{x} + \omega_n^2 x = -\mu g \quad (\text{ix})$$

The corresponding response is given by

$$x = B_1 \sin(\omega_n t) + B_2 \cos(\omega_n t) - \frac{\mu g}{\omega_n^2} \quad (\text{x})$$

Using the initial conditions $x = -(x_0 - (2\mu g/\omega_n^2))$ and $\dot{x} = 0$ at $t = \pi/\omega_n$, we get $B_1 = 0$ and $B_2 = x_0 - (3\mu g/\omega_n^2)$. Hence, Equation x becomes

$$x = \left(x_0 - \frac{3\mu g}{\omega_n^2}\right) \cos(\omega_n t) - \frac{\mu g}{\omega_n^2} \quad (\text{xi})$$

The object will come to rest ($\dot{x} = 0$) next at $t = 2\pi/\omega_n$, hence the position of the object at the end of the present half cycle would be

$$x_1 = x_0 - \frac{4\mu g}{\omega_n^2} \quad (\text{xii})$$

The response for the next cycle is determined by substituting x_1 as given by Equation xii with Equation vi for the left motion and with Equation xi for the right motion. Then, we can express the general response as

$$\text{left motion in cycle } i: x = [x_0 - (4i - 3)\Delta] \cos \omega_n t + \Delta \quad (\text{xiii})$$

$$\text{right motion in cycle } i: x = [x_0 - (4i - 1)\Delta] \cos \omega_n t - \Delta \quad (\text{xiv})$$

where

$$\Delta = \frac{\mu g}{\omega_n^2} \quad (\text{xv})$$

Note that the amplitude of the harmonic part of the response should be positive for that half cycle of motion to be possible. Hence, we must have

$$x_0 > (4i - 3)\Delta \text{ for left motion in cycle } i$$

$$x_0 > (4i - 1)\Delta \text{ for right motion in cycle } i$$

Also note from Equation xiii and Equation xiv that the equilibrium position for the left motion is $+\Delta$ and for the right motion is $-\Delta$. A typical response curve is sketched in [Figure 19.17](#).

19.5.1 Friction in Rotational Interfaces

Friction in gear transmissions, rotary bearings, and other rotary joints has a somewhat similar behavior. Of course, the friction characteristics will depend on the nature of the devices and also the loading conditions, but, experiments have shown that the frictional behavior of these devices may be represented by the interface damping model given here. Typically, experimental results are presented as

FIGURE 19.17 A typical cyclic response under Coulomb friction.

FIGURE 19.18 Frictional characteristics of a pair of spur gears.

curves of coefficient of friction (frictional force/normal force) vs. relative velocity of the two sliding surfaces. In the case of rotary bearings, the rotational speed of the shaft is used as the relative velocity, while for gears; the pitch line velocity is used. Experimental results for a pair of spur gears are shown in Figure 19.18.

What is interesting to notice from the result is the fact that, for this type of rotational device, the damping behavior may be approximated by two straight line segments in the velocity–friction plane; the first segment having a sharp negative slope and the second segment having a moderate positive slope that represents the equivalent viscous damping constant, as shown in Figure 19.19.

FIGURE 19.19 A friction model for rotatory devices.

19.5.2 Instability

Unstable behavior or self-excited vibrations, such as stick–slip and chatter, that are exhibited by interacting devices such as metal removing tools (e.g., lathes, drills, and milling machines) may be easily

explained using the interface damping model. In particular, it is noted that the model has a region of negative slope (or negative damping constant), which corresponds to low relative velocities, and a region of positive slope, which corresponds to high relative velocities. Consider the single-DoF model:

$$m\ddot{x} + b\dot{x} + kx = 0 \quad (19.109)$$

without an external excitation force. Initially the velocity is $\dot{x} = 0$. But, in this region, the damping constant, b , will be negative and hence the system will be unstable. Hence, a slight disturbance will result in a steadily increasing response. Subsequently, \dot{x} will increase above the critical velocity where b will be positive and the system will be stable. As a result, the response will steadily decrease. This growing and decaying cycle will be repeated at a frequency that primarily depends on the inertia and stiffness parameters (m and k) of the system. Chatter is caused in this manner in interfaced devices.

Summary

This introductory chapter synthesizes the many, though largely disjointed attributes of friction as they relate to damping. Among other means, events selected from the history of physics are used to show that damping models have suffered from the inability of physicists to describe friction from first principles. To support fundamental arguments on which the chapter is based, evidence is provided for a claim that important nonlinear properties have been mostly missing from classical damping models. The chapter illustrates how the mechanisms of internal friction responsible for hysteretic damping in solids can lead to serious errors of interpretation. Such is the case even though hysteretic damping often masquerades as a linear phenomenon. One attempt to correct common model deficiencies is the author's work toward a "universal damping model," that is described in Section 20.17. Section 20.17 is developed in a "canonical" damping form. It shows the value of a direct, as opposed to an indirect, involvement of energy in model development. To keep a better perspective on how the treatment of damping is likely to evolve in the future, the last section of the chapter addresses some of the remarkable complexities of damping that are only beginning to be discovered. The manner in which technology has played a role in some of these discoveries is addressed in [Chapter 21](#).

20.1 Preface

The sheer volume of published material on the subject is a testament to the difficulty of selecting topics for inclusion in a chapter on damping. Viscoelasticity alone is the basis for several voluminous engineering handbooks. The present chapter is purposely different from similarly titled chapters of other reference books. There is little repetition of well-known and proven classical methods, for which the reader is referred to excellent other sources, such as de Silva (2000) and [Chapter 19](#) of the present handbook. They provide solution techniques for many of the routine problems of engineering. The goal of the present chapter is to provide assistance with problems that are not routine, problems that are being encountered more frequently as technology advances. It is thought that this goal is best served by revisiting fundamental issues of the physics responsible for damping.

Once a multibody system has come to steady state, its damping treatment can be far less formidable than its description during approach to steady state. When dealing with limit cycles involving aeroelasticity and joints in helicopters, nonlinearity has a profound influence on the transient behavior. Attempts to model it have been largely unsuccessful, forcing the empirical selection of elastomers to reduce the vibration. (In the old days hydraulic dampers were used; Hodges 2003). At a much lower level

of sophistication, our understanding is quite limited on some common phenomena, such as the negative damping character of sound generated by a violin or a clarinet. Historically, when technology “hit the wall” because of too much theoretical handwaving, it became apparent that fundamental assumptions needed to be examined. In physics, a complete alteration of conventional wisdom was sometimes necessary, one of the best examples being the events that gave birth to quantum mechanics. Hopefully, from the multitude of seemingly disparate (but assumed by the author to be connected) observations which follow, the purpose for the architecture of this chapter can be partially realized. The enormous complexity of damping in general makes it unrealistic to hope for complete success.

Physics played a prominent role in developing the classical foundations of damping, starting in the 19th century. Subsequently, engineers uncovered many features of the subject that physicists never even thought about. In recent years, however, physics has been circumstantially forced to reconsider damping fundamentals. With the advent of personal computing, and an increased awareness of the importance of nonlinearity, new discoveries point to serious limitations of the classical foundation. The field of mechanics was severely limited until it began tackling problems of nonlinearity (not of damping type), and became concerned with previously ignored features giving unique system properties. Just as these unique properties could only be solved by techniques more sophisticated than the equations of linear type, there is mounting evidence that nonlinear damping may be the key to understanding some bewildering engineering cases.

It is important to try to identify the major mechanisms responsible for energy dissipation. This is easier said than done, since a host of different friction processes are usually at work. Moreover, the description of friction from first principles remains a daunting task. Thus we are forced to work with phenomenological models. There are also conflicts of nomenclature, with a given word meaning two different things from one profession to another. Thus, much of this chapter will attempt to define carefully terms while focusing on the physics, the treatment of which follows naturally along the lines of historical developments.

Engineers tend to be interested in higher frequencies and higher amplitudes of vibration than are scientists. A perfect damping model would be unconcerned with such differences of application; however, such a model is far from being realized. Because small-amplitude, long-period (low and slow) oscillations provide a valuable means for studying many processes of damping in general, much of this chapter focuses in that direction.

From the multitude of choices available to writers on the subject of damping, this author has selected a single (hopefully) unifying theme — nonlinear damping, especially as found in low and slow oscillations. Because it is a field still in its infancy, many of the ideas that follow are more speculative than one would prefer; however, they deserve discussion because of their perceived importance. To this author’s knowledge, damping has not been previously treated in the manner of this chapter. Concerning the earliest relevant paper (Peters, 2001a, 2001b), the following was indicated by oft-cited Prof. A.V. Granato: “I don’t know of anyone thinking about internal friction along the lines you have mentioned.”

There are two important elements to the unifying theme of nonlinear dissipation: (i) the influence of nonlinear damping on multibody systems in their approach to steady state, and (ii) the close connection between damping and mechanical noise. When vibration decay is not exponential because of nonlinearity, there are significant ramifications and they are only beginning to be appreciated.

The novel features of this chapter are possible because of dramatic improvements in both sensing and data collection/analysis in the last decade. Demonstrating that a decay is not purely exponential requires both (i) a good linear sensor and (ii) the means to study readily long-time records when the damping is small (high Q). The first prerequisite has been met through the use of this author’s patented fully differential capacitive sensor. The second has been realized with the availability of good, inexpensive analog-to-digital (A/D) converters having user-friendly, yet powerful Windows-based software. In addition to the “preview” software that comes with Dataq’s A/D converter, a proven means for identifying nonexponential decay has been the analysis of records imported to Microsoft Excel. Details of these novel methods will be provided in the various sections that follow.

There are many examples in the engineering literature of nonlinear damping; even Coulomb damping is nonlinear because the friction force involves the algebraic sign of the velocity rather than the velocity itself, as in linear viscous damping. What has been realized for the first time in the course of writing this chapter is the following. As will be shown in the subsequent material, a decay process is not usually a pure exponential. Whatever the reason for a pure exponential, whether fundamentally linear (viscous) or nonlinear (hysteretic present model), the quality factor Q for such a pure exponential decay is constant. When there is a second mechanism, such as amplitude-dependent damping (even if it is the only mechanism), the Q now becomes time dependent. This is significant to mode coupling for the following reason. When a pair of modes couple because of elastic nonlinearity (a process that is impossible assuming linear dynamics), the strength of the coupling is proportional to the product of the individual amplitudes of the pair.

Consequently, variability in Q can influence the evolution to steady state. It is a factor in determining which modes ultimately survive and/or dominate. Moreover, the distribution of the modes which remain depends on initial conditions, including the intensity of excitation.

Long ago, musicians learned to deal with nonlinearity, due in part to properties of the ear that are responsible for aural harmonics. A pair of purely harmonic signals can beat in the ear to produce a “sound” that does not exist when sensed with a linear detector. For example, consider a strong and undistorted 500 Hz signal sounded simultaneously with a pure 1003-Hz sound. The ear will hear a 3-Hz beat due to the superposition of the ear’s aural second harmonic of the first with the fundamental of the second. However, there’s more to this story. Conductors call for *fortissimo* and *pianissimo* sounds, not only because of the ear’s nonlinearity, but also because of nonlinearities inherent to musical instruments. For example, it is easy with a good microphone and LabView ([see Appendix 15A](#)) to demonstrate that the timbre of stringed instruments is intensity dependent. Not only is the mix of harmonics, as displayed in a fast Fourier transform (FFT) power spectrum, different according to volume, but their distribution also changes with time.

Noise is not typically treated in an engineering discussion of damping; however, mechanical noise is an important part of the technical material included in this chapter. Believing that there is a great deal of connectivity among vibration, damping, and noise, evidence will be provided in support of a premise — that the most important and least understood form of internal mechanical damping (material = hysteretic = “universal”) is closely allied with the most important and least understood form of noise ($1/f$ = flicker = pink). If this premise is true, then the foundations of damping physics need reconstruction on several counts. Evidence in support of the premise will be provided through tidbits of experimental discoveries from a host of independent investigations. It is hoped that the unusual and lengthy introduction that follows will be beneficial in this regard. Historical elements serve to synthesize the many parts and are offered without apology. Following the introduction, some practical and novel equations of damping will eventually be provided. Even if readers find little identification with the philosophies that birthed them, it is hoped they will at least carefully examine the equations that are presented here in Section 20.17 for the first time.

20.2 Introduction

20.2.1 General Considerations of Damping

The etymology of the word “damping” is difficult to determine. It is obviously allied with the word damper, commonly defined as a “device that decreases the amplitude of electronic, mechanical, aerodynamic or acoustical oscillations,” used for centuries, for example, to describe the sound attenuator pedal on the piano. Perhaps the German word *dampfen* (to choke) has had an influence in the evolution of the word. One can only wonder if water, as a moistening agent, played any role. Certainly, liquid water is important to some cases of energy dissipation in oscillators. Moreover, friction determined by the viscosity of a fluid (gas or liquid) is an important type of damping. A curious piece of history, in the

celebrated work of Stokes, is why his expression “index of friction” did not take precedence over our modern word, viscosity. Peculiar terminology is also encountered to describe damping, such as the engineering device known as a dashpot, which is a mechanical damper. The vibrating part is attached to a piston that moves in a liquid-filled chamber.

We will see that the number of adjectives used to describe various types of damping is extensive. This multiplicity of terms to describe the loss of oscillatory energy to heat is no doubt an indicator of the complexity of damping phenomena in general. We will attempt (i) to identify similarities and differences among various types of damping, while (ii) explaining some of the physics responsible for the characteristics observed. Conceptual ideas and techniques of both theory and experiment will be provided, targeting the lowest level of sophistication for which semimeaningful results can be obtained. The reader should be aware that a “grand-unified” theory of damping does not exist, nor is it likely that one will ever be created.

Damping causes a portion of the energy of an oscillator, otherwise periodically exchanged between potential and kinetic forms, to be irreversibly converted to heat, sometimes by way of acoustical noise. Whether by suitable choice of materials during design of passive equipment, or by using feedback in active control of a sophisticated system, control of damping is important since mechanical vibrations can be detrimental or even catastrophic. An oft-quoted example of catastrophe is the Tacoma Narrows bridge, which collapsed in high winds on November 7, 1940. Like the vibration of a clarinet reed, this disaster is probably best described by the term negative damping, which can drive parametric oscillations.

The optimal amount of damping for a given system might fall anywhere in a wide range from great to extremely small, depending on system needs. The engineering world frequently wants oscillations to be as close to critically damped as possible. Physics experiments, such as those searching for the elusive gravitational wave (centered at the Laser Interferometer Gravitational Observatories, or Laser Interferometer Gravitational Wave Observatories [LIGO], in the United States; GEO600 in Germany [involving the British]; VIRGO in Italy [with the French], and TAMA in Japan), want damping in some of their components to be as small as possible. Frequency standards the world over require very small damping to insure high precision for timekeeping.

For the specific components of a system, a successful design frequently requires identification of the specific mechanisms primarily responsible for the dissipation of energy. Even after identifying the dominant sources, the theoretical difficulty of their treatment can also range from great to small, depending on the type of damping. For dashpot fluid damping, adequate models have existed for decades. For material damping, on the other hand, theories of internal friction are numerous and largely lacking in self-consistency.

The fundamental mechanisms responsible for damping are in most cases nonlinear; however, the oscillator's motion can itself be approximated in many cases by a linear second-order differential equation. If the potential energy is quadratic in the displacement, then the undamped linear equation of motion is that of the simple harmonic oscillator, because its solution is a combination of the sine and cosine (harmonic) functions. This undamped equation comprises the sum of two terms, one being a displacement and the other term an acceleration. The constant parameter multiplying each term of the pair depends on the nature of the system. For example, in the case of a mass–spring oscillator, the acceleration is multiplied by the mass, and the displacement by the spring constant. Thus, the equation corresponds to Newton's Second Law applied to a Hooke's Law (idealized) spring. In an electronic L–C oscillator, the “displacement” corresponds to the charge on the capacitor (divided by C) and the “acceleration” corresponds to the second time derivative of the capacitor's charge (multiplied by inductance L).

The usual means to describe damping, which is always present with oscillation, is to add a velocity term to the aforementioned displacement and acceleration. Although the damping could derive from several causes, there is usually a single dominant process. For example, the damping of current in a series-connected resistor, inductor, capacitor (RLC) circuit may depend mostly on Joule heating in the resistor R , in spite of the fact that there must also be energy loss in the form of radiation. Thus, the equation of motion includes a first-time derivative of the capacitor's charge (current) multiplied by R , in accord with Ohm's law.

Whether radiation is important for damping of the RLC circuit depends on the amount of coupling to the environment. If the circuit communicates with a final amplifier connected to an antenna, then radiation may become more important than Joule losses. The frequency of oscillation is a key parameter in this case, and also for damping problems in general. Unfortunately for some common systems, theoretical efforts to account properly for the effects of frequency have proven largely unsuccessful — except for models of phenomenological type developed by empiricism.

20.2.2 Specific Considerations

The mass–spring oscillator is the textbook example of harmonic motion, for which one of the most sophisticated mechanical oscillators ever built is the LaCoste version of vertical seismometer. Significant portions of the experimental data presented in this chapter were generated with an instrument designed around the LaCoste zero-length spring (LaCoste, 1934). The instrument used for this data collection was part of the World Wide Standardized Seismograph Network (WWSSN) during the 1960s. The spring of this seismometer is responsible for hysteretic damping of the instrument, rather than viscous damping as commonly assumed. Contrary to popular belief, air damping is not important for this seismograph at its nominal operating period, which is typically greater than 15 sec. Since every long-period pendulum apparently exhibits similar behavior, we thus find strong synergetic evidence in support of an old (mostly unheeded) claim that hysteretic damping (friction force independent of frequency) is universal (Kimball and Lovell, 1927). Their claim in 1927 to have discovered a universal form of internal friction (damping) is strengthened since the same behavior is seen in three distinctly different systems: (i) a mass–spring oscillator (as demonstrated by Gunar Streckeisen, details given later); (ii) a pendulum whose restoration depends on the Earth’s gravitational field (demonstrated by several independent groups); and (iii) a rotating rod strained by a transverse deflection (1927 experiments of Kimball and Lovell).

The assumption of universality for hysteretic damping is a key point of this chapter. It will be shown that the damping of even a vibrating gas column (Ruchhardt’s experiment to measure the ratio of heat capacities) is likely also hysteretic. The models that are described represent a departure from common theories of damping. Interestingly, the author’s model has similarities to ordinary sliding friction, as given to us by Charles Augustin Coulomb. It effectively modifies the Coulomb coefficient of kinetic friction to yield an effective energy-dependent internal friction coefficient. The energy dependence is necessary to obtain exponential decay, as opposed to the linear decay of Coulomb damping. Just as with conventional Coulomb damping, its form is nonlinear, involving the algebraic sign of the velocity. We will see that the damping capacity predicted by the model permits an equivalent viscous form. Yet the underlying physics is related to creep of secondary type as opposed to the primary creep of viscoelasticity.

It is this author’s opinion that much of the existing theory of damping is not the best means for modeling dissipation. The difficulties arise from approximating oscillator decay with linear mathematics. Although most individuals recognize the oft-stated caveat that viscous damping is an approximation to the actual physics of dissipation, they do not recognize some of the many serious limitations of the approximation. The situation is similar to the place in which we found ourselves at the beginning of the era labeled “deterministic chaos.” The “butterfly effect” (Lorenz, 1972) has radically altered the thinking of many, but only in relationship to large-amplitude motions of a pendulum, where the instrument is no longer isochronous because of nonlinearity. As an archetype of chaos, the pendulum must be rigid and capable of “winding” (displacement greater than π) before chaos is possible. Nonlinearity is a prerequisite for the chaos, but it is not sufficient, since there are many examples of highly nonlinear but nonchaotic motions. For example, amplitude jumps of nonlinear oscillators, during a frequency sweep of an external drive, have been known for many years. They were observed before chaos was recognized, in systems like the Duffing and Van der Pol oscillators. Yet chaos, with its sensitive dependence on initial conditions (responsible for the butterfly effect), was not contemplated at the time. As with most significant advances, Lorenz’s discovery was by accident, as he modeled convection in the atmosphere. The author’s confrontation with complexity that derives from mesoscale structures in metals was likewise unexpected. “Strange phenomena” (as Richard Feynman would probably have labeled them)

were encountered while using his patented fully differential capacitive sensor to study various mechanical systems, mainly oscillators.

As with chaos, the pendulum may ultimately serve as an archetype of complexity. When operated at low energy, especially through a combination of long period and small amplitude, the free decay of the physical pendulum departs radically from the predictions based on linear equations of motion. Such complexity can be easily demonstrated when the pendulum is fabricated from soft alloy metals. For example, Figure 20.1 illustrates the decay of a rod pendulum constructed with ordinary (heavy-gauge lead–tin) solder of the type used for joining electrical conductors (Peters, 2002a, 2002b, 2002c).

The “jerkiness” (discontinuities) in the record of Figure 20.1 is in no way related to amplitude jumps of the type previously mentioned; rather, these are jumps of the Portevin–Le Chatelier (PLC) type (Portevin and Le Chatelier, 1923). They are a fundamental, yet “dirty” phenomenon that physics has chosen for decades to try and ignore (even though materials science and engineering took early note of the PLC effect). The most obvious and profound thing that can be said about Figure 20.1 is the following: the presence of PLC jerkiness means that the concept of a potential energy function is not really valid, since the requirement for its definition is that a closed integral of the force with respect to displacement must vanish.

No matter the form of hysteresis, which is the cause for damping, it disallows the curl of the force to be zero, so that potential energy is never formally meaningful for a macroscopic oscillator (since there is always damping). In those cases where the damping is essentially continuous (not true for the example of Figure 20.1), the assumption of a potential energy function retains some computational meaning. For oscillators influenced by the PLC effect, this is no longer true. The resulting properties are important to a variety of technology issues, such as sensor performance, since noise is no longer the simple thermal form predicted by the fluctuation–dissipation theorem (used to characterize white, i.e., Johnson, noise).

FIGURE 20.1 Free-decay of a rod pendulum fabricated from solder.

Practical means for dealing with systems influenced by “stiction” have been known by engineers for decades. Because of metastabilities in the assumed potential function, the system is prone to latching (stuck in a localized potential well). One means for mastering the metastabilities (unstuck the part designed to move) is to “dither” the system. The process has become more sophisticated in the last decade, which saw a major growth of interest in stochastic resonance. In the definition by Bulsara and Gammaitoni (1996):

A stochastic resonance is a phenomenon in which a nonlinear system is subjected to a periodic modulated signal so weak as to be normally undetectable, but it becomes detectable due to resonance between the weak deterministic signal and stochastic noise.

The phenomenon is related to dithering (Gammaitoni, 1995). It is a case where the signal-to-noise ratio (SNR) can be increased by the counterintuitive act of raising the level of noise. Such a gain in SNR is not possible with a harmonic potential.

In recent studies of granular materials, “tapping” has become a popular means to study behavior that violates the fundamental theorem of calculus. Years ago, this author used tapping as a means to accelerate creep in wires under tension. Evidently, hammering the table on which the extensometer rested caused vibrational excitations of the wire that stimulated length changes of discontinuous PLC type. Because of the broad spectral character of an impulse, various eigenmodes of the wire (see [Chapter 4](#)) could be thus readily excited. After “hammering-down” under load, a silver wire could by this same means be stimulated, after partial load removal, to exhibit length contractions. Since the total number of atoms is fixed, the process must involve exchange of atoms between the surface of the sample and its volume.

Extensometer studies of wires at elevated temperature have also displayed strange behavior. A polycrystalline silver wire of diameter 0.1 mm and approximate length 30 cm was found to exhibit large fluctuations when heated in air to within 100 K of its melting point, using a vertical furnace (Peters, 1993a, 1993b). The large fluctuation in length at these temperatures (reminiscent of critical phenomena and visible to the naked eye) may be associated with oxide states of the metal, since the experiments were not performed in vacuum. When cycled in temperature, fluctuations in the length of a gold wire were found to exhibit dramatic hysteresis. With influence from Prof. Tom Erber of Illinois Tech University, it was postulated in (Peters, 1993a) that there may be some mesoscale quantization of fundamental type responsible for the thermal hysteresis (hysteron).

Mechanical hysteresis resulting from mesoanelastic defect structures is evidently ubiquitous. Piezotranslators, which are used as actuators in atomic force microscopes and other nanotechnology applications, are afflicted with high levels of hysteresis when operating open loop. This behavior is consistent with the anomalously large damping that was observed with a pendulum (reported elsewhere in this document) in which there was a steel/PZT interface for the knife-edge.

Even the common strain gauge exhibits complex hysteresis behavior. The normally large hysteresis that is observed in preliminary cycling of a gauge is typically reduced by significant amounts after repeated cycling, a type of work hardening (if strained well below failure limits). It should be noted that the hysteresis of all the discussions in this chapter is not to be confused with backlash (as in a gear train).

All of these experiments are in keeping with the premise that *mesoanelastic complexity* determines the nature of hysteretic damping. It is seen that there are a plethora of examples where strain (and thus damping) of a sample is not simple, is not smooth, but more like the complex behavior of granular materials. In the case of polycrystalline metals, the same grains that are made visible by methods of acid etching decoration are evidently responsible for mesoscale (nonsmooth) internal friction damping. To assume that damping is quantal at the atomic scale, rather than the mesoscale, is without experimental justification. Nevertheless, this is a popular assumption with which estimates of the noise floor of an instrument such as a seismometer is estimated, to calculate SNR.

20.2.3 The Pendulum as an Instrument for the Study of Material Damping

Because of its early contributions to physics, which in those days was called natural philosophy, one might be tempted to believe that the pendulum is only important to (i) the history of science or (ii) teaching of fundamental principles. A single observation should be sufficient to resist this temptation — (as already noted) the pendulum has in the last 30 years become the primary archetype for the new science of chaos. Additionally, many of the data sets of this document, which show significant and previously unpublished results, were generated with a pendulum.

To a student of elementary physics, the choice of a pendulum may seem unsophisticated. Yet, to the author, who has spent 15 intense years trying to understand harmonic oscillators, the pendulum is the most versatile instrument with which to understand damping. It has been central to the development of science in general. It was studied by Galileo, Huygens, Newton, Hooke, and all the best-known scientists of the Renaissance period. It served to establish collision laws, conservation laws, the nature of Earth's gravitational field and, most of all, it was the basis for Newton's two-body central force theory. This theory was foundational to the development of classical mechanics, which is central to all of physics and engineering. Historian Richard Westfall has remarked: "Without the pendulum, there would be no Principia" (Westfall, 1990).

In 1850, Sir George Gabriel Stokes published a foundational paper (Stokes, 1850). His treatment of pendulum damping permitted the understanding, decades later, of a number of important phenomena in physics and engineering. For example, his studies were foundational to the Navier–Stokes equations of fluid mechanics. Moreover, viscous flow known as Stokes' Law was the basis for Millikan's famous oil drop experiment that determined the charge of the electron.

Stokes noted in his paper that, "... pendulum observations may justly be ranked among those most distinguished by modern exactness." He also noted

The present paper contains one or two applications of the theory of internal friction to problems which are of some interest, but which do not relate to pendulums. ... the resistance thus determined proves to be proportional, for a given fluid and a given velocity, not to the surface, but to the radius of the sphere. ... Since the index of friction of air is known from pendulum experiments, we may easily calculate the terminal velocity of a globule [water] of given size. ... The pendulum thus, in addition to its other uses, affords us some interesting information relating to the department of meteorology.

The last statement of this quotation speaks to some of the errors in the "common theory" of his day. In similar manner, some of the common-to-physics damping models of today are erroneously applied. Those who hold the viscous damping linear model in unwarranted regard, fail to recognize the limitations under which it is valid. There are frequent misapplications for reason of experimental deficiencies. We can all profit by taking seriously the following well-known words of Kelvin:

When you can measure what you are speaking about, and express it in numbers, you know something about it. But when you cannot measure it, when you cannot express it in numbers, your knowledge is of a meager and unsatisfactory kind. It may be the beginning of knowledge but you have scarcely in your thoughts advanced to the state of science. William Thomson, Lord Kelvin (1824 to 1907)

Simple (viscous) flow of the Stokes' Law type is possible only according to the restrictive conditions that Stokes spelled out in his paper. We now specify those conditions for viscous flow according to the nondimensional parameter given us late in the 19th century by Osborne Reynolds. Specifically, Stokes' Law is valid only for $Re = \rho v L / \eta < 60$ (approximately, for spheres); where ρ is the density of the retarding fluid, v is the speed of the object relative to the fluid, L is a characteristic dimension of the object, and η is the viscosity of the fluid. The requirement is not generally met for oscillators, and recent experiments have shown that contributions to the damping from air drag proportional to the square of

the velocity cannot generally be ignored (Nelson and Olssen, 1986). This is just one example of how two or more damping types must sometimes be folded into an adequate model of dissipation. A novel method for combining all the common forms of damping in one mathematical expression is provided in this document. Additionally, it is shown how to calculate analytically the history of the amplitude of free-decay for such cases.

Considering the importance of Stokes' work, it is surprising that some of his requests for further experiments were apparently never seriously considered. On page 75 of his paper, one reads the following: "Moreover, experiments on the decrement of the arc of vibration are almost wholly wanting." Having noted this, Stokes appealed to experimentalists to generate such data. In the 19th century, collecting the data he requested would have been labor-intensive and therefore the experiments were probably never attempted. Sensors and data processing of the modern age now make them straightforward, but the pendulum has by now been viewed by too many as a relic rather than the important instrument described by Stokes. Much of the author's efforts have been directed at showing that the pendulum is still an important research instrument. For example, one physical pendulum of simple design was the basis for the generalized model of damping (modified Coulomb) that is here presented. Another has been used to illustrate surprisingly rich complexities of the motion that results from the ubiquitous defects of its structure (Peters 2002a, 2002b, 2002c). Thus studying the complex motions of "low and slow" physical pendula could yield significant new insight into the defect properties of materials — a field where relatively little first-principles progress has been made.

20.2.4 "Plenty of Room at the Bottom"

Richard Feynman gave a now-famous talk in 1959 titled, "There's plenty of room at the bottom" (presented at the American Physical Society's annual meeting at CalTech). Drawing on observations from biology, he spoke of a solid-state physics world involving "... strange phenomena that occur in complex situations." In the 44 years since Feynman's prophetic comments, there have been spectacular achievements in very large-scale integrated (VLSI) electronics, microelectromechanical systems (MEMS), and even nanotechnology. Progress in the mechanical (including sensor) realm has been much slower than in electronics; consequently, our present processing power far exceeds our acquisition (and actuator) capabilities.

One of the major obstacles to miniaturization involves dramatic change to physical properties that can occur as the size of a system shrinks below the mesoscale toward the atomic. For example, VLSI electronics is already beginning to be impacted by quantum properties of the atom, as component size continues to decrease in accord with Moore's law (Moore, 1965). Among other things, Feynman predicted that lubrication would no longer be "classical" at such a scale. On a related note, a paper by Nobel Laureate Edward M. Purcell (Purcell, 1977) draws a striking contrast between our macroscopic world and that of micro-organisms. At low Reynolds number, inertia becomes unimportant, and mechanics is dominated by viscous effects. The adoption of a new paradigm will be necessary for engineers to deal with these differences.

In the article "Plenty of room indeed" (Roukes, 2001), it is noted that there is an anticipated "dark side" of efforts to build truly useful micro- and nano-sized devices. Gaseous atoms and molecules constantly adsorb and desorb from device surfaces. This process is known to exchange momentum with the surface, even permitting scientific study of the gas–solid interface (Peters, 1990). The smaller the device, the less stable it will be because of adsorption/desorption. As Roukes has noted, this instability may pose a real disadvantage in various futuristic electromechanical signal-processing applications (Cleland and Roukes, 2002).

There is direct evidence, provided in the present chapter, that we need to be more concerned with noise: (i) the evacuated pendulum where it is speculated that outgassing influenced its free-decay, and (ii) the seismometer free-decay that showed both amplitude and phase noise and evidence for nonlinear damping. Concerning (i), when the vacuum chamber pressure is reduced, the preexisting steady state (normal rate balance between adsorption and desorption) becomes disturbed, so that there is a complex

emission of gases from the surface of the pendulum. The emission is not likely to be spatially uniform, but more like the jets seen on Halley's comet when photographed by the Giotto spacecraft in 1986. In case (ii), the noise is seen to derive from mesoanelastic complexity of the structure of the pendulum itself rather than involving gases.

Miniaturized devices have the potential to serve as on-chip clocks, and the importance of phase noise to clocks is well documented. There is another, more subtle issue that points out the importance of phase noise. One of the best means for improving SNR is the technique of phase-sensitive detection, first employed by Robert Dicke at Princeton to improve solar experiments. The performance of miniaturized electromechanical sensors using "lock-in" amplifier methods may be influenced significantly by mechanical phase noise.

Phase noise of miniaturized devices is still mostly speculative. In addition to the mechanism just mentioned (adsorption/desorption), there is the matter that constitutes the theme of this chapter, defect organization. It is not possible to grow materials without dislocations and/or other disturbances to crystalline order, such as vacancies, interstitials, or substitutional impurities. Thus, "when mother nature fills the vacuum she abhors, she rarely does so with perfection."

Long before defects organize to the point of incipient failure (at much larger strains), they still influence vibration. They may even be a primary source of $1/f$ noise. Electronic noise of $1/f$ type is known to involve defects by means of trapping states, and these states derive from crystalline defects sometimes involving the surface. The interaction of the surface and the volume of a solid are important. For example, consider pure copper single crystals of the type used by the author in his doctoral work. A practical joke suggested by Vic Pare (that we never conducted because of the cost of these samples) would be to have a 98-lb weakling bend one by hand, then ask an NFL linebacker to straighten it back out! The striking irreversibility is the result of work hardening as dislocations develop at the surface and propagate into the bulk where they entangle.

In the case of polycrystalline materials, the memory features of hysteresis may be important according to the method of their fabrication. Wires are typically produced by pulling through successively smaller dies. This "swaging" may be conducive to the exchange of monolayer groups of atoms between the volume and the surface during fluctuation length changes. The fluctuation–dissipation theorem does not hold or, if it does, only in terms of larger entities than the atom. Thus, there are many yet-to-be-quantified elements of noise in the vibration of miniaturized devices. Feynman was right when he spoke of strange phenomena of the solid state.

Technology of the future is expected to be confronted increasingly with damping problems that must address issues of scaling — to deal with some factors discussed in this chapter, which, to the author's knowledge, have not been previously published. Until small (MEMS) oscillators become more common to the engineering world, we must study the mechanisms responsible for their damping by other than traditional means. One approach is similar to experimental techniques for the verification of the kinetic theory of gases. As noted by Present in his textbook (Present, 1958), there are two ways that Brownian motion can be studied: either (i) with small objects and an unsophisticated detector, or (ii) with larger objects and a very sensitive detector. It is the latter that provided some of our present knowledge of damping at the mesoscale. The fully differential capacitive transducer, whose patent label is "symmetric differential capacitive" (SDC), is a robust new technology that is sensitive, linear, and user-friendly (Peters, 1993a, 1993b). As with other sensitive detectors that have been used to predict the properties of small objects by studying larger ones, small-energy studies of various macroscopic pendula are demonstrating some of the "strange phenomena" of complex type predicted by Feynman.

From the author's perspective, we of the physics community have been guilty of two significant errors: (i) oversimplification of many problems by assuming a linear equation of motion based on viscous damping, and (ii) losing sight of fundamental issues by working with inappropriate, overly complicated damping models. The goal of this chapter is to assist progress toward a healthier balance between these extremes. It is hoped that readers will be thus better equipped to identify, and then dismantle, some of the impediments to the development of future technologies.

20.3 Background

20.3.1 Terminology

The large number of mechanisms capable of energy dissipation has resulted in a host of adjectives to describe damping phenomena in mechanical systems. They include (nonexhaustive list): viscous, eddy current, Coulomb, sliding, friction, structural, fluid, thermoelastic, internal friction, viscoelastic, material, solid, phonon–phonon, phonon–electron, and hysteretic. For present purposes, damping types will be grouped according to one of the following three categories: (i) fluid (including viscous), (ii) Coulomb, and (iii) hysteretic. Although hysteretic damping has come to be associated in engineering circles with a particular form of material damping in solids, it should be noted that all forms of damping involve hysteresis (for which the Greek meaning of the word is “to come late”). In a plot of periodic stress vs. strain, which is a straight line for displacements of a nondissipative, idealized substance, hysteresis causes the line to open into a loop. The size of the loop — more specifically the area inside this hysteresis loop — is a measure of the amount of nonrecoverable work done per cycle because of the damping. An actual force of friction is not readily recognizable in those cases that are labeled “internal friction.” The word friction is used in a generic sense, meaning any process responsible for conversion of the oscillator’s coherent motion into incoherent thermal activity.

With each of viscous, eddy current, and Coulomb damping, a force external to the oscillator is responsible for the dissipation of energy. The external force is associated respectively with (i) laminar fluid flow, (ii) induced currents, and (iii) surface friction. The surface friction case is not necessarily the trivial textbook presentation involving a coefficient of kinetic friction and a normal force. The cases just mentioned, along with thermoelastic damping; which is of internal rather than external origin, are much easier to treat theoretically than other cases. Viscous damping and eddy current damping (over the full range of the motion) are adequately described by a velocity term, which yields a linear equation of motion. Coulomb damping, however, is not proportional to velocity, but rather depends only on the algebraic sign of the velocity. The equation of motion is consequently nonlinear. Additionally, and unlike most other forms, Coulomb damping is not exponential. The turning points lie along a straight line when the motion is plotted vs. time. Similarly, if eddy current damping exists only over a small part of the motion, the decay is linear rather than exponential (Singh et al., 2002).

20.3.2 General Technical Features

Historically, viscous damping has been the model of choice because the resulting equation of motion is mathematically attractive and, for the RLC circuit, the form is appropriate. For mechanical oscillators, it is not generally appropriate, since viscous damping amounts to some part of the system moving in an external Newtonian fluid that removes energy because of a friction force that is proportional to velocity.

The defects responsible for material damping, such as dislocations, are also responsible for creep, so that high strength and high damping tend to be incompatible attributes. Magnesium alloys tend to be better than many other metals in this regard. Hardness of a material is neither a prerequisite for toughness nor for small damping, as recognized by those familiar with the mechanical properties of cast iron.

On a different scale, defects determine “how things break”; concerning which Marder and Fineberg have stated the following:

the strength of solids calculated from an excessively idealized starting point comes out completely wrong; it is not determined by performance under ideal conditions, but instead by the survival of the most vulnerable spot under the most adverse of conditions. (Marder and Fineberg, 1996)

Three famous scientists are primarily responsible for the highly popular viscous damping model of the simple harmonic oscillator; they are Lord Kelvin (Thomson and Tait, 1873), G.G. Stokes and

H.A. Lorentz. Stokes is best known for his equations of fluid dynamics that also include the name Navier. Stokes' Law, which describes the terminal velocity of a raindrop, was developed through his treatment of the damping of a pendulum. Not only does his law provide a basis for the simplest approximation for damping of a macroscopic oscillator, it was used by Robert Millikan to determine the charge of the electron. It should be noted that harmonic oscillation in a fluid (even at low Reynolds number) is much more complicated than steady-flow viscous friction. This topic is treated in [Chapter 21, Section 21.9](#).

The first individual to use the term "simple harmonic oscillator" was probably Lord Kelvin. Such an oscillator is a key tool of experimental physics and also the foundation for much of theoretical physics. It is the basis for communication via electromagnetic waves and even esoteric theories of superfluids and superconductors.

Much of the underpinnings of theory involving harmonic oscillation derive from the work of Hendrik Anton Lorentz (1853–1928). Lorentz is well known for a variety of classical physics contributions, such as (i) the transformation of special relativity associated with Einstein and (ii) the force law for the acceleration of charged particles, both of which bear his name. Before the existence of electrons was proved, Lorentz proposed that light waves were due to oscillations of an electric charge in the atom. For his development of a mathematical theory of the electron, he received the Nobel Prize in 1902. The importance of his contributions is further realized by noting that it is common practice to describe the lineshape of atomic spectra by the term Lorentzian. The Lorentzian is equivalent to the resonance response of the driven viscous-damped simple harmonic oscillator.

It is easy to show how resistance in an electric network is responsible for damping; however, it is a challenge to understand anelastic processes of mechanical damping in terms of viscosity. From comments of his Ph.D. dissertation, it has been said that even Lorentz was never apparently satisfied with the velocity damping term in his equation — not knowing just how to relate it to the underlying physics. It is also clear from Stokes' paper that he recognized the need for caution in the use of his law of viscous friction. It appears that both Lorentz and Stokes were very careful compared with the carelessness with which the viscous model has been employed by many individuals in recent years.

The failure of solids influenced by "hysteretic" damping to be adequately described by the methods of viscoelasticity is not widely appreciated. It is unfortunate that too few people have expanded their view of damping to include other important types, such as derive from the anelasticity of solids. It is important in this work to recognize some subtle differences, for example, inelastic (not elastic) is not to be equated with anelastic (other than elastic).

20.3.3 Active vs. Passive Damping

With improvements in cost/performance of electronics, active damping is increasingly popular. Using force-feedback with integration/differentiation circuitry (opamps), a mechanical oscillator can sometimes be tailored for a specific purpose. A sophisticated example of this technology is the broad-band seismometer that began to replace earlier version (passive) instruments roughly 35 years ago. The Sprengnether–LaCoste spring instrument that was used for some of the experiments reported in this document has been superseded by force-feedback units such as the Streckeisen STS-1 and STS-2.

In lieu of feedback, another way actively to influence the damping of a mechanical oscillator is to connect the sensor to an amplifier having a negative input resistance. The seismometers marketed by Lennartz Electronics in Germany use this in a patented technique to improve the performance of ordinary, off-the-shelf electrodynamic geophones.

Active damping depends on the nature of the transfer function of the composite system (electronics plus mechanical). The characteristics of the transfer function are determined by the location of its poles and zeros in the complex plane. Seismometers operate nominally near 0.707 of critical damping. This is done for two reasons: (i) the instrument is easier to adjust and (ii) the interpretation of earthquake records is simpler. Of course, to increase damping is to decrease sensitivity because of the fluctuation–dissipation theorem.

The force-feedback technique is not practical for some situations, regardless of cost. Additionally, it must be recognized that the method is not the answer to all problems, since electronics cannot compensate for a poor mechanical design. The description of commercial products is in some cases highly exaggerated, giving the impression that almost any sensor can perform flawlessly in this manner. Some accelerometers have employed dithering to offset the effects of “stiction” in bearings. The dithering was necessary because the potential energy function is not truly harmonic, being afflicted with the consequences of nonlinear damping. Even with sensing schemes that do not use a bearing, the effects of nonlinearity persist. In “Seismic Sensors and their Calibration” (Bormann and Bergmann, 2002), Erhard Wielandt, in talking about transient disturbances in the spring of a seismometer, says the following:

Most new seismometers produce spontaneous transient disturbances, quasi-miniature earthquakes caused by stress in the mechanical components.

In other words, internal friction from defects at the mesoscale cause behavior that is in some ways similar to ordinary sliding friction, where the static coefficient is greater than the kinetic coefficient. The postulate of Bantel and Newman is consistent with this idea (Bantel and Newman, 2000) when they refer to their observations as being consistent with a “stick–slip” model of internal friction.

It is seen then that one must use a detector that responds faithfully to the signal around which the servo-network functions. The linearity and sensitivity of that sensor are of paramount importance, since the basis for force-feedback design is linear system theory. For some less-challenging cases, the design approach is straightforward, since software packages like MATLAB (see Chapter 6 and Appendix 32A) have built in functions to describe behavior.

20.3.4 Magnetorheological Damping

A recent approach to damping control, that is quite different from the servo-networks mentioned above, is one that uses an magnetorheological (MR) fluid. It takes advantage of the large variation in viscosity of certain compound fluids according to the size of an applied magnetic field. J. David Carlson (Carlson, 2002) describes how an MR sponge damper is activated during the spin cycle of a washing machine to keep it from “walking out of the room.” The peak in the Lorentzian (resonance response) of the machine is shown in his article to be substantially lowered by supplying current to the electromagnet of the damper.

20.3.5 Portevin–LeChatelier Effect

Physics, engineering, geoscience, and mathematics have all contributed greatly to a better understanding of damping phenomena; however, there has been little cross-discipline exchange of ideas and lessons learned. Some of the impediments to strong interdisciplinary programs derive from (i) the complexity of damping problems in general and (ii) the tendency for physics and mathematics research to be, on the one hand, less pragmatic and, on the other hand, highly specialized — focused on specific energy dissipation mechanisms. A good example of (i) involves the PLC effect, discovered in 1923. Why physics mostly ignored this early example of “dirty science” by two of their own number is not easily understood, although the birthing of quantum mechanics around this time may have been a factor. Had history turned in a different direction, perhaps we would already be able to explain from first principles the most important, but still barely understood, form of noise known as $1/f$, or flicker, or pink noise. Even though R.B. Johnson (well known for his discovery of white electronics noise in a resistor) was one of the first to see this form of noise, it still is not explained from first principles — although recent discoveries suggest an intimate connection with fractal geometry involving self-similarity. Such geometry is associated with the mesoscale of materials where the grain, rather than the atom, is the basic element of statistical mechanics.

For alloys, the PLC effect appears to be, in some ways, what the Barkhausen effect is to magnetic systems. In the case of ferrous materials, the noise which derives from the mesoscale has long been recognized; however, similar noise of mechanical type has not been seriously studied. This oversight is even more puzzling when one considers the admonition by G. Venkataraman, as recorded in the

proceedings of a Fermi conference, for scientists to get involved in what he felt should become an important new field (Venkataraman, 1982).

20.3.6 Noise

Noise is purposely discussed in this chapter (also see the chapters in Section IX of this handbook) because it has been a, largely, missing component of efforts to understand the physics of damping. A feel for the importance of noise to damping research is to be gleaned from a comment by Kip Thorne in his foreword to the English translation of a book by V.B. Braginsky et al. (1985). Mainly because of instrumental needs of the Laser Interferometer Gravitational Wave Observatories (LIGO), Thorne writes,

The central problem of such experiments is to construct an oscillator that is as perfectly simple harmonic as possible, and the largest obstacle to such construction is the oscillator's dissipation. If dissipation were perfectly smooth, it would not be much of an obstacle, but the fluctuation–dissipation theorem of statistical mechanics guarantees that any dissipation is accompanied by fluctuating forces. The stronger the dissipation, the larger the fluctuating forces, and the more seriously they mask the signals that the experimenter seeks to detect.

This comment by Thorne suggests a frequently important impediment to dialogue between engineering and physics — concern for different issues. LIGO is trying to minimize damping, whereas many engineering problems are concerned with just the opposite — making the damping as large as possible without compromising strength. More detailed discussions of noise are provided later.

20.3.7 Viscoelasticity

Within the world of polymers, damping is frequently described by the expression “viscoelasticity.” This word, around which handbooks have been written (e.g., Lakes, 1998), is a combination of the two words, viscous and elastic. We like to think of ideal fluids as being viscous in the manner described by Newton. Likewise, ideal solids that obey Hooke's Law (stress proportional to strain) are described as elastic. Unfortunately, nature contains neither ideal solids nor ideal fluids. Real springs do not obey Hooke's Law, but rather are influenced by “anelasticity” (other than elastic) which gives rise to hysteresis in the stress–strain relationship. Real fluids usually have some (if not near total) degree of non-Newtonian character. Thus an envisioned “mixing” of fluid-like and solid-like character has dominated the thinking of those who, through the decades, attempted to develop theoretical models of damping.

It should be noted that the springs and dashpots used in models of viscoelasticity do not actually exist. They serve as a phenomenological means for (hopefully) understanding the elementary processes which their arrangement is designed to mimic. Consider, for example, high polymers, in which the interwoven structure of the long-chain molecules is one of extensive mechanical interference. (One popular visualization is that of an entanglement of a huge number of long, writhing snakes.) An increase of temperature is met with overall length reduction (negative temperature coefficient of expansion for the so-called entropy spring), which stands in stark contrast with metals. Such behavior is clearly important to damping since, as noted by Gross years ago, “...thermal movement interferes with the orientation and disorientation of the molecules and ultimately causes delay in the expansion and contraction of the specimen” (Gross, 1952).

20.3.8 Memory Effects

In this same article, Gross is one of the first to mention “memory” properties of creep. He describes a by-then old demonstration in which a “firmly suspended metal or plastic wire is twisted first in one direction for a long time and then in the other direction for a short time. Immediately after release,

the deflection will be in the direction of the last twisting, but it decreases rapidly. Presently, a reversal occurs, and the wire begins to turn in the other direction, corresponding to the first twisting — the memory of the recent short-term handling has been obliterated by that of the more remote but longer lasting and therefore more impressive one!” Perhaps this old demonstration (sometimes today called the anelastic after-effect) is not so startling to those familiar with more modern shape-memory-alloys, which are expected by many to play increasingly important roles in the applied science of damping.

20.3.9 Early History of Viscoelasticity

Those who provided seminal influence in the development of the theories of viscoelasticity during the 19th century were some of the most famous names in physics, like Maxwell and Kelvin. Maxwell is best known for the electromagnetic equations associated with his name. He is far less known for two other significant contributions: (i) kinetic theory of gases and (ii) viscoelasticity — both of which are important to theories of oscillator damping. Maxwell’s interest in the problem of viscoelasticity is first documented in a paper during his teen years, titled “The Equilibrium of Elastic Solids.” Through his development with Boltzmann of the kinetic theory of gases, Maxwell showed a counterintuitive property of the viscosity of a gas. The viscosity does not decrease significantly as the pressure is reduced, until the mean free path between collisions of the molecules begins to approach dimensions of the chamber holding the gas. Important even to modern innovations such as MEMS oscillators, his surprising prediction was quickly verified by experiment. Maxwell’s model of viscoelasticity combines a purely elastic spring with a purely viscous dashpot (fluid damper in which the friction force is proportional to the velocity).

Kelvin, probably the first to include a viscous damping term in the equation of motion of the simple harmonic oscillator, developed a similar model of viscoelasticity. Each of the two models is usually represented in literature (without original references) as containing a single spring and a single dashpot. They differ in that one connects the pair in series (Maxwell), while the other connects them in parallel (Kelvin–Voigt).

Both the Maxwell model and the Kelvin–Voigt model have been found by engineers to be less useful than the standard linear model (SLM) of anelasticity, largely advanced in the 20th century by Clarence Zener (Zener, 1948). In the three-component Zener model, a spring is connected in series with a parallel combination of spring and dashpot. Curiously, Zener is widely associated with electronics because of the common diode named after him, but fewer people know of his work in anelasticity. No doubt, his understanding of anelasticity helped him to better understand the complex processes at work in his diode.

20.3.10 Creep

The prevailing models of anelasticity appear frequently in the literature, but mostly in relationship to primary creep. Some of the papers exceptional to this rule are those by Berdichevsky (Berdichevsky et al., 1997). Recent work of a more heuristic type has shown that the equations of viscoelasticity are also able to accommodate secondary creep, in which the decay of strain rate with time has disappeared (Peters, 2001a, 2001b).

The importance of creep (and relaxation) physics to damping warrants some discussion. When a sample is subjected to a constant stress, the strain evolves through three phases of creep: (i) primary, (ii) secondary, and (iii) tertiary. An example of the first two of these phases is shown in [Figure 20.2](#).

In the primary stage, the sample is deformed by anelastic processes involving defects of the crystalline structure. Influence of the disordering mechanisms is progressively reduced as the sample undergoes work hardening (such as pinning of dislocations). Work hardening would result in a purely exponential creep, in the absence of thermal effects which strive to undo the hardening (via diffusion processes). (At zero Kelvin, the creep would eventually cease, if described by a single time constant.) In the secondary stage, a balance between work hardening and thermal softening is attained, in which the strain vs. time has converted from exponential to linear. This balance cannot continue forever, if the stress is larger than

FIGURE 20.2 Example of creep in the spring of a vertical seismometer.

a threshold associated with failure (the elastic limit), and thus a final complex fracture of the sample finally occurs as the sample passes through the tertiary stage. Although one might want to divorce the issues of tertiary creep from considerations of damping, there is clearly a link between damping and failure, involving defects. We will return to this point later.

In Figure 20.2, creep resulted from the instrument having been severely disturbed (relocated accidentally by plumbers working in the building). As with any long-period mechanical oscillator, it is necessary for this instrument to stabilize after a major rebalancing. Primary creep is seen to have endured for about 5 h and what is labeled secondary creep in the figure does not continue indefinitely with the implied constant rate. Thus, the instrument will typically stabilize after one or several days, when the period of oscillation is of the order of 20 sec.

The total amount of creep in Figure 20.2 deserves mention. In the indicated 14.2 h, the mass of the seismometer moved a vertical distance of only 0.25 mm, which can be ascertained from the ordinate axis using the sensor calibration constant of 2000 V/m.

20.3.11 Stretched Exponentials

Systems typically demonstrate a more complex behavior than can be simply described by the SLM of viscoelasticity. In 1847, Kohlrausch (1847) discovered that the decay of the residual charge on a glass Leyden jar followed a *stretched exponential* law. The functional form that he discovered is often associated with a broad distribution of relaxation times, and has been found to describe a remarkably wide range of physical processes. To describe damping that is of the stretched exponential type, Kelvin chains or Maxwell elements in parallel have been used. Although an improved fit to the data can be realized by this means, the technique results in a high number of material parameters which have to be identified.

20.3.12 Fractional Calculus

A promising alternative to multiexponential decay models is to replace classical rheological dashpots by “fractional” elements. It is claimed that with only a few parameters, material behavior of many viscoelastic media can be described over large ranges of time and/or frequency (Hilfer, 2000). It may also be possible with fractional derivatives to treat the discontinuities that are sometimes present in decay (Asa, 1996). The disadvantages of fractional calculus are (i) the increasing computational/storage requirements and (ii) the esoteric mathematics, which is alien to the training of most.

20.3.13 Modified Coulomb Damping Model

Published here formally for the first time, with details described later, the heuristic “modified Coulomb” model is an alternative to all of the aforementioned damping models. It is thought to be closely related to secondary creep (Peters, 2001a, 2001b) and (like fractional calculus) accomplishes good fits with a small number of parameters. Developed from energy considerations, its equations are expressed in canonical form involving the quality factor Q .

20.3.14 Relaxation

Formally, relaxation is defined by the behavior of a sample subjected to a constant strain. Because of the mechanisms just discussed in relationship to creep, the stress relaxes exponentially toward zero (in the simplest approximation). In practice, the definition just given can be misleading since the word relaxation is used to describe a host of processes in which some quantity decays exponentially in time — for example, the relaxation of strain at constant stress in the Kelvin–Voigt model of viscoelasticity.

Some of the viscoelastic models using dashpots and springs have been quite successful in the limited regime of their applicability. For example, the Zener (Debye) model, which will be discussed again later, has been used for years to describe a particular form of damping in solids, which derives from relaxations associated with dislocations. Seminal experimental work of this type was conducted by Berry and Nowick in the 1950s (Berry and Norwich, 1958). A well-known theoretical model to describe dislocation damping was developed by Granato and Lucke (Granato and Lucke, 1956). The Granato model is that of a vibrating string (bowed Frank–Read source), where the end points of the “string” are points on the dislocation line that have been pinned. Recent theory shows that the Granato model is not always adequate; that “dislocation interactions may alter substantially the dislocation component of the spectrum observed during internal friction experiments.” (Greaney et al., 2002) (excellent introductory material on this subject is to be found online at <http://mid-ohio.mse.berkeley.edu/alex/rachel/rachel/rachel.html>).

Bordoni (1954) performed experiments that led to his observation of relaxation-type internal friction processes where the acoustic attenuation is seen to peak at certain temperatures. The so-called Bordoni peaks occur at low temperatures or at ultrasonic frequencies. These losses, which are maximum when dislocation relaxations can take place in step with the driving frequency, were first observed in the FCC metals: lead, copper, aluminum, and silver.

Dislocation damping as just described is characterized by a temperature-dependent relaxation that exhibits Arrhenius behavior. By plotting the internal friction vs. reciprocal temperature, one may estimate the activation energy of the process responsible for the damping. The following quotation from the introduction of the Berry paper assists in defining some of the many expressions used historically to describe damping:

Internal friction is often loosely described as the ability of a solid to damp out vibrations. More strictly, it is a measure of the vibrational energy dissipated by the operation of specific mechanisms within the solid. Internal friction arises even at the smallest stress levels if Hooke’s Law does not properly describe the static stress–strain curve of the material. The nonelastic behavior which Zener has called anelasticity arises when the strain in the material is dependent on variables other than stress.

In a recent private communication, Prof. Granato has indicated the following:

Dislocations do follow the Zener (or Debye) form fairly well for the damping, but not for the elastic modulus. This is because the response to a stress is given as a Fourier series. The higher order terms in the series have little effect on the damping, but a strong effect on the modulus at high frequencies. This makes the modulus fall off more slowly than with the reciprocal frequency.

20.4 Hysteresis — More Details

Hysteresis and creep are common to many systems, such as electromechanical actuators, especially when used at high drive levels. Their transfer function is influenced by “rate-independent memory effects.” The state of the actuator depends not only on the present value of the input signal but also on the nature of their past amplitudes, especially the extremum values, but not on rates of the past (Visintin, 1996). This statement is in support of the author’s secondary creep model of hysteretic damping, where the amplitude of the previous turning point determines the magnitude of the internal friction force for the half-cycle that follows. One of the most dramatic examples of a memory effect is the demonstration mentioned above, by Gross in the 1950s, concerning a twisted wire.

Damping complexities derive from the defect structures that are found in real materials and which give rise to hysteresis, which in the Greek language means to “come late.” Although, almost everybody seems to appreciate magnetic hysteresis at some level, too few individuals (at least in physics) have been trained in the mechanisms of mechanical hysteresis responsible for damping. Dislocations, for example, are usually an add-on chapter to a solid-state physics text — even though they are known to be indispensable with regard to actual, as opposed to idealized, properties of materials.

In the case of ferrous materials, the magnetization of a specimen lags behind the field generated by an electric current, to which the specimen responds. In the case of real springs that do not obey Hooke’s Law $F = -kx$, the displacement x lags behind the spring’s restoring force F . It is convenient to express the resulting hysteresis in terms of “intrinsic” variables instead of x and F . Thus, the strain ϵ (fractional change in the spring’s length if it were a wire in tension) lags the stress σ (force per unit area). Usually in engineering practice, the stress is reckoned with respect to the external force (negative of the spring F), so that the equivalent to Hooke’s Law is $\sigma = E\epsilon$, where E is an elastic modulus descriptive of the material from which the spring is fabricated. In the case of a straight wire, E would be Young’s modulus but, for coil springs, E is determined primarily by the shear modulus. Some of the ways in which hysteresis can be represented for a freely decaying oscillator are shown in Figure 20.3. The generalized coordinate q would be spring elongation for the force case shown, or it would be strain when the ordinate quantity is stress. The graph of velocity vs. displacement is referred to as a phase-space plot. It is commonly used in describing chaotic systems and, if “strobed” at the frequency of the oscillator, becomes the Poincaré section. Notice that the circulation is of opposite sign when using external force as opposed to spring force, in addition to the curves occupying different quadrants. It is important to recognize this difference, particularly when discussing negative damping where the oscillation amplitude builds in time, as illustrated in the right hand part of the figure.

Although not very common in mechanical oscillators, it is possible to realize negative damping. One example is that of an optically driven pendulum, because of the LiF crystals that were placed in its support structure (containing a high density of color centers produced by radiation) (Coy and Molnar, 1997). An interesting feature of this pendulum was its unwillingness to entrain to the driving laser.

FIGURE 20.3 Three different ways to represent hysteresis damping for an oscillator in free-decay. Cases of both positive and negative damping are illustrated.

There are also examples of negative damping from aerodynamics, such as flutter. Since buildings and bridges can experience negative damping in catastrophic manner (Tacoma Narrows bridge as an example), it is not a subject to be ignored.

Another example of hysteresis that is very much like negative damping (though not usually labeled as such) is to be found in a heat engine (Peters, 2001a, 2001b). The motion is not simple harmonic; rather, the speed with which the hysteresis curve is traversed (in pressure vs. volume) increases as the size of the hysteresis loop increases. A larger loop (greater work done by the gas) results in higher revolutions per minute (r/min) of the engine as opposed to a larger amplitude of the motion at constant period. The gas pressure provides a force similar to the Hooke's Law force of the spring in a mass/spring oscillator.

It is usually assumed that hysteresis loops are "smooth," which is not necessarily true. For example, in the case of magnetic hysteresis, the "jerky" parts known as the Barkhausen effect (Barkhausen, 1919) are well known. The equivalent jerky behavior in metallic alloys is known as the Portevin–LeChatelier effect (Portevin and LeChatelier, 1923). Although we have historically avoided these cases that appear to be intractable in a mathematics sense (not obeying the fundamental theorem of calculus), their presence is undeniable testimony of the complex nature of hysteresis.

20.5 Damping Models

20.5.1 Viscous Damped Harmonic Oscillator

As first seen by students in a textbook, the equation of motion for a damped, driven harmonic oscillator is likely as follows:

$$m\ddot{x} + c\dot{x} + kx = F(t) \quad (20.1)$$

where m is mass, k is spring constant, c is a "constant" of viscous damping, and $F(t)$ is the external force driving the oscillator. It is convenient to work with a coefficient of performance, or quality factor Q , and rewrite Equation 20.1 in canonical form as

$$\ddot{x} + \frac{\omega_0}{Q}\dot{x} + \omega_0^2 x = \omega_0^2 \frac{F(t)}{k}, \text{ with } \omega_0^2 = \frac{k}{m} \quad (20.2)$$

For $F(t) = 0$ and an assumed solution, $x = A \exp(p\theta)$ with $\theta = \omega_0 t$, the differential equation becomes algebraic (quadratic) in $x(\theta)$, with the roots given by

$$p = -\frac{1}{2Q} \pm \sqrt{\frac{1}{4Q^2} - 1} \quad (20.3)$$

Depending on the value of Q , the motion is either overdamped (nonoscillatory), critically damped, or underdamped. Here, we restrict our attention to the last case corresponding to $Q > 1/2$, in which the square root term of Equation 20.3 is imaginary. Moreover, we are mostly concerned with systems in which $Q \gg 1$.

20.5.2 Definition of Q

The quality factor Q is in general defined as 2π times the ratio of the energy of the oscillator to the energy lost to friction per cycle. For viscous damping (and hysteretic damping, later discussed), the Q is independent of the amplitude of oscillation. For other types of damping, we will see that the Q is not constant. In the case of the viscous damped oscillator, $Q = \omega_0/2\beta$ where β appears in the solution as an amplitude decay "constant." The parameter β is not really constant, as discussed in [Chapter 21, Section 21.9](#).

$$x = A e^{-\beta t} e^{\pm j\omega_0 t \sqrt{1-1/4Q^2}} \quad (20.4)$$

Since x is real, we use the real part of Equation 20.4 and employ Euler's identity to obtain

$$x(t) = A e^{-\beta t} \cos(\omega_1 t - \phi), \text{ with } \omega_1 = \sqrt{\omega_0^2 - \beta^2} \quad (20.5)$$

where ϕ is a constant determined by the initial conditions.

20.5.3 Damping “Redshift”

It is seen that the frequency of oscillation depends on the damping constant, β ; however, the fractional change $\Delta\omega/\omega_0$ is almost always negligibly small. For example, the reduction in frequency is only 1.4% for $Q = 3$, which is close to critical damping of $Q = 0.5$. At these small values of Q , the lifetime of a freely decaying oscillator is so short that the frequency is ill-defined because of the Heisenberg uncertainty principle. At larger Q s, where the frequency is well-defined, the shift is negligible; i.e., at $Q = 100$, the fractional shift is only 1.3×10^{-5} . In the case of internal friction (hysteretic) damping, there is no redshift anyway because the oscillator is isochronous.

20.5.4 Driven System

When $F(t)$ is not zero, but rather corresponds to harmonic drive at angular frequency ω and amplitude A , the response involves the sum of Equation 20.5 (transient) and a particular solution (steady state).

$$x_p(t) = A_p \cos(\omega t - \delta), \text{ with } \delta = \tan^{-1} \left(\frac{2\omega\beta}{\omega_0^2 - \omega^2} \right). \quad (20.6)$$

The system resonates (amplitude a maximum) at $\omega \rightarrow \omega_R = \sqrt{\omega_0^2 - 2\beta^2}$, and the variation of the amplitude with ω at steady state at any drive frequency ω is given by

$$A_p = \frac{A\omega^2}{\sqrt{(\omega_0^2 - \omega^2)^2 + 4\omega^2\beta^2}} \quad (20.7)$$

The resonance response curve described by Equation 20.7 is called the Lorentzian. More frequently in physics, the term is used to describe pressure-broadened line widths (Milonni and Eberly, 1988). As noted previously, Lorentz was never apparently content with the damping term, $2\beta \, dx/dt$. In his Ph.D. dissertation concerned with the damping of electron oscillators through electromagnetic radiation, he was not able to satisfactorily describe the damping from first principles. Although we might be tempted to say that this failure derived from his classical (prequantum mechanics) description of the problem, such a viewpoint is an oversimplification.

20.5.5 Damping Capacity

20.5.5.1 Viscous Damping

The loss per cycle, called the damping capacity, is computed for the viscous damping case as follows (per unit mass):

$$d_v = 2\beta \oint \dot{x} \, dx = 2\beta\omega A^2 \int_0^{2\pi} \sin^2 \theta \, d\theta = 2\pi\beta\omega A^2 \quad (20.8)$$

where A is the amplitude of the oscillation. Because the total energy per unit mass is $\omega^2 A^2/2$, we see that $Q = \omega/(2\beta)$.

20.5.5.2 Hysteretic Damping, Linear Approximation

The equation of motion in this case is given by $m\ddot{x} + h/\omega\dot{x} + kx = 0$ where h is a constant. The energy loss in one cycle is given by

$$-\Delta E = md_h = \frac{h}{\omega} \int_0^T \dot{x}^2 dt = \frac{h}{\omega} \omega A^2 \int_0^{2\pi} \cos^2 \theta d\theta = \pi h A^2 \rightarrow d_h = \frac{\pi}{m} h A^2 \quad (20.9)$$

so that $Q = m\omega^2/h$.

20.5.5.3 Hysteretic Damping, Modified Coulomb Model

The nonlinear equation of motion introduced in this chapter to describe hysteretic damping is as follows:

$$\ddot{x} + c\sqrt{\frac{2E}{k}} \text{sgn}(\dot{x}) + \omega^2 x = 0 = \ddot{x} + \frac{\pi\omega}{4Q_h} \sqrt{\omega^2 x^2 + \dot{x}^2} \text{sgn}(\dot{x}) + \omega^2 x = \ddot{x} + cA_{\text{prev}} \text{sgn}(\dot{x}) + \omega^2 x \quad (20.10)$$

where, in the last expression, the subscript “prev” implies amplitude at the last (previous) turning point of the motion. This particular form for the damping term (Peters, 2002a, 2002b, 2002c), thought to result from secondary as opposed to primary creep (Peters, 2001a, 2001b), is not as computationally useful as the middle expression involving the Q . The damping capacity is given by

$$-\Delta E = md_h = 4cmA \int_0^{\pi/2} A \cos \theta d\theta \rightarrow d_h = 4cA^2 \quad (20.11)$$

yielding $Q = \pi\omega^2/(4c)$, so that the constant in the nonlinear model is related to the linear approximation constant through

$$c = \pi h/(4m)$$

20.5.6 Coulomb Damping

One of the simplest friction models is that in which a Hooke’s Law spring is connected on one end to a mass that slides on a level table. The other end of the spring is connected to a stationary wall. The friction force of the mass against the table is of the type first described quantitatively by Charles Augustin Coulomb (1736–1806), although Leonardo da Vinci is probably the first to consider it scientifically. The equation of motion and its solution, for the free-decay of an oscillator damped by Coulomb friction, is given by

$$\begin{aligned} m\ddot{x} + f \text{sgn}(\dot{x}) + kx &= 0 \\ \text{Solution} & \\ x(t) &= [x_0 - (2n + 1)\Delta_x] \cos \omega t + (-1)^n \Delta_x \end{aligned} \quad (20.12)$$

The equation is nonlinear because of the sign of the velocity term, but it is easily integrated numerically; additionally, it is one of the few nonlinear equations for which an analytic solution is known and is given above (for more details, the reader is referred to Peters and Pritchett, 1997). The integer, n , specifies the number of half-cycle turning points from $t = 0$, and Δ_x is the decrement (linear, not logarithmic, having units of m) per half-cycle. There are occasions to use Equation 20.12; for example, problems in civil engineering where relative motion of members (slipping) occurs at a structural joint. The work against friction in one cycle can be obtained from energy considerations and is given by

$$f(4x_0 - 8\Delta_x) = \frac{1}{2} kx_0^2 - \frac{1}{2} k(x_0 - 4\Delta_x)^2 \quad (20.13)$$

which, for small decrement, yields

$$\Delta_x = \frac{f}{k} = \frac{f}{m\omega^2} \quad (20.14)$$

Damping characteristics for the models presently treated are summarized in Box 20.1.

Box 20.1

DAMPING CHARACTERISTICS

Type	Equation of Motion	Damping Capacity	Q
Viscous	$\ddot{x} + 2\beta\dot{x} + \omega_0^2x = 0$	$2\pi\beta\omega A^2m$	$\frac{\omega}{2\beta}$
Hysteretic (linear approximation)	$\ddot{x} + \frac{h}{m\omega}\dot{x} + \omega^2x = 0$	πhA^2	$\frac{m\omega^2}{h}$
Hysteretic (modified Coulomb)	$\ddot{x} + c_hA \operatorname{sgn}(\dot{x}) + \omega^2x = 0$	$4c_hA^2m$	$\frac{\pi\omega^2}{4c_h}$
Coulomb	$\ddot{x} + \frac{f}{m}\operatorname{sgn}(\dot{x}) + \omega^2x = 0$	$4fA$	$\frac{\pi m\omega^2A}{4f}$
Amplitude dependent	$\ddot{x} + c_fA^2 \operatorname{sgn}(\dot{x}) + \omega^2x = 0$	$4c_fA^3m$	$\frac{\pi\omega^2}{4c_fA}$

20.5.7 Thermoelastic Damping

A microphone with Labview was used to analyze vibratory data of an aluminum rod. A rod of 1 m length can be excited to ear-piercing intensities by holding it at its center between thumb and finger of one hand, and stroking along the length with the other hand that is coated with violin-bow rosin. The decay of this “singing rod”, which is a common part of physics demonstration equipment, was found to be in agreement with the following theoretical expression for thermoeleastic damping (Landau and Lifshitz, 1965):

$$\frac{1}{Q_{\text{Th.d}}} = \frac{\kappa T \alpha^2 \rho \omega}{9C^2}$$

(20.15)

where ω is the vibrational angular frequency, T is the temperature, ρ is the density of the bar, C is the heat capacity per unit volume, α is its thermal expansion coefficient, and κ is the thermal conductivity. The expression assumes adiabatic vibrations and there is no thermoelastic dissipation in pure shear oscillations (e.g., torsional oscillations of a bar) because the volume does not change and hence there is no local oscillation of the temperature. Notice, in particular, that the Q is inversely proportional to frequency, unlike viscous damping that is proportional to the frequency, or hysteretic damping that is proportional to the square of the frequency. Thermoelastic damping is important for high-frequency compressional oscillations in materials with significant thermal coefficients, and especially for metals because of their large thermal conductivity.

The demonstration of comparable behavior in polymers (entropy spring, but opposite sign compared with metals) is quite easy. Stretch a rubber band between the hands and immediately touch it to the forehead. The increase in temperature is easily sensed. Conversely, releasing the tension in the band cools it enough to be sensed by placing the band to a part of the face that is sensitive to temperature change. Equation 20.15 does not apply to polymers.

20.6 Measurements of Damping

20.6.1 Sensor Considerations

The challenge to any measurement is to accomplish the task without significantly altering the system under study (see Chapter 15). For measurements on mechanical oscillators of the type described in

this document, two types of sensor are generally superior to every other kind: (i) optical and (ii) capacitive. Optical sensors are probably the least perturbative but they do not readily yield themselves to large dynamic range with good linearity (and small quantization errors for digital type). Inductive sensors, such as the linear variable differential transformer (LVDT), are known from seismology to be inherently more noisy (up to 100 times) because of ferromagnetic granularity. Additionally, transformers are not amenable to miniaturization, and the components are inherently less stable. It is therefore a mystery why the widespread use of the fully differential inductive sensor (LVDT) continues when we have available the superior fully differential capacitive sensor, which is electrically equivalent (apart from its reactance type) and capable of miniaturization to the MEMS level. The challenge with really small capacitive sensors is the increase in output reactance of the device as they approach femtoFarad levels of individual capacitors.

All measurements reported in this document were taken with the fully differential unit whose patent name is “symmetric differential capacitive” (see Peters, 1993a, 1993b). It is especially useful for studying mechanical oscillators of macroscopic size and, morphed to various forms, it recently has found application in MEMS. It is capable of great sensitivity when configured in the form of an array, as shown in Figure 20.4.

Various lines in Figure 20.4 correspond to narrow insulator strips, such as the single vertical line in the set that connects to the amplifier. In the cross-connected static set, the plates labeled “1” are electrically distinct from the others labeled “2”. The total-plate arrangement constitutes a symmetric AC bridge, and the central position of the moving set ($x = 0$ as shown in the figure) corresponds to bridge balance with $V_0 = 0$. Displacement away from balance gives a voltage output that is linear between $-w/4$ and $w/4$, as illustrated in the graph at the bottom of Figure 20.4.

The oscillator frequency is typically tens of kHz, and the amplifier is of instrumentation type (Horowitz and Hill, 1989). Unlike a bridge null detector, the linear response through $x = 0$ is realized

FIGURE 20.4 Illustration of a fully differential capacitive transducer array. For clarity, the three electrode-sets are shown separated from their operating positions (parallel with a small separation gap, with the moving electrodes in the middle).

when synchronous detection is employed. This can be accomplished with a lock-in amplifier, but the most recent Cavendish balance to employ the sensor uses diodes (Tel-Atomic Inc., online at <http://www.telatomic.com/sdct1.html>).

A tutorial (“detailed explanation”) of the SDC sensor using diodes can also be found at this website.

In Figure 20.4, four individual SDC units have been shown connected in parallel. The total number, N , of individual units in an array depends on the characteristic width, w , for which the total range of detectable motion is $w/2$. If the requirement on range is small, then N can in principle be made very large, which is desirable for the following reason. The sensitivity of this position sensor is inversely proportional to w if output capacitance of the device is not a factor. As w is reduced, however, the degrading influence of increased output reactance (capacitive) is more significant than the improved sensitivity that would result if the sensor could be connected to an amplifier with infinite input impedance. Since the instrumentation amplifier’s input capacitance is not negligible, shrinking w is beneficial only if the output reactance can by some means be kept low. This is accomplished with the array of individual units. In principle, the output capacitance could be held reasonably constant as N approaches 100, by using photolithographic techniques and small spacing between the parallel electrodes. The concept has been deemed feasible because of existing technologies as well as the following: although not in the form of an array, Auburn University has fabricated a mesoscale accelerometer around the SDC sensor. The prototype was built on printed wire board (PWB) under U.S. Army contract (Dean, 2002).

No doubt the popular silicon-based MEMS accelerometers marketed by Analog Devices utilize the impedance advantages of an array, employing a large number of “fingers” in a force-feedback arrangement. Although employed mostly otherwise, the first case of a fully differential capacitive transducer using force-feedback was one based on simultaneous action of actuator and sensor functions in a single unit of nonlinear type (Peters et al., 1991).

20.6.2 Common-Mode Rejection

In attempts to measure damping, one can be confronted with difficulties of mode mixing. For example, the historical Cavendish experiment, using optical detection, has been traditionally difficult unless the instrument is placed in a very quiet location to avoid pendulous swinging of the boom. The high-frequency pendulous motion (of the order of 1 Hz) as a “noise” becomes superposed on the low-frequency torsional signal. The computerized Cavendish balance sold by Tel-Atomic overcomes this problem by means of a mechanical common-mode rejection feature. An SDC sensor placed near one boom end is connected in electrical phase opposition to a second SDC sensor placed near the other end of the boom. The boom itself serves as the moving electrode for both sensors. Neither sensor has a first-order response to boom motion parallel to its long axis. Pendulous motion perpendicular to the boom orientation is largely canceled.

20.6.3 Example of Viscous Damping

The aforementioned Sprengnether–LaCoste spring seismometer is well-suited to the demonstration of viscous damping, when damping is imposed in the following manner: the instrument was built with a Faraday Law (velocity) detector; i.e., a coil that moves with the mass of the instrument, in the field of a stationary magnet. As originally employed, the coil was connected to the amplifier of a recorder. In the present configuration, however, the velocity detector is not employed, since its sensitivity is severely limited at low frequencies. Instead, an SDC array of the type shown in Figure 20.4 is used to measure the position of the mass (a pair of lead weights, total mass 11 kg). If the instrument is operated with the coil open-circuit, there is no induced current. By connecting a resistor across the coil (through very fine copper wires that go to terminals on the case), mass motion induces a current. The induced current opposes the motion through Lenz’s Law, resulting in damping. The damping depends on the size of the

FIGURE 20.5 Examples of induced current damping of a vertical seismometer using two different resistors.

current and is thus an inverse function of the resistor's magnitude through Ohm's Law. The phenomenon is illustrated in Figure 20.5.

As compared with the "undamped" instrument, whose Q is approximately 80 at a period of 17 sec, it is seen that the addition of a 990-ohm resistor lowered the Q by more than an order of magnitude to 4.9. A 330-ohm resistor reduced it even further to 3.1. The amount of damping is also governed by the resistance of the coil winding, which is 480 ohm.

The envelopes that have been fitted to the decay curves were the basis for estimating the Q . The decay data were imported to Excel by first outputting the Dataq DI-154RS A/D generated record as a *.dat (CSV) file. The fits were produced by trial and error using the drag and autofill functions. Notice that the 990-ohm resistor (first) case is not as pure an exponential decay as the other case because of creep. The rate of creep is greater at large initial amplitudes of the motion.

20.6.4 Another Way to Measure Damping

Curve fitting (full nonlinear, in general) is the best way to estimate damping parameters, especially if the decay is not exponential. For more routine cases, simpler methods can be used. Among the host of ways that have been defined to specify the damping of an oscillator, one of the most common uses the logarithmic decrement. The solution to Equation 20.1 with zero right-hand side is given by

$$x(t) = x_0 e^{-\beta t} \cos(\omega t + \phi). \quad (20.16)$$

The full-cycle turning points, $x_N = x_0 e^{-\beta NT}$, with $N = 0, 1, 2, \dots$ can be used to compute the logarithmic decrement through

$$\beta T = \frac{1}{N} \ln \frac{x_0}{x_N} \quad (20.17)$$

Unfortunately, an estimate based on Equation 20.17 can be difficult due to the presence of either or both of two problems: (i) mean position offset in the decay record or (ii) asymmetry of the decay, where the turning points on one side of equilibrium decay at a different rate than those on the other side. Case (ii) occurs more often than one might expect; it is frequently a consequence of material complexity and not the result of nonlinearity in the electronics of the detector. It is important, however, to be sure that the detector is either linear or that corrections for the nonlinearity be utilized before estimating the damping.

A method to provide partial compensation uses half-cycle turning points $n = 2N$, and works with a minimum of three such points.

$$\beta T = -2 \ln[1 - (x_{n-1} - x_{n+1})/(x_{n-1} - x_n)] \quad (20.18)$$

Advantage is taken of random error reduction by using Equation 20.18 on a set of turning points (optimal number sometimes being about a dozen). The calculations are straightforward in a spreadsheet such as Excel by means of the autofill function.

20.7 Hysteretic Damping

20.7.1 Equivalent Viscous (Linear) Model

The few mechanical oscillators governed by Equation 20.1 tend to be those in which there is an external control, such as eddy current damping. For oscillators in which the damping derives from internal friction of its members, the following linear approximate form of the hysteretic damping model has been used:

$$m\ddot{x} + \frac{h}{\omega}\dot{x} + kx = F \quad (20.19)$$

It should be noted that hysteresis is the cause for all damping; however, engineers have come to use the term “hysteretic damping” for systems described by Equation 20.19. This equation differs in two important ways from Equation 20.1. For the viscous damped oscillator, Q is proportional to the frequency, but for the hysteretic damped oscillator, Q is proportional to the square of the frequency. Also, viscous damping changes the frequency of the oscillator, since $\omega_1 < \omega_0$ and, for resonance, the frequency is even lower. However, the hysteretic oscillator is isochronous, requiring only a single frequency $\omega = \sqrt{k/m} \rightarrow \omega_r$ to describe all features of the motion. For example, it is easy to show that the oscillator resonates at this frequency. Off resonance, the response is not the standard Lorentzian. To show this, assume steady state and use the phasor method given to us by Steinmetz, 1893 (complex exponential form for the variables); i.e., $F = F_0 e^{j\omega t}$ and $x = x_0 e^{j\omega t}$ to get the frequency transfer function

$$\frac{kx}{F} = \frac{1}{1 - \omega^2 \frac{m}{k} + j \frac{h}{k}} = \frac{1}{1 - r^2 + j\alpha} = Z, \text{ with } r = \frac{\omega}{\omega_r} \text{ and } \alpha = \frac{h}{k} = \frac{1}{Q} \quad (20.20)$$

for which the real and imaginary parts are given by

$$\text{Re } Z = \frac{1 - r^2}{(1 - r^2)^2 + \alpha^2}, \quad \text{Im } Z = \frac{-\alpha}{(1 - r^2)^2 + \alpha^2} \quad (20.21)$$

which is expressible in polar form as

$$Z = |Z| e^{j\delta}, \text{ where } |Z| = \frac{1}{\sqrt{(1 - r^2)^2 + \alpha^2}} \text{ and } \delta = -\tan^{-1} \frac{\alpha}{1 - r^2} \quad (20.22)$$

It is interesting to compare the steady-state response of the driven, hysteretic damped oscillator with that of the driven, viscous damped oscillator; i.e., Equation 20.22 compared with normalized Equation 20.7. A Bode plot comparison (log–log, for the amplitude case) is provided in [Figure 20.6](#). At small values of the damping parameter α (large Q), there is insignificant difference between the two cases. At large values, however, the difference is significant.

20.7.2 Examples from Experiment of Hysteretic Damping

The vertical seismometer that was used for several of the present studies is known to decay according to hysteretic damping. In Section 20.16.4 titled “Failure of Viscoelasticity”, details are provided of the work by Gunar Streckeisen (1974) that showed this to be true. Decay curves of the instrument are

FIGURE 20.6 Bode plot comparison of steady-state driven system with (i) hysteretic damping (dark curves) and (ii) viscous damping (light curves).

frequently a near-perfect exponential, once corrected for secular drift of the record. Sometimes, this drift is the result of creep in the spring of the instrument, but it may also be the result of other factors, such as (i) temperature change, or (ii) barometric pressure variation, or even (iii) tidal influence. The temperature sensitivity is due to the difference of thermal coefficients of the materials from which the instrument is constructed, and the pressure variation is a buoyancy effect. Tidal influence is the smallest of the three, which causes minute accelerations of the crust of the Earth with a period of about 12 h.

In the discussions which follow, two different decay records are provided. In both cases, the initial amplitude of oscillation is quite large, being a significant fraction of 1 mm, and the period for the two cases is different — the first case being 17 sec and the second one 21 sec. The first case time record, shown in Figure 20.7, contains 9800 points. Once a 12 $\mu\text{V/s}$ (upward) drift was removed, the decay (left curve) is seen to be “nearly textbook” exponential.

The adjective “nearly” is appropriate because there is a 12% difference in the decay constants defining the upper and lower turning points (0.0022 top, 0.0025 bottom), which were determined by trial and error “eyeball” exponential fits using Excel. In this author’s experience, such is the norm for virtually all mechanical oscillations; perfectly symmetric exponential decays have rarely been seen in the hundreds of cases studied.

FIGURE 20.7 Free-decay of a vertical seismometer due to hysteretic damping. The period of oscillation is 17 sec.

FIGURE 20.8 Free-decay of a seismometer due to hysteretic damping.

Because there are roughly 150 oscillations in the time record of Figure 20.7, it is not possible to resolve individual turning points of the motion, but the oscillations are very nearly that of a pure damped sinusoid, as noted from the right-side graph of the figure. This spectrum was generated with a 4096-point FFT, comprising the first 1090 sec of the time record. The second harmonic is the only distortion observed, and it is about 65 dB below the fundamental. For the case presented in Figure 20.7, $Q = 80$.

Another example of free-decay hysteretic damping is provided in Figure 20.8. As usual, the record was afflicted by drift, possibly from creep in the spring, in this case a constant rate of $60 \mu\text{V/s}$, as observed in the graph on the right. All of these graphs were produced with Excel, as noted earlier in the discussion of induced current damping. As with the decay curve of Figure 20.7, the creep-corrected graph on the left was generated by adding a secular term to the raw data. Once corrected, the decay is a near-perfect exponential of hysteretic type. We will see other examples (from pendulum studies) in which two damping mechanisms are simultaneously active in a decay.

The Q values corresponding to Figure 20.7 and Figure 20.8 are consistent with hysteretic damping; i.e., 80 for the 17-sec oscillation and 52 for the 21-sec oscillation. As noted elsewhere in this document, $Q\alpha\omega^2$ for hysteretic damping as opposed to an exponent of 1 for viscous damping. Of course, one must collect data over a very much larger range of frequencies to verify this, as was done by Streckeisen (1974).

20.8 Failure of the Common Theory

Many mechanical oscillator studies in decades past, mainly by engineers, have shown that the so-called decay constant β is proportional to ω^{-1} instead of being constant (e.g., Bert, 1973). The damping for these cases came to be called “material”, “structural”, or “hysteretic.” A common way to obtain the correct frequency dependence was to divide the velocity by frequency and call the result an “equivalent viscous” form of damping. The adjective “equivalent” draws attention to the fact that internal friction in a solid cannot really result from fluid effects. Moreover, elsewhere in this document, there is plenty of support for the position that the linear equations of viscous damping type cannot produce truly meaningful (predictive) models when doing modal analysis on multibody systems.

An important early work by Kimball and Lovell (1927) is evidently the first experiment to show that internal friction (“force”) of many solids is virtually independent of frequency. In other words, their elegant technique, in which a rotating rod is deflected by a transverse force, was the first to demonstrate the “universality” of hysteretic damping. Although both researchers were physicists at General Electric in the time of Steinmetz, few physicists of the 21st century know of this important work. As with the important contributions of Portevin and LeChatelier, their study of systems influenced by “dirty physics” was evidently ignored in favor of the “clean” new quantum mechanics of that era.

It is interesting that a bell made of lead does not tinkle at room temperature, but it can be made to do so at 77 K, by immersion in liquid nitrogen. This demonstration, which is often employed in physics “circuses,” shows clearly that the internal friction of lead at audio frequencies can be reduced substantially by lowering the temperature. An important lesson to be learned from these observations is that damping, in general, is a complex function of temperature, frequency, conductivity, ... (who knows where to terminate this list). Not only is a multitude of state variables necessary for a complete description of dissipation, but the previous history of stress–strain cycling may also be critical. Such is the nature of defect structures responsible for damping.

20.9 Air Influence

Even when operating an oscillator in high vacuum, there is a significant remanent damping that derives from internal friction. This fact is illustrated in Figure 20.9, which provides data for two different “simple” pendula. They are simple in the sense that the bob mass is concentrated near the bottom of the pendulum structure. In the figure, decay time (reciprocal of the decay constant, β) has been plotted against the natural log of the pressure in mtorr. Pressure reduction was done with a high-quality roughing pump, and the pressure was measured with (i) a mechanical gauge in the range $8 \text{ torr} < P < 760 \text{ torr}$ and (ii) a thermocouple vacuum gauge for $0 < P < 100 \text{ mtorr}$. In the range from 100 mtorr to 8 torr, the pressure could not be accurately measured with either of these gauges. Similarly, pressures below 1 mtorr could not be presently measured, but in similar other experiments with this pump, and using an ion gauge, it was easy to pump below 0.01 mtorr.

The period of each pendulum was very close to 1 sec, and the starting amplitude of the motion for every case was about 25 mrad. The heavier pendulum used a pair of pointed steel supports resting on single-crystalline silicon wafers to provide the axis of rotation. At the bottom of the pendulum was attached a solid lead ball whose mass was approximately 1 kg. The lighter pendulum was supported by a steel knife-edge resting on hard ceramic flats, and a large (10.3 cm dia.) lightweight (143 g) hollow metal sphere was attached at the bottom to provide as much air drag as possible. The motion was measured with an SDC sensor feeding the computer through a Dataq DI-154RS A/D converter.

Although air damping is evident in Figure 20.9, it is not as influential as one might expect, at least for the heavy pendulum. Moreover, at atmospheric pressure, it was easy to demonstrate the importance of nonlinear drag. As also noted in Nelson and Olssen (1986), this form of fluid friction caused a significant amplitude-dependent damping.

The remanent damping, once air influence is eliminated (pressure below 1 mtorr), is substantial relative to atmospheric damping, for both pendula. Removing the air increased the Q from 7500 to

FIGURE 20.9 Pendulum damping as a function of pressure in a vacuum chamber.

10,100 for the heavy pendulum and, for the light pendulum, the increase was from 1000 to 4600. We thus see that even a pendulum designed to be heavily influenced by air drag also has significant damping that depends on the material from which the pendulum is fabricated or on the material upon which it rests.

The difference in internal friction damping between the heavy and light instruments was not expected to be so great. Although this might be due to the difference in axis-type (points for the heavy instrument and knife-edge for the light), no systematic effort was made to determine the primary source of the damping difference. In addition to different axis designs, the means for holding the instruments together were different. The light pendulum used a large-diameter solid brass wire between the axis and the lower mass, and the heavy pendulum used an aluminum tube.

Both of the pendula used to generate [Figure 20.9](#) were relatively high-frequency instruments (period of 1 sec). The pivot was located, in each case, near the top end of the instrument. As such, they stand in stark contrast with the instruments that motivated this paper, where long-period pendula were used. A simple instrument to demonstrate some of the complexities of long-period instruments is a rod-pendulum of adjustable period (refer to [Figure 20.1](#) above). The closer the axis to the center, the longer the period and the greater the influence of internal friction. It is easy to show that the sensitivity of a pendulum to external forces is proportional to the square of the period. Similarly, the ability to detect influence of internal configurational change is quadratic in the period.

20.10 Noise and Damping

20.10.1 General Considerations

Damping is inseparable from noise issues having nothing to do with undesirable sounds that might be produced by oscillation. In the simplest cases, the noise associated with damping can be described by the fluctuation–dissipation theorem. The viscous damped, thermally driven oscillator is a classic example of thermodynamic equilibrium, for which this theorem is applicable. The classic electronics analogous case is the Johnson noise of a resistor, described by the Nyquist (white) noise formula.

The largest obstacle to constructing a perfectly simple harmonic oscillator is the oscillator's dissipation. If damping were perfectly smooth, this would not be so great a challenge. However, the fluctuation–dissipation theorem of statistical mechanics guarantees that damping is accompanied by fluctuating forces. The larger the damping, the larger the fluctuating forces, i.e., the larger the noise. It is a standard problem in statistical mechanics to show that the magnitude of relative fluctuation is inversely proportional to the square root of the number of particles involved. In the case of internal friction noise, defects associated with mesoscale structures cause the effective number of particles responsible for the noise to be much smaller than the total number of atoms in a sample. Unfortunately, the fluctuation–dissipation theorem probably does not apply. It has been long known that it does not apply to the Barkhausen effect (Barkhausen, 1919). It has been recently demonstrated that it does not apply to structural glass (Grigera and Israeloff, 1999). The close relationship postulated by the author between the PLC effect and the Barkhausen effect implies that the fluctuation–dissipation theorem should also not generally apply to internal friction damping.

Internal friction noise is not white but rather more like $1/f$ (or flicker = pink) noise, a ubiquitous form that has not yet been explained from first principles. A frequently cited paper on self-organized criticality states the following:

We shall see that the dynamics of a critical state has a specific temporal fingerprint, namely “flicker noise,” in which the power spectrum $S(f)$ scales as $1/f$ at low frequencies. Flicker noise is characterized by correlations extended over a wide range of timescales, a clear indication of some sort of cooperative effect. Flicker noise has been observed, for example, in the light from quasars, the intensity of sunspots, the current through resistors, the sand flow in an hourglass, the flow of rivers such as the Nile, and even stock exchange price indices. Despite the ubiquity of flicker noise, its origin is not well understood. Indeed, one may say

that because of its ubiquity, no proposed mechanism to date can lay claim as the single general underlying root of $1/f$ noise. We shall argue that flicker noise is in fact not noise but reflects the intrinsic dynamics of self-organized critical systems. Another signature of criticality is spatial self-similarity. It has been pointed out that nature is full of self-similar “fractal” structures, though the physical reason for this is not understood. (Bak, 1988)

It should be noted that controversy exists concerning this self-organized criticality paper, summarized in the following excerpt from Bak’s book on $1/f$ noise called *How Nature Works: The Science of Self-Organized Criticality* (page 95):

In an earlier work (CFJ), performed while an undergraduate student in Aarhus, Denmark, (Kim Christensen) showed that our analysis of $1/f$ noise in the original sandpile article was not fully correct. Fortunately, we have since been able to recover from that fiasco in a joint project by showing that for a large class of models, $1/f$ noise does indeed emerge in the SOC state.

In the last few years, mathematicians have been drawn to “... an analogy, in which three areas of mathematics and physics, usually regarded as separate, are intimately connected. The analogy is tentative and tantalizing, but nevertheless fruitful. The three areas are eigenvalue asymptotics in wave physics, dynamical chaos, and prime number theory” (Berry and Keating, 1999). Some mathematicians speculate that a dynamical system (perhaps some form of a mesoanelastic pendulum, in the thinking of this author) could become a “machine” to generate prime numbers.

20.10.2 Example of Mechanical $1/f$ Noise

Shown in Figure 20.10 is an example of mechanical flicker noise made worse by creep that originates in the spring (LaCoste type) of a Sprengnether vertical seismometer. The data are from two separate time records, the first run preceding the second run by about a half-hour. Just before collecting the data of the first run, a clamping pin was removed from the seismometer. Used to constrain the mass from moving, this pin had been left in place overnight to determine the amount of electronics noise, including drift. The measured electronics noise (white = $1/f^0$) was more than an order of magnitude smaller than the smallest (high frequency) noise components of mechanical (seismometer) type. The peak-to-peak amplitude of the oscillation in both cases was 0.5 mm (calibration constant for the sensor being 2000 V/m). The peak-to-peak amplitude for SNR = 1 for this system is of the order of $1\ \mu\text{m}$.

Although the spring force was not unloaded with the pin in place overnight, nevertheless, its removal caused a significant change to defect structures in the spring, as noted by the residuals between the data and their harmonic fits (magnified by a factor of ten).

FIGURE 20.10 Evidence in support of $1/f$ mechanical noise in a seismometer.

The flicker character of the noise was demonstrated by computing power spectra of the residuals (not shown). The log–log plot, generated with the FFT (Cooley–Tukey FFT), showed $1/f$ frequency dependence for the second run. The larger noise of the first run was concentrated in the upper frequencies. The relaxation toward $1/f$ character suggests that flicker noise is a remanent of “work hardening.” To demonstrate that the flicker noise was not due to the electronics, sensor output was recorded with the mass of the instrument locked. The electronics noise proved to be more than an order of magnitude smaller and “white” in character, probably mainly the result of A/D quantization (see Chapter 16).

Because the spring was not in equilibrium at the time the pin was removed (perhaps because of temperature change while the system was clamped), a great deal of initial molecular rearrangement occurred, involving atoms at grain boundaries. It is seen that the amount of fluctuations has noticeably decreased during the half-hour separating the two runs. Although the creep-noise would be undoubtedly much greater if the spring were relaxed altogether, it is not easy in such a case to quickly rebalance the seismometer to oscillate with a period in excess of 20 sec. These observations are in keeping with known properties of sensitive seismometers, as noted by Erhardt Wieland in “Instrumental self noise — transient disturbances” (ed. Borman and Bergmann, 2002):

Most new seismometers produce spontaneous transient disturbances, quasi miniature earthquakes caused by stresses in the mechanical components. Although they do not necessarily originate in the spring, their waveform at the output seems to indicate a sudden and permanent (step-like) change in the spring force. Long-period seismic records are sometimes severely degraded by such disturbances. The transients often die out within some months or years; if not, and especially when their frequency increases, corrosion must be suspected. Manufacturers try to mitigate the problem with a low-stress design and by aging the components or the finished seismometer (by extended storage, vibrations, or alternate heating and cooling cycles). It is sometimes possible to relieve internal stresses by hitting the pier around the seismometer with a hammer, a procedure that is recommended in each new installation. (Wielandt, 2001)

Material damping noise appears to have features that are similar to Barkhausen noise — a magnetic phenomenon involving a system far-from-equilibrium. Such noise is associated with the granular nature of ferromagnetic domains and has consequence in the design of electronic instruments using iron alloys. For example, it is known (though not widely) that the popular LVDT is inherently less sensitive than a capacitive sensor of equivalent electrical type, because of its ferrous component (the rod-component that moves). As noted by Wielandt (2001), the capacitive sensor “...can be a hundred times better than that of the inductive type.” Fully differential capacitive sensors, being electrically equivalent to the LVDT have still greater advantages borne of the higher symmetry. Additionally, by configuring the capacitive device as an array, it is possible for the sensitivity to also be greater.

Barkhausen noise and hysteretic damping noise may be much more similar than has been realized — involving granularity at the mesoscale, intermediate between micro- and macrophenomena. For such systems, first principle methods are very difficult to employ due to complexities that originate from a host of nonlinear interactions. For example, in the case of internal friction of solids, damping derives from stress–strain hysteresis determined by defect structures in the solid. Involving roughly 10^{12} atoms per “grain” in metal specimens, flicker noise evidently derives from self-similar structures of fractal geometry with a higher degree of spatial correlation than is true of white noise. The ubiquitousness of $1/f$ noise is consistent with the labeling of hysteretic damping as “universal,” as first suggested by Kimball and Lovell (1927).

20.10.3 Phase Noise

The previous example was concerned with amplitude noise. It is also possible to see phase noise of mechanical type, as illustrated in Figure 20.11.

For the sensor calibration constant of 2000 V/m, it is seen that the initial amplitude of oscillation is 1.3 mrad, which is much too large to observe the discontinuities of mechanical Barkhausen type.

FIGURE 20.11 Illustration of phase noise in the free-decay of a vertical seismometer.

The phase noise is made obvious by comparing the decay to a “reference,” i.e., by looking at the residuals from an Excel-generated fit to the data. By adjusting in a computer-generated damped sinusoid, (i) the initial values of amplitude and phase, (ii) the decay parameter, and (iii) the frequency, one can visually by trial and error come close to an optimum fit to the data. Having done so with Figure 20.11, the striking feature of the residuals (difference between data and fit) is the structure that looks something like “beats” but is not. The phase noise responsible for this behavior is thought to be consistent with $1/f$ mechanical noise. To visualize the noise, it is convenient to think in terms of a small randomizing (noise) vector whose tail is positioned at the head of the phasor used to generate the record. The component of the noise vector that is in the direction of the phasor generates amplitude noise as in Figure 20.10, whereas the perpendicular component is responsible for the phase noise of Figure 20.11.

Vibration phase noise imposes a serious limit on the performance of precision quartz crystal oscillators, since they are sensitive to acceleration. The phase noise in these oscillators can be observed by beating against a reference oscillator of known character; i.e., the reference serves the same purpose as the computer “fit” of Figure 20.11. To reduce the phase noise, crystals are isolated with low natural frequency vibration isolators (as described in the marketing literature of Wenzel Assoc., Austin, X).

20.11 Transform Methods

20.11.1 General Considerations

For linear systems, the Laplace and Fourier transforms (Laplace being more general) have been pre-eminent tools with which to study equations of motion (see Appendix 2A and Chapter 10). The author’s transform experience (like most physicists) is mainly with Fourier transforms (FT). The discrete FT can be understood in terms of phasors (Peters, 1992). For linear differential equations, transforms are the means to convert differential forms to an equivalent algebraic form. Unfortunately, they cannot be directly employed on nonlinear equations due to the failure of superposition. Nevertheless, the linear approximations continue to be very valuable, so a chapter on damping deserves to mention some of their properties.

Ideas concerning the FFT were evidently originally treated by Gauss in the early 1800s, but the digital signal processing (DSP) “explosion” of the 1960s was largely due to the work of Cooley and Tukey (1965). For an interesting historical account about an “accident” in the publication of their paper, the reader is referred to Cipra (1993), who says the following about the FFT:

The Fourier transform stands at the center of signal processing, which encompasses everything from satellite communications to medical imaging, from acoustics to spectroscopy. Fourier analysis, in the guise of x-ray crystallography, was essential to Watson and Crick’s discovery of the double helix, and it continues to be important for the study of protein and viral structures. The Fourier transform is a fundamental tool, both theoretically and

computationally, in the solution of partial differential equations. As such, it is at the heart of mathematical physics, from Fourier’s analytic theory of heat to the most modern treatments of quantum mechanics. Any kind of wave phenomenon — be it seismic, tidal, or electromagnetic — is a candidate for Fourier analysis. Many statistical processes, such as the removal of “noise” from data and computing correlations, are also based on working with Fourier transforms.

Concerning the last statement about noise, this author has used autocorrelation as a powerful means for identifying short-lived, low-frequency periodic signals in time records that do not readily show up in power spectra (FFTs). For example, they are the means for studying free-earth oscillations — eigenmodes excited by rapid relaxations of the Earth under tidal stressing (12 h periodic) (Peters, 2000). The FFT is used to generate the autocorrelation by means of the Wiener–Khintchine theorem (Press et al., 1986).

The great advantage of the FFT compared with the DFT has to do with degeneracy. The DFT proceeds to calculate the components of every “vector” in the reciprocal space (frequency reciprocal to time, units of “second”, or wave number (spatial frequency) reciprocal to displacement, units of “meter”) with disregard for the fact that many components have the same value, apart from a change of sign.

20.11.2 Bit Reversal

The key to the power of the FFT (central processor unit [CPU] time proportional to $n \log n$) compared with the discrete Fourier transform (DFT) (CPU time proportional to n^2) is the bit reversal scheme of the Cooley–Tukey algorithm. It is illustrated very simply by the following. Instead of a practically sized number of samples in the record to be transformed (minimum of $n = 1024$, typically), consider (for pedagogy) $n = 8$, distributed on the unit circle as shown in Figure 20.12.

Observe that the roots of unity in the complex plane, which have been numbered 0 to 7, divide the “pie” into eight equal pieces. (The algorithm requires that n be expressible as a power of 2). The usual decimal counting scheme for the eight “vectors” is as indicated, traversing the phasor diagram (circle on left) sequentially. In the Cooley–Tukey algorithm, a choice is made to reverse the bits of the binary representation of the vector. Usually, the least significant bit is on the right and the most significant bit on the left, so that decimal counting is as shown on the right in the table, from 0 to 7. With bit reversal, “lsb” becomes the leftmost binary digit and the “msb” is the rightmost digit. Thus, for example, binary 110 (usually 6) becomes 3.

Using bit reversal, the phasor diagram is not traversed in the usual phasor (circulatory) sense, but rather in a “flip-flop” back and forth across the circle. By this means, there is no needless repetition in the calculation of “vector” components (real and imaginary values of a given term in the transform). For example, 5 is the simple negative of 1. It is much faster to reverse the sign on 1 to get 5 than to

FIGURE 20.12 Graphical illustration of why the Cooley–Tukey FFT algorithm is significantly faster than the original DFT.

needlessly calculate values for sine and cosine terms a second time. The saving in time is substantial as n gets large, since there are then a great number of circulations of the phasor circle. For a 1K record, the FFT computes the transform 102.4 times faster than does the DFT. Additional details are provided in Peters (2003a, 2003b, 2003c).

20.11.3 Wavelet Transform

Recent work suggests that the wavelet transform (WT) may in the future replace the FT in some applications (see Chapter 11). It uses the Haar function, which is orthogonal on $[0,1]$, as opposed to the orthogonality of the harmonic functions (sine and cosine) corresponding to $[0,2\pi]$ (Strang, 1993). It is claimed that the WT is better able to address features of the Heisenberg uncertainty principle than the FFT.

20.11.4 Heisenberg's Famous Principle

The heart and soul of quantum mechanics is the Heisenberg uncertainty principle. As noted elsewhere in this chapter, it has things to say about damping models. According to well-known physicist Hans Bethe (1992), the principle has received "bad press":

Many people believe that the uncertainty principle has made everything uncertain. It is quite the opposite. Without the uncertainty principle there could not exist any atoms, there could not be any certainty in the behavior of matter. So it is in fact a certainty principle.

Curiously, a failure figured in Heisenberg's discovery of the principle. During his thesis defense, in front of great theoretical physicist Arnold Sommerfeld (his director) and the famous experimentalist Wilhelm Wien, he proved unable to derive the magnifying power of a simple microscope. The scandal culminated with Professor Wien asking him to explain how a battery works, and he could not answer that question either. Knowing his extraordinary theoretical giftings, Sommerfeld gave him the highest possible grade to compensate for Wien's choice of an F. Thus, Heisenberg was awarded his doctorate.

Later, in an ironic turn of events, Heisenberg chose a microscope to illustrate features of the matrix quantum mechanics that he originated, and which corrected problems with the Bohr wave mechanics theory. His greatest source of embarrassment served to make Heisenberg famous!

20.12 Hysteretic Damping

20.12.1 Physical Basis

The model of simple harmonic oscillation with viscous damping assumes dissipation from an externally acting force. It is not suited to a conceptual understanding of hysteretic damping. To accommodate internal friction requires more than a single mass connected to the elastic component responsible for restoration. Two systems are pedagogically useful in this regard, one being a long-period physical pendulum (mechanical), and the other being the oscillator used by Ruchhardt to measure the ratio of heat capacities of a gas (mainly thermodynamic). Because of widespread confusion concerning the difference between viscous and hysteretic damping, both cases are presented here. The treatments are provided as evidence for the premise that hysteretic damping is the more important case for applied physics and engineering.

It is common knowledge that the damping of a mechanical oscillator results from the conversion of mechanical energy into thermal energy. One might expect, then, that a direct consideration of thermodynamics could yield conceptual understanding of the underlying physics. Although an ideal gas is rarely considered in this context, there is a classic experiment which speaks to its relevance. It is the ingenious technique used first in 1929 by Ruchhardt to measure γ , the ratio of heat capacity at constant pressure to that at constant volume (Zemansky, 1957).

20.12.2 Ruchhardt's Experiment

Consider a piston of mass m moving in a cylinder of cross-sectional area A , alternately compressing and expanding a volume of ideal gas V_0 about the residual pressure P_0 . Assume that there is no sliding friction between the piston and the cylinder. A small displacement x of the mass results in volume change $\Delta V = V - V_0 = Ax$. There is a restoring force $F = A\Delta P$, where the pressure difference ΔP relates to ΔV through an assumed adiabatic process; i.e., the period of the motion is assumed too short for appreciable heat transfer into and out of the gas. Using $PV^\gamma = \text{constant}$, one obtains

$$\gamma P_0 V_0^{\gamma-1} \Delta V + V_0^\gamma \Delta P = 0 \quad (20.23)$$

from which one obtains

$$m\ddot{x} + \frac{\gamma P_0 A^2}{V_0} x = 0 \quad (20.24)$$

This is the equation of motion of a simple harmonic oscillator. There is no damping because of the assumed adiabatic process. By measuring the period $T = 2\pi/\omega = 2\pi\sqrt{V_0 m / \gamma P_0 A^2}$, one can estimate γ .

Historically, it appears that such measurements slightly underestimate γ , which can be understood as follows.

The ideal gas equation of state $PV = NkT$ yields, through differentiation

$$\begin{aligned} P_0 x A + V_0 \frac{F}{A} &= Nk\Delta T \\ m\ddot{x} + \frac{P_0 A^2}{V_0} x &= \frac{NkA}{V_0} \Delta T(t) = F_d(t) \end{aligned} \quad (20.25)$$

Notice the difference between Equation 20.24 and Equation 20.25. In Equation 20.25, damping is possible (a type of “negative drive” term) from temperature variations associated with heat transfer during traversal of the cycle. If it were possible for the oscillation to be isothermal ($\Delta T = 0$ at very low frequency, essentially quasistatic), then the frequency would be lower than that of the adiabatic case, since $\gamma > 1$ is missing from Equation 20.25. In the isothermal case, there would also be no damping, since the heat into the gas during compression would be balanced by that which leaves during expansion. The only way to get damping is for the paths of compression and expansion in a plot of pressure vs. volume to separate, i.e., for there to be hysteresis. Reality must correspond to something between the two extremes of adiabatic and isothermal, with experiment obviously favoring adiabatic. The process must depart somewhat from adiabatic, however, since there is damping, which Equation 20.25 shows to derive from temperature variations yielding hysteresis. It is interesting to look at the temperature variations relative to a “driving force,” $F'_d(t)$. In the Ruchhardt experiment, there must be small variations $\Delta T'(t)$ that lag behind $x(t)$. (These are not the reversible temperature variations of the adiabat, onto which the $\Delta T'(t)$ are superposed.) By comparing with Equation 20.25, the right-hand zero of Equation 20.24 may be replaced with a damping force that can be written in terms of the velocity as

$$F'_d(t) \propto \Delta T'(t) \rightarrow -\frac{c}{\omega} \dot{x} \quad (20.26)$$

where $c = \text{constant}$. Notice that the multiplier on the velocity is not simply a constant, but rather a constant divided by the angular frequency. The use of velocity is mathematically convenient, but the magnitude of the velocity (speed) is not expected to be a first order influence on the temperature changes of hysteresis type. The derivative of x with respect to time not only shifts the phase by 90° , which accommodates the lag with which heat is transferred, but it also introduces a frequency multiplier through the chain rule. Thus, to make damping proportional to the velocity would cause increased dissipative heat flow and thus increased damping as the frequency is increased. Since this does not happen, and lest we introduce a nonphysical term into the equation, it is necessary to divide by the frequency. Replacing the right-hand-side zero of Equation 20.24 with Equation 20.26, we obtain the

modified equation of motion, with damping

$$m\ddot{x} + \frac{c}{\omega}\dot{x} + \frac{\gamma P_0 A^2}{V_0}x = 0 \quad (20.27)$$

Additional justification for the form of the damping term in Equation 20.27 can be realized by looking at cases where there is negative damping, i.e., $c < 0$. Such is true when the gas is caused to cycle as an engine. An illustrative case study was that of a low temperature Stirling engine (Peters, 2002a, 2002b, 2002c), in which reasonable agreement between theory and experiment was realized through the use of an equation based on the same arguments used to derive Equation 20.27.

It is seen that a straightforward modeling of Ruchhardt's experiment to include damping yields an equation of motion that is in the form of hysteretic damping. It appears that, for many systems in which the dissipation is dominated by internal friction, hysteretic damping is a near universal form.

20.12.3 Physical Pendulum

In the paper by Speake et al. (1999), one finds the following statement:

the logarithmic decrement (Q^{-1}) varied as the inverse of the square of the frequency. We interpreted this as evidence that, in Cu–Be over this frequency range, the imaginary component of Young's modulus was independent of frequency, contrary to that which was predicted by the Maxwell model.

To fit their theory with experiment, they used a “modified” Maxwell model with a distribution of time constants that ranged from 30 sec to more than 4000 sec. Motivation for their continued modeling efforts derived partly from the observation by Kuroda (1995) that anelasticity was cause for some of the huge errors that have been present in estimates of the Newtonian gravitational constant, G , by the time-of-swing method.

Although it gives agreement with their particular experiment, the model of Speake et al. (1999) does not have the blessing of Occam's razor. Moreover, their claim that damping derived primarily from their flex pivot of Cu–Be may not be true. Other studies suggest that the material defining the axis of a long-period pendulum is for many cases no more important (and sometimes much less important) to the damping than the material from which the pendulum proper is constructed. A model which also agrees with experiment of the type they conducted, but which is simpler, is now presented.

Illustrated in Figure 20.13 is an idealized long-period mechanical oscillator which could be labeled a “physical pendulum.” The top and bottom masses are the same, M , assumed to be much greater than the mass of the connecting structure, which is represented by the curved line.

A primary mechanism for internal friction damping can be understood by looking at the external forces acting on the pendulum, which are pictured in the “negative displacement” (b) case. The upward “normal” force that acts through the pivot (usually a knife-edge) is opposed by the pair of bob-weights situated left and right, respectively, of the axis of rotation. As the pendulum swings alternately between positive and negative displacements, the structure undergoes periodic flexure. It should be pointed out that internal friction could still be operative throughout the structure even without net bending; i.e., there

(a) positive displacement (b) negative displacement

FIGURE 20.13 Idealized physical pendulum used to develop the modified Coulomb damping model.

could be complementary pieces of the structure undergoing compression and tension. Even if the oscillator were in the weightlessness of space, a drive torque would result in dynamic reactionary forces that give rise to damping by this means.

Assume that the masses are separated a distance $2L$ and the axis of rotation is ΔL above the geometric center. Applying Newton's Second Law, with the lower mass causing a restoring torque and the upper mass a "destoring" torque, yields

$$\ddot{\theta}_1 + \frac{g}{2L} \left(1 + \frac{\Delta L}{L}\right) \theta_1 - \frac{g}{2L} \left(1 - \frac{\Delta L}{L}\right) \theta_2 = 0, \quad \theta_2 = \theta_1 + \eta \quad (20.28)$$

(Note: Equation 20.28 can be rewritten to accommodate larger displacements, where elastic nonlinearity gives rise to unusual behavior. The amplitude trend of the period is opposite to that of the gravitational nonlinearity, thus providing for improved isochronism. For details refer to Peters, 2003a, 2003b, 2003c).

The difference in displacement of the masses involves an elastic term proportional to θ_1 and a dissipative term that depends on its time rate of change, i.e.

$$\eta = c \left(\theta_1 \cos \delta - \frac{\dot{\theta}_1}{\omega} \sin \delta \right), \quad \omega = \sqrt{g \frac{\Delta L}{L^2}} \quad (20.29)$$

where c is a dimensionless constant. This result can be obtained by the complex exponential Steinmetz (phasor) method. The equation is consistent with the common assumption that stress and strain are related through a complex constant. The angle δ is the phase angle with which η strain) lags behind θ_1 (stress). To describe the motion of the lower mass, we can ignore the elastic part of η , since it does not contribute to the damping (or if the rod does not bend, assuming there still is damping as noted previously). We thus remove the subscript, and after some algebra obtain the result

$$\ddot{\theta} + \frac{\alpha}{\omega} \dot{\theta} + \omega^2 \theta = 0, \quad \alpha = \frac{gc}{2L} \sin \delta, \quad \text{for } \Delta L \ll L \quad (20.30)$$

which can also, in terms of $Q = 2\pi E/(-\Delta E)$, be expressed as

$$\ddot{\theta} + \frac{\omega}{Q} \dot{\theta} + \omega^2 \theta = 0, \quad Q = \frac{2L}{gc\delta} \omega^2, \quad \delta \ll 1 \quad (20.31)$$

If, as a material property, δ is independent of frequency, then Q is quadratic in the frequency; i.e., the damping of the pendulum due to internal friction is inversely proportional to the square of the frequency — even though the internal friction (determined by δ) is itself frequency-independent. It is important to note that the frequency dependence of internal friction is not to be equated with the frequency dependence of the Q of the oscillator, even though internal friction is frequently stated as simply $1/Q$. This will be discussed in greater detail in Section 20.13.2.

20.12.3.1 Test of Q Dependencies

The dependence of Q on frequency and length in Equation 20.31 was tested experimentally with a physical pendulum. Two Pb spheres, each of mass approximately 1 kg, were each drilled through a diameter to allow the insertion of the shaft of an aluminum alloy arrow (length approx. 70 cm) of the type commonly used with compound hunting bows. A second hole was drilled perpendicular to the first and tapped for a set screw. The shaft was sawed into two pieces, which were rigidly rejoined around a carbon-steel knife-edge using force fit and epoxy to machined protuberances above and below the knife-edges. The knife-edges extend perpendicularly outward on opposite sides of the arrow at its center.

20.12.3.2 Simple Method to Measure Damping

Although an SDC sensor could have been employed instead, the experiments to be described were performed with a measurement technique that warrants description because of its novel simplicity — yet it is reasonably accurate. To measure both period and damping, a small "flag" was super-glued to the top of the upper shaft. This flag was a small, thin, U-shaped piece of plastic in which the upper legs of the U were about 1 mm wide, with a spacing between centers of about 0.5 cm. An infra-red photogate of the

type used in general education laboratories was mounted so the flag would trip the photogate during pendulum oscillation. Two different timing measurements were then performed, using a Pasco Smart Timer. In every run, the pendulum was displaced initially about 10° by hand and then released. There was no need for precision initialization.

In the pendulum mode of the timer, the period was directly measured. For this case, the photogate was positioned, relative to the U-shaped flag (for which one vertical arm is slightly longer than the other), so as to be interrupted only once by the pendulum per pass. In the time-interval mode, the flag was positioned so that both arms interrupted the photogate beam. The reciprocal of this time of interruption proved to be a reasonable measure of the instantaneous speed of the pendulum at the position of the photogate, which was that of maximum kinetic energy. The time intervals were recorded manually for traversals separated by one period, through five cycles of oscillation. These numbers were then typed into Excel and their reciprocals graphed. A trendline (using the option to print the slope) was applied to the near linearly declining graph. The decrement of this line (fractional decrease per cycle) proved to be a good approximation to the logarithmic decrement of the motion, which could have been estimated with exceptional precision by means of the other techniques mentioned in this chapter.

In the first set of experiments, the sphere on the lower shaft was maintained at a constant distance from the knife-edge, while the mass on the upper shaft was positioned at increasingly greater distances from the knife-edge to lengthen the period. Over the full range of periods considered, the distance between the two masses changed by a small amount around its nominal value of 67 cm. The results of this first study are shown in the left graph of Figure 20.14, where the log-decrement has been plotted vs. the square of the period. The Q of the pendulum (π/Δ) may be calculated for any value of the period using the indicated slope of 0.0004. For example, the Q at a period of 10 sec was 76, this being near the shortest period considered. Near the other extreme of $T = 35$ sec, $Q = 6$. At the shortest possible periods, damping due to air drag would begin to become important.

The reasonable fit of the linear regression vs. period squared is consistent with the prediction by Equation 20.31 that Q should be quadratic in the frequency.

The Equation 20.31 also indicates that the log-decrement should be proportional to the reciprocal of the distance, L , between the masses. To test this prediction, the period of the pendulum was measured as a function of mass separation, also using the smart timer. In generating the data for the right graph of Figure 20.14, the period was maintained constant at 20 sec. For every datum, the top sphere was always only slightly closer to the knife-edge than the lower sphere. At 0.049, the intercept of the trendline differs enough from zero, relative to the size of the error bars, to imply a systematic error. Possible sources of the error include: (i) the masses are of finite size, rather than being points as assumed by the model, and (ii) a nonnegligible mass from parts other than the spheres. Nevertheless, the data show a clear size dependence of the Q .

FIGURE 20.14 Results of experiments to test the dependencies of Q on (i) frequency and (ii) length of pendulum.

The experiments just described do not permit one readily to isolate the source of the damping, which, for the cases in [Figure 20.14](#), had the knife-edge resting on silicon wafers (integrated circuit stock material). It is not known to what extent the dissipation was dominated by strain in the knife-edge–silicon interface or by flexure of the aluminum arrow. Although the model that generated equation 20.31 assumed only the latter, there is nevertheless theoretical and experimental basis for model acceptance, regardless of the details of the damping.

20.12.3.3 Highly Dissipative, yet Hard Materials

The same pendulum was used to demonstrate some counterintuitive features of internal friction damping by replacing the Si wafers with various materials. When very soft material, such as lead, was the support for the knife-edges, there was a significant increase of the damping, as expected. It was also found, however, that cast iron increased the log-decrement (10-sec period) by more than 40%. The same was also true of ceramic PZT wafers of the type used to ignite gas grills by striking the wafer impulsively. Both the cast iron and the lead–zirconate–titanate samples are very hard, so the internal friction must derive from large defect densities in which atomic disorder is a sensitive function of stress. Some other hard interfaces, such as steel on glass, or steel on sapphire, did not show a difference from steel on Si, which suggests that the dominant source of damping for the pendulum in all these cases was flexure of the aluminum shaft.

The observation involving cast iron is consistent with its known excellent damping properties at higher frequencies — important, for example, to engine blocks. Some magnesium alloys have also been developed that have excellent damping characteristics without seriously sacrificing strength.

20.13 Internal Friction

20.13.1 Measurement and Specification of Internal Friction

Mechanical spectroscopy is a popular means for measuring internal friction of materials (Fantozzi, 1982). Typically, a torsion pendulum is used to stress harmonically a sample and the lag of the response (strain), relative to the stress, provides the loss tangent and thus the internal friction. In such experiments, it is widespread practice to report internal friction as Q^{-1} . There can be confusion because of this practice, depending on the nature of the measurement technique, i.e., whether one actually measures Q as opposed to measuring something proportional to the stress–strain lag angle. If Q is obtained from an oscillatory free decay, using the logarithmic decrement defined as follows, then there is no problem.

$$\Delta = \ln \frac{x_n}{x_{n+1}} = \beta T = \frac{\pi}{Q} \quad (20.32)$$

Here, x_n and x_{n+1} are adjacent turning point amplitudes separated by one period of the motion, T . In practice, it is very difficult to adjust a mechanical system to oscillate over a wide frequency range. The widest range known to the author, for a mass–spring system, involved the work of Gunar Streckeisen (1974), in which a vertical seismometer using the LaCoste spring was adjusted to have periods in the range between 7 and 140 sec. Because of the difficulties in attaining a wide range of eigenmodes, internal friction is typically determined with a specimen that does not oscillate. We now consider that case.

20.13.2 Nonoscillatory Sample

In the typical torsional pendulum used to measure internal friction, the sample is of very small mass. Such a pendulum was built, for example, around the original version of the fully differential capacitive sensor, to study magnetoelastic wires (Atalay and Squire, 1992). As with many delicate instruments, the Atalay and Squire instrument was of the type labeled “inverted.” A silk fiber at the top of the specimen was used to provide minimal tension in the sample. They used one linear rotary differential capacitance

transducer (LRDCT) (Peters, 1989) in the drive mode to provide a known stress to the delicate magnetoelastic sample and a second LRDCT to measure the strain magnitude and the angle by which it lags behind the stress because of an elasticity. As such, they were measuring the lag angle and not Q , as will now be shown.

Without an inertial term, the sample response x to a periodic external force F is governed by

$$F = Kx = (k + j\zeta)x = F_0 e^{j\omega t} \quad (20.33)$$

so that the transfer function is given by

$$\frac{x}{F} = k^{-1} - j \frac{\zeta}{k^2} \quad (20.34)$$

from which it is seen that the measurement does not yield Q^{-1} but rather the lag angle ζ/k , where k is constant. Perhaps the measured angle, which is an indicator of the internal friction, has been called Q^{-1} because $k = m\omega_0^2$ for an oscillator of frequency ω_0 , and $Q = m\omega_0^2/\zeta$ for the freely decaying oscillator. Bear in mind, however, that this expression for k does not apply to the nonoscillatory measurement just described. There is a frequency square difference between such a measurement and what would be measured if an adjustable oscillator were being considered.

An example of the importance of this issue is found in the article by Lakes and Quakenbush (1996), in which one reads from the abstract the following statement:

The damping, $\tan \delta$, followed a ν^{-n} dependence, with $n \approx 0.2$, over many decades of frequency ν . This dependence corresponds to a stretched exponential relaxation function, and is attributed to a dislocation-point defect mechanism. It is not consistent with a self-organized criticality dislocation model which predicts $\tan \delta \propto A^{-2}$. Dislocation damping in metals is relevant to development of high damping metals, the behavior of solders and of support wires in Cavendish balances.

The present arguments suggest that the experiment by Lakes and Quackenbush is (1996) not in strong disagreement with the SOC model; that the magnitude of the exponent difference between theory and experiment is really 0.2 and not 1.8 as they have indicated.

20.13.3 Isochronism of Internal Friction Damping

It is well known that, in the viscous damping free-decay case, the frequency of oscillation is lowered by damping according to

$$\omega_1 = \sqrt{\omega_0^2 - \beta^2} = \omega_0 \sqrt{1 - (2Q_v)^{-2}} \quad (20.35)$$

and the resonance frequency of the driven oscillator is lowered even further (Marion and Thornton, 1998). It is not well known how difficult it is to measure this damping “red-shift,” which brings in features of the Heisenberg uncertainty principle. Additionally, it is not well known that extensive damping experiments suggest that the frequency may not, for some systems, depend on the damping at all; i.e., the oscillator is isochronous. Isochronism cannot be realized with a linear homogeneous differential equation, but it can be realized with a nonlinear form that is obtained by modifying the damping term as follows:

$$\frac{\omega}{Q} \dot{x} \rightarrow \frac{\pi}{4} \frac{\omega}{Q} \sqrt{\omega^2 [x(t)]^2 + [\dot{x}(t)]^2} \text{sgn}(\dot{x}) \quad (20.36)$$

where $\text{sgn}(dx/dt)$ is the algebraic sign of the velocity — it causes the equation of motion to be nonlinear even if the square root term were not present. For small damping, the square root term can be shown to be equal to the time-dependent amplitude of the motion multiplied by the angular frequency.

Other damping types are possible and are indicated in Peters (2002a, 2002b, 2002c) (...universal...) where evidence is also provided for harmonic distortion in the waveform because of the nonlinearity. It is shown in Peters and Pritchett (1997) that the oscillation is isochronous.

For large values of Q , the lag angle (radian measure) is given by $\delta = 1/Q$. Researchers usually measure δ and specify the magnitude of the internal friction as Q^{-1} . As noted previously, Q is proportional to frequency for the viscous damped oscillator. Thus, for viscous damping, the internal friction is inversely proportional to the frequency.

For hysteretic damping we obtain the result

$$\tan \delta = \alpha = \frac{h}{k} \quad (20.37)$$

where the variables are defined in Equation 20.19. For small damping in which $\tan \delta = \delta = Q^{-1}$, we find that the internal friction for hysteretic damping is inversely proportional to the square of the frequency, since h is constant and $k = m\omega^2$.

20.14 Mathematical Tricks — Linear Damping Approximations

20.14.1 Viscous Damping

In the Hooke's Law expression, $F = -kx$, it is common practice to approximate hysteresis of oscillatory motion by letting k become a complex coefficient. This is also standard practice in a variety of fields, such as the description of lossy electromagnetic media. No doubt the practice has been further popularized by the standard approach of solving electrical engineering ac circuit problems by means of phasors, the technique developed by Steinmetz (1893).

We recognize in the expression $x(t) = x_0 e^{j\omega t} = x_0 \cos \omega t + jx_0 \sin \omega t$ that harmonic variation is contained in the real part (or alternatively the imaginary part) of the complex exponential form. Using Newton's Second Law, and representing the spring constant by $k e^{j\delta}$ with $\delta \ll 1$ (small damping), we obtain the damped harmonic oscillator equation

$$m\ddot{x} + kx + (jk\delta)x = 0 \quad (20.38)$$

where the approximations $\cos \delta \rightarrow 1$ and $\sin \delta \rightarrow \delta$ have been employed.

However, since $\dot{x} = j\omega x$, and $\frac{k}{m} = \omega^2$, Equation 20.38 can be rewritten as

$$\ddot{x} + \omega\delta\dot{x} + \omega^2 x = 0 \quad (20.39)$$

We thus see that the damping constant $\omega\delta = \omega/Q = 2\beta$ permits us to express the logarithmic decrement Δ in terms of the angle δ with which x lags F ; i.e., $\Delta = \beta T = \pi\delta$. (Note that we are making no distinction here between the periods with and without damping, since the difference is small and hard to measure.) If β were independent of frequency, then δ would be inversely proportional to the frequency, which is rarely realized in practice.

20.14.2 Hysteretic Damping

Equation 20.39 does not properly represent some of the most important engineering systems. For those labeled "hysteretic," we must use a different form for the complex spring constant. We assume that $F = -(k_{\text{complex}})x = (k + jh)x$ where h is a real constant. Since $dx/dt = j\omega x$, this yields the equation of motion

$$\ddot{x} + \frac{h}{m\omega}\dot{x} + \omega^2 x = 0 \quad (20.40)$$

Since h is assumed to be a true constant (independent of frequency), the lag angle between displacement and force is given by

$$\delta = \frac{h}{k} = \frac{1}{Q} = \frac{h}{m\omega^2} \quad (20.41)$$

which is seen to be inversely proportional to the square of the frequency. (Note that δ here is the same as α in Figure 20.6.) It should be noted that the complex form for the spring constant is not simply obtained using the common theory of viscoelasticity. Such theory requires a multitude of relaxation times (stretched exponentials) (Speake et al., 1999).

20.15 Internal Friction Physics

20.15.1 Basic Concepts

All damping derives from varying degrees of complexity because of the myriad interactions that are present, either internal of nonconservative type or external involving the environment. This is true even for systems that come closest to being governed by the textbook equations. For example, the author has attempted to produce ideal harmonic oscillators using viscous liquids for damping. Even they are complicated and do not strictly obey Stokes' Law of drag force proportional to the velocity. The nonlinear Navier–Stokes equation may be capable of describing them, but not in a simple form except to a first approximation that is not really very good relative to the precision that is possible with modern sensors.

Perhaps the closest to being an ideal viscous damped oscillator is that in which the damping force derives from eddy currents through Faraday's Law. A magnet is attached to the oscillator and, as it moves in proximity to a conductor, the time rate of change of magnetic flux gives rise to a retarding force that is proportional to velocity. Because there really is a force involved, and because of Lenz's Law, the damping term makes sense physically. This case might be completely ideal except for one factor — the magnet is part of a mechanical system that must possess structural integrity if it is to oscillate. Because of loads present in the structure (reactionary normal forces to the various weights), there will always be some creep. The creep is ultimately unavoidable, since there is apparently no stress threshold below which plastic deformation ceases to exist. It is important to realize that forces associated with inertial mass (Newton's Second Law) are just as important as the weights. Systems designed around an elastic member (such as a spring, in contrast to a simple pendulum) will experience damping in the weightlessness and the airlessness of space.

20.15.2 Dislocations and Defects

The extent to which mechanical defects, such as dislocations, have been ignored by large segments of the scientific community is surprising. The surprise is even greater when one considers the importance of defects in another field — that of electronics. Our present information age (world of computing) came into existence only after widespread recognition of the importance of the defects called impurities. The n-type and p-type semiconductor materials necessary to our modern age result from the substitution of silicon atoms with others of pentavalent and trivalent type in surprisingly small concentrations.

The strength of solids is very much less than as predicted by theories of an ideal (perfect) crystal. Dislocations are the primary culprits. Their influence on materials used in engineering has prompted the statement: "when mother nature fills the vacuum she abhors, she rarely does so with perfection." Unfortunately, few students exposed to fundamental science receive training in defect physics. Moreover, it is difficult to provide a self-consistent fundamental description of their properties, so very few scientists have more than a superficial knowledge of their importance.

"Viscoelasticity" is a misleading term. To combine the words viscous and elastic suggests that the state variables vary smoothly in time, i.e., as a fluid in the viscous part. Unfortunately, this is not true of hysteresis associated with either "domains" or with "grains." In the case of magnetic domains, it is quite easy to demonstrate nonsmooth (jerky) behavior that is called Barkhausen noise. Although the phenomenon was demonstrated by Barkhausen in 1919, only recent studies have begun to understand some of its complexities better (Urbach et al., 1995a,b).

A similar phenomenon, that must relate in some manner to the Barkhausen effect, is the PLC effect. Under applied stress, alloys frequently display discontinuous strain increase (jumps). The author has

even demonstrated strain recovery of a similar type, catalyzed by “tapping.” The polycrystalline metals that demonstrate these effects are obviously influenced by “granularity.” They differ from the “granular materials” that have become a hot topic of recent research. Even pure polycrystalline metals exhibit these features. The German word to describe the deformation of tin under large stresses is *zinnigeschrei* (=tin cries). Anyone who has ever bent large-diameter tungsten wire has experienced this phenomenon, since the nonsmooth strain can be both felt and heard.

There is still another type of material, thought to have great engineering potential in the future, that shows “granular” behavior — that of shape memory alloys (SMA). If an SMA specimen is cycled in temperature around the martensitic phase, it generates acoustic emissions (Amengual et al., 1987). For a figure taken from their work and other good pages about hysteresis, refer to the webpages of Prof. Sethna at <http://www.lassp.cornell.edu/sethna/hysteresis/ReturnPointMemory.html>. These emissions are probably related to the PLC effect and are characterized by surprising reproducibilities in spite of their complex behavior.

Thus, there is abundant experimental evidence against the overly simplistic view that hysteretic damping can be meaningfully described by simple, linear differential equations. The nonlinear terms necessary for a good mathematical treatment go beyond “chaos” to the world of “complexity.” Chaos of deterministic type, though bewildering to many, is in many cases tractable (using equations that can be integrated numerically). Damping problems are much more complex than deterministic chaos. The challenges to our understanding derive in part from the long time that it has taken before there were any serious investigations of the mesoscale, the place where defect structures abide. If, as with Zener, we use the word anelasticity to describe systems that are “other than” elastic, then the term *mesoanelastic complexity* is an appropriate label for this poorly understood physics that is important and yet mostly unknown to many fields of both science and engineering.

20.16 Zener Model

20.16.1 Assumptions

The SLM of viscoelasticity provides a sound basis for some damping phenomena, yet it fails badly as an approximation for hysteretic damping. Its prominence in both the worlds of physics and engineering warrants the following detailed discussion so that the failure case may be properly documented.

Following the example of Zener, the following linear differential equation relates the stress, σ , the strain, ε , and their first time derivatives:

$$\sigma(t) + \tau_\varepsilon \dot{\sigma} = E_1(\varepsilon + \tau_\sigma \dot{\varepsilon}) \quad (20.42)$$

The τ s are relaxation times (subscript ε meaning at constant strain and subscript σ at constant stress), and E_1 is the relaxed elastic modulus (ratio of stress to strain in a very slow process). Nominally, $\tau_\sigma > \tau_\varepsilon$, consistent with strain lagging stress. For periodic variations

$$\sigma(t) = \sigma_0 e^{j\omega t}, \quad \varepsilon(t) = \varepsilon_0 e^{j\omega t} \quad (20.43)$$

which, when substituted into Equation 20.42, yields

$$(1 + j\omega\tau_\varepsilon)\sigma_0 = E_1(1 + j\omega\tau_\sigma)\varepsilon_0 \quad (20.44)$$

The complex modulus of elasticity is defined by

$$E_C = \frac{1 + j\omega\tau_\sigma}{1 + j\omega\tau_\varepsilon} E_1 \quad (20.45)$$

and is seen to relate stress and strain according to

$$\sigma(t) = E_C \varepsilon(t) \quad (20.46)$$

From Equation 20.45, the real and imaginary parts of the modulus are found to be

$$\text{Real } (E_C) = \frac{1 + \omega^2 \tau_e \tau_\sigma}{1 + \omega^2 \tau_e^2} E_1 \quad (20.47)$$

$$\text{Imag } (E_C) = \frac{\omega(\tau_\sigma - \tau_e)}{1 + \omega^2 \tau_e^2} E_1 \quad (20.48)$$

The independent variable, or “frequency,” for all cases is the convenient dimensionless parameter, $\omega\tau = \omega\sqrt{\tau_e \tau_\sigma}$.

It is convenient to use polar form, so that

$$E_C = |E_C| e^{j\delta} \quad (20.49)$$

where $|E_C|$ is obtained by computing the square root of the sum of the squares of the real and imaginary parts. In this form, it is apparent that δ is a lag angle which determines the damping loss for the system. Moreover, from Equation 20.47 and Equation 20.48, it is seen to obey

$$\tan \delta = \frac{\omega(\tau_\sigma - \tau_e)}{1 + \omega^2 \tau_\sigma \tau_e} \quad (20.50)$$

20.16.2 Frequency Dependence of Modulus and Loss

The essential features of the Zener model are illustrated in Figure 20.15, where the “unrelaxed” high-frequency modulus obeys the relation $(E_1 E_2)/(E_1 + E_2) = E_1(\tau_\sigma/\tau_e)$.

In viscous damping models, the damping is quantified by the product βT , which is equal to the logarithmic decrement. The logarithmic decrement is directly proportional to the period when the damping “constant” β is truly constant. The graph in Figure 20.16 compares the logarithmic decrement computed by the standard model against a case where $\beta = \text{constant}$. Also shown in the figure is a set of hysteresis curves for $\omega\tau = 10, 1$, and 0.1 , respectively. Notice that the damping is large only for $\omega\tau$ near 1, in accord with the bottom plot of Figure 20.15. For that case, points (a) to (f) and back to (a) are shown, labels to illustrate work done by the stress in traversing the hysteresis loop. The algebraic sign of the work changes around the loop and the net work done in one cycle is just the area enclosed by the loop.

For damping based on the Zener (standard linear) model to agree with the simple viscous approximation, it is necessary that $\omega\tau \gg 1$; i.e., the period of the oscillator must be significantly shorter than the smaller of the relaxation times, as illustrated in the bottom graph of Figure 20.16.

FIGURE 20.15 Zener Model of anelasticity. Bottom curves are “frequency” variation of modulus and loss respectively.

20.16.3 Successes — Models of Viscoelasticity

Viscoelasticity, as an approximation for damping, is evidently quite adequate for some materials. The assumption of fluid character as a basis for hysteresis is expected to be closest to correct when

FIGURE 20.16 Characteristics of the Zener model.

applied to those cases in which variations in strain are almost continuous. The materials of rheological type for which this appears to be most true are solids built from long chain polymers, i.e., various plastics. Such materials can yield surprising results, however. Shown in Figure 20.17 are results from a study that used a nylon monofilament sample (8-lb fishing line). The pair of torsional free-decay records corresponds to two different temperatures — 290 K (room temperature) and 390 K (above the glass transition temperature of the nylon). Although a significant increase in the period was observed as the temperature was increased above the glass transition temperature (changing from 18.2 to 27.8 sec), the logarithmic decrement was found to be almost unchanged. This was not in keeping with the expectation that softening of the material at the higher temperature would result in significantly greater damping. The effect is just the opposite of what was mentioned concerning cast iron, which, though very hard, does not have small damping. Here, a softening does not result in significantly increased damping.

Although there was some creep observed for both the decays of Figure 20.17, the creep was more pronounced in the higher temperature case. This is illustrated by the lower curve of the bottom graph, which is a computer fit in which the secular term necessary for best fit was removed to illustrate the creep. In both decay cases, the log decrement was calculated by importing the A/D data (Dataq DI-154RS) to Excel and then using trial and error adjustment of parameters to achieve the best fit.

Although the damping of glasses is normally treated using the theory of viscoelasticity, Granato (2002) has recently modeled these materials via defects. In his paper, Granato states the following: “As dislocations carry the deformation in crystals, interstitials are the basic microscopic elements carrying the deformation in glasses near and above the glass temperature.”

20.16.4 Failure of Viscoelasticity

Unfortunately for the elegant theory of the Zener model that has been presented, there are many mechanical systems for which the Q is not proportional to frequency, but rather proportional to the square of the frequency. The logarithmic decrement ($\Delta = \pi/Q$) has been measured for a host of

FIGURE 20.17 Torsional free-decay records of monofilament nylon at temperatures first below and then above the glass transition temperature. Although the modulus decreased dramatically at the higher temperature, the damping did not.

long-period mechanical oscillators, configured as some form of a pendulum. In all cases, these systems were described approximately by $\Delta = \beta T \alpha T^2$ rather than by $\beta T \alpha T$. Similar behavior has been noted in mechanical oscillators other than the pendulum — for example, in the geophysics research of Gunar Streckeisen and Erhard Wielandt, who are well known for the development of the widely employed STS-1 seismometer. During his pursuit of the Ph.D., Streckeisen (1974) measured the numerical damping (fraction of critical damping) of a vertical Sprengnether long-period seismometer 5100-V. After removing the magnet of the velocity transducer (to eliminate eddy currents and reduce viscous air damping, he found that the numerical damping was proportional to the square of the period between periods of 7 and 140 sec. He took about 30 measurements over this interval of periods, and showed that the damping increased from about 0.0008 to about 0.3 — a factor of roughly 400, not 20 as one would expect for viscous damping. To quote Wielandt (private communication), “the data are very clear.”

20.17 Toward a Universal Model of Damping

20.17.1 Damping Capacity Quadratic in Frequency

The quadratic dependence on frequency of Q (log decrement proportional to period squared) is equivalent to friction force being frequency-independent. In support for the claim of universality, it was noted in the Introduction (Section 20.2.2) that three very different systems showed this characteristic: (i) the vertical seismometer just discussed, (ii) various pendula, and (iii) the rotating rod direct measurement of internal friction first done by Kimball and Lovell (1927), who measured the transverse deflection of the end of a rod when it was rotated about a horizontal axis.

20.17.2 Pendula and Universal Damping

An example of one of the author's experiments that illustrate universal (hysteretic) damping is provided in [Figure 20.14](#). Other works that illustrate hysteretic damping include those by Peter Saulson of Syracuse University, who has been frequently cited in the literature (see Saulson et al., 1994).

The pioneering work of Braginsky (important to LIGO) has already been mentioned in the context of small force measurements and noise. He and his Moscow group members argue that the internal friction in fused silica may be roughly independent of frequency from 0.1 Hz to 10 kHz (Braginsky et al., 1993).

An oft-cited paper speaking to the issues of hysteretic damping is an article by Quinn et al. (1992) concerned with material problems in the construction of long-period pendula. (The type of pendulum on which they based their studies was first described in the scientific literature 2 years earlier (Peters, 1990).) In a follow-on paper, Speake et al. (1999) state the following: "The analogues of anelasticity and its resultant $1/f$ noise are seen in a wide range of other processes (for example, dielectric and magnetic ones) described in terms of frequency-dependent susceptibilities."

The jerkiness (discontinuous change) that is the hallmark of the Barkhausen effect may have been first seen mechanically in the experiments that generated the metastable states paper. From a consideration of the chapter by James Brophy (Brophy, 1965), it was postulated in this 1990 paper that the jerky behavior of a mesodynamic pendulum is a type of mechanical Barkhausen effect.

20.17.3 Modified Coulomb Model — Background

The results that follow grew naturally out of the application of fully differential capacitive sensors to the study of mechanical oscillators. Efforts to model internal friction influence on long-period pendula uncovered something surprising to most — that the foundation for physics laid by Charles Augustin Coulomb may be much broader than had been realized. Most individuals in the physics community do not associate Coulomb's name with contributions other than to the laws of electrostatics. Engineers, however, have long used his name in the context of sliding friction, since, in fact, Coulomb gave us the empirical description which involves static and kinetic coefficients. Because of his interest in the civil engineering of soils (Heyman, 1997), Coulomb also provided something else — a basis for understanding granular flows and even some types of fracture. Concerning the latter, the Mohr criterion, applied to the Coulomb failure envelope, defines a "coefficient of internal friction," which is used to predict brittle failure (Gere and Timoshenko, 1996).

Coulomb friction is empirically simple, at least as a first approximation, since it depends only on the normal force between surfaces and the algebraic sign of the velocity when there is relative motion. Like so many problems of multibody type, a complete theory of sliding friction is far from being realized. Simplistic textbook efforts to explain energy loss, by picturing "hills and valleys" of the surface of two solids in contact, are useless. An example of such naivete can be realized by trying to understand the phenomenon of optical contacting. Two orthogonally oriented fused silica cylindrical fibers, allowed to touch, can experience atomic bonding forces that are surprisingly strong, being much greater than the weak attraction of the van der Waals type. Cleanliness of the surfaces is paramount for success in such a demonstration, which speaks to another issue — a connection between internal friction and surface physics.

The conversion of mechanical energy to thermal energy must involve nonlinear (avalanche or cascade) processes. A heuristic description of defect structural interactions that generate heat and eventual failure is the phonon triangle of Tom Erber (Illinois Tech University) shown in Figure 20.18. The author has

FIGURE 20.18 Heuristic description of how materials fail — processes connected with damping.

extended Erber's triangle to include the larger-scale Earth in an attempt to explain earthquakes. Everybody recognizes that the bending of a wire does not take it from the virgin initial state to the failed state along the macroscopic upper leg.

There must first be a downward path to the microlevel, through cascading. These cascades can cause Barkhausen noise in the case of ferromagnetic samples, and acoustic emission in nonmagnetic metallic alloys (PLC effect). Failure requires the upward path of defect organization, the mechanisms of which are not yet understood. One of the first theories with possible implications to the organization leg is that of self-organized criticality. In the magnetic case, Erber has used a fluxgate magnetometer to improve failure predictions, since magnetic hysteresis is proving to be a sensitive indicator of mesoscale structure changes during cycling toward failure. Inferred from these studies is some yet-to-be discovered connectivity between noise, damping, and failure.

Surface friction is expected somehow to be connected with internal friction, the biggest difference being that the surface has many more defect states with which to redistribute energy. The larger density of states of the surface (reduced order) is probably an important factor in the difference between surface friction and the modified internal friction model which follows.

20.17.4 Modified Coulomb Damping Model — Equations of Motion

In the following damping model for internal friction, Coulomb's law of sliding friction is modified by assuming that the coefficient of friction is not constant, but rather involves the energy of oscillation E in a power law; i.e.

$$m\ddot{x} + cm \left[\frac{2E}{k} \right]^\lambda \text{sgn}(\dot{x}) + kx = 0, \quad E = \frac{1}{2}m\dot{x}^2 + \frac{1}{2}kx^2 \quad (20.51)$$

where c = constant that is different for each λ . For Coulomb (sliding) friction $\lambda = 0$. For amplitude-independent damping of hysteretic type, $\lambda = \frac{1}{2}$. For amplitude-dependent (such as large Reynolds number fluid) damping, $\lambda = 1$. In all cases, if $c \ll 1$ (small damping), the damping capacity is quadratic in the frequency, so that the internal friction $Q^{-1} \sim \omega^{-2}$. Equation 20.51 is easily implemented, in spite of its nonlinearity, which we will see later to be a cause for harmonics in the decay.

It is convenient to rewrite Equation 20.51 in canonical form so as to involve the Q of the oscillator. For the case of hysteretic damping ($\lambda = \frac{1}{2}$), the equation becomes

$$\ddot{x} + \frac{\pi\omega}{4Q_h} \sqrt{\omega^2 x^2 + \dot{x}^2} \text{sgn}(\dot{x}) + \omega^2 x = 0 \quad (20.52)$$

Similarly, for amplitude-dependent damping ($\lambda = 1$)

$$\ddot{x} + \frac{\pi}{4y_0 Q_{f0}} (\omega^2 x^2 + \dot{x}^2) \text{sgn}(\dot{x}) + \omega^2 x = 0 \quad (20.53)$$

where y_0 is the initial value of the amplitude of x (largest maximum of x), and Q_f is found not to be constant, as in the case of hysteretic damping. Rather, in this case, the Q increases as the amplitude decreases. On the other hand, the Q of an oscillator influenced only by Coulomb ($\lambda = 0$, sliding) friction decreases with the amplitude, and the equation of motion in canonical form is given by

$$\ddot{x} + \frac{\pi\omega^2 y_0}{4Q_{c0}} \text{sgn}(\dot{x}) + \omega^2 x = 0 \quad (20.54)$$

In Equation 20.53 and Equation 20.54, the subscript 0 is used to identify the initial value of the time varying Q . Equation 20.54 is equivalent to equation 20.12 with $Q_{c0}/y_0 = \pi/(4\Delta_x)$.

As will be illustrated with some examples, it is possible for an oscillator to be influenced simultaneously by all three types of friction. One may treat such a system with the following equation of motion

$$\ddot{x} + \left[\frac{\pi\omega^2 y_0}{4Q_{c0}} + \frac{\pi\omega}{4Q_h} \sqrt{\omega^2 x^2 + \dot{x}^2} + \frac{\pi}{4y_0 Q_{f0}} (\omega^2 x^2 + \dot{x}^2) \right] \text{sgn}(\dot{x}) + \omega^2 x = 0 \quad (20.55)$$

At any instant during the decay, the total (time-dependent Q) is given by

$$\frac{1}{Q(t)} = \frac{1}{Q_c} + \frac{1}{Q_h} + \frac{1}{Q_f} \quad (20.56)$$

in which it is seen that the smallest Q in the set (largest damping term) is dominant in a manner reminiscent of capacitors connected in series.

It is instructive to look at the analytical solution for the time dependence of the amplitude (turning points, $y(t) = |x_{\max}|$), when all the Q s $\gg 1$. Such a solution is obtained from energy considerations by noting first that the time rate of change of the energy is zero in the absence of friction, i.e.

$$\dot{E} = \frac{d}{dt} \left(\frac{1}{2} m \dot{x}^2 + \frac{1}{2} k x^2 \right) = \dot{x}(m\ddot{x} + kx) = 0, \quad \text{no friction} \quad (20.57)$$

With friction, dE/dt is determined by the rate of doing work against the friction force; i.e., dE/dt is proportional to $\omega y f$, where f is the friction force. In the case of Coulomb friction, f is constant (determined by y_0), so dE/dt is proportional to $E^{1/2}$. For hysteretic damping, f is proportional to y , so dE/dt is proportional to E . For fluid damping, f is proportional to y^2 , so dE/dt is proportional to $E^{3/2}$. Thus, the general case is described by

$$\dot{E} = -(c_1 + c_2 \sqrt{E} + c_3 E) \sqrt{E} \quad (20.58)$$

Because the energy is proportional to y^2 , we can write down the equation for the time varying amplitude as

$$\dot{y} = -c - by - ay^2 \quad (20.59)$$

where a , b , and c are constants. The solution to this first-order equation can be found in integral tables, and the result depends on the size of c relative to the product ab . For present purposes, we will restrict ourselves to the case where Coulomb damping is not dominant, in which the solution involves an exponential. (For large c , one may develop the corresponding general case in terms of the tangent or its inverse.) The present result is as follows, using $r = (b^2 - 4ac)^{1/2}$, where $4ac < b^2$

$$\begin{aligned} \text{with } \alpha &= 2ay_0 + b - r, & \beta &= 2ay_0 + b + r, & p &= \frac{\alpha}{\beta} e^{-rt} \\ y &= \frac{b(p-1) + r(p+1)}{2a(1-p)} \end{aligned} \quad (20.60)$$

In the case where $c = 0$, Equation 20.60 can be simplified to the following form, which is useful for curve fitting:

$$\frac{1}{y} = \left(\frac{a}{b} + \frac{1}{y_0} \right) e^{bt} - \frac{a}{b} \quad (20.61)$$

For the case where $a = 0$, the better form for curve fitting is

$$y = \left(y_0 + \frac{c}{b} \right) e^{-bt} - \frac{c}{b} \quad (\text{until } y = 0) \quad (20.62)$$

Curve-fits based on the modified Coulomb damping model are summarized in Box 20.2.

Box 20.2

CURVE-FIT TO THE TURNING POINTS

If no damping

$$\dot{E} = \frac{d}{dt} \left(\frac{1}{2} m \dot{x}^2 + \frac{1}{2} k x^2 \right) = \dot{x}(m \ddot{x} + kx) = 0, \quad \text{no friction}$$

with damping (E prop. to y^2 , \dot{E} prop. to $\omega y \cdot$ friction force)

$$\dot{E} = -(c_1 + c_2 \sqrt{E} + c_3 E) \sqrt{E}$$

equivalent to (c for Coulomb, b for hysteretic, a for fluid)

$$\dot{y} = -c - by - ay^2$$

general solution

$$\text{with } \alpha = 2ay_0 + b - r, \quad \beta = 2ay_0 + b + r, \quad p = \frac{\alpha}{\beta} e^{-rt}$$

$$y = \frac{b(p-1) + r(p+1)}{2a(1-p)}$$

special case, $c = 0$

$$\frac{1}{y} = \left(\frac{a}{b} + \frac{1}{y_0} \right) e^{bt} - \frac{a}{b}$$

special case, $a = 0$

$$y = \left(y_0 + \frac{c}{b} \right) e^{-bt} - \frac{c}{b} \quad (\text{until } y = 0)$$

20.17.5 Model Output

Shown in [Figure 20.19](#) is a case in which the decay is influenced by all three types of friction. Notice how the Q rises initially, peaks at a value less than what would be true for hysteretic damping alone (constant Q case), and then later declines. The initial rise is due to the amplitude-dependent damping term (size determined by coefficient a), and the later decline is due to the Coulomb damping term (determined by coefficient b).

The code in [Table 20.1](#) that was used to generate Figure 20.19 has been reproduced here for two reasons: (i) to show the ease with which the modified Coulomb model may be numerically applied in general to a damping problem, and (ii) to illustrate an integration algorithm that has proven to be intuitive, simple, and powerful — the Cromer–Euler technique, which Alan Cromer first described as the “last point approximation (LPA)” (Cromer, 1981) in contrast to the unstable “first point approximation” given to us by Euler. Over the last 20 years, the author has employed the LPA in a host of applications that span from the generation of satellite ephemerides in the U.S. antisatellite program to both simple and several-body nonlinear problems of deterministic chaos type.

FIGURE 20.19 Model generated results based on Equation 20.55 and Equation 20.60.

20.17.6 Experimental Examples

The code of Table 20.1 is useful in determining the nature of a given experimental case. Too frequently in the past, it has been naively assumed that the entire decay record was exponential. Particularly when longer records are collected, it is found that most damping is nonlinear. In the two experimental examples that follow to backup this claim, one is a near-perfect (nonlinear) particular case of amplitude-dependent (fluid) damping, and the other is a mixture of amplitude-dependent and hysteretic damping, but devoid of any Coulombic influence. Coulomb friction frequently tends to be either “all or nothing,” depending on whether there is an unwanted mechanical contact that involves slippage. A notable exception is found in the case where a pendulum is influenced by eddy current damping in a narrow region of its total motion (Singh et al., 2002).

The pendulum that was used to generate the data displayed in Figure 20.14 was also used as follows. A large flat piece of plastic was attached to the bottom of the pendulum, so that its movement (normal vector to the surface in the direction of motion) would disturb a great amount of air in turbulent manner. As expected, there was a dominant initial (large level) amplitude-dependent damping, as shown in Figure 20.20.

The speed (maximum) was measured with a photogate as previously discussed. The expressions shown in the figure are consistent with Equation 20.59 and Equation 20.61. The data, which were collected by hand and typed into Excel, produced the “jagged” curve, and the computerized fit according to Equation 20.61 is the smooth curve of the pair. It is noteworthy that the quadratic drag of the air (determined by $a = 0.036$) is 40% greater than the viscous drag at the start of the decay. By cycle 37, the quadratic part has become much less significant than the constant Q viscous part, having become roughly 60% smaller.

The fluid damping “soup-can” pendulum data of Figure 20.21 was generated with a can of Bush’s black-eye peas. The container with enclosed unbroken contents, being a right circular cylinder of length 11 cm \times diameter 7.4 cm, was suspended horizontally by a pair of knife edges under opposing end-lips

(Peters, 2002a, 2002b, 2002c). The motion of the can was measured with an SDC sensor connected to a Dataq A/D converter. Whereas experiments of similar type, with homogeneous fluid contents, have produced viscous decay records, the present case involved only friction of so-called “fluid” type; i.e., quadratic in the “velocity.” To generate the figure, the A/D record was exported to the Microsoft software package, Excel. Fits to the data were then obtained by adjusting, through trial and error, the a , b , and c

FIGURE 20.20 Decay of an air-damped pendulum as a function of cycle number n .

coefficients of a “fit” to the amplitude. For this case, the fit was easily accomplished because both b and c proved to be essentially zero.

The second case, involving an evacuated pendulum, was not a single pure type of damping, but can be seen in Figure 20.22 to have both hysteretic and amplitude-dependent contributions. Although fluid damping is amplitude-dependent in the same manner, with the damping term being proportional to the square of the amplitude, the word “fluid” is not used to describe this case since the system involved exclusively solid materials.

Not all decay records of this pendulum in vacuum yielded a mix of friction types as displayed in the figure. The effect was observed to be transient, and it is speculated that outgassing of components may have been a factor.

FIGURE 20.21 Example of fluid damping of a “soup-can” pendulum. The granular contents (black-eye peas and water) result in a friction force that is quadratic in the velocity.

FIGURE 20.22 Example of a mix of two damping types, hysteretic and amplitude-dependent.

20.17.6.1 Numerical Integration

Instead of integrating the second-order equation of motion twice — first the acceleration, followed by the resulting velocity — more accurate results are obtained by integrating the equivalent pair of first-order equations (also see Chapter 6).

For example, the equation of the simple harmonic oscillator with viscous damping is expressible as

$$\dot{p} = -q - kp \quad \dot{q} = p \quad (20.63)$$

where the position variable has been represented by the generalized coordinate q (x elsewhere), and for the momentum $p = m dq/dt$, and here the mass, m , has been set to unity. Likewise, the spring constant has been set to unity. It is generally useful to distill a given problem to its most basic form when attempting to understand the physics. Constants that provide no useful information for trend analysis purposes are conveniently “normalized.” Such is common practice, for example, in modeling chaotic systems.

The second-order set can always be reduced mathematically to a first-order pair; however, the pair results naturally from the use of the Hamiltonian as opposed to the Newtonian formulation of mechanics.

20.17.7 Damping and Harmonic Content

Equation 20.52 to Equation 20.54 are the nonlinear, modified Coulomb damping model forms that correspond, respectively, to (i) hysteretic, (ii) amplitude-dependent, and (iii) Coulomb damping. The damping term for each of the three cases can be expressed as follows:

$$\frac{f}{m} = \frac{\pi}{4} \frac{\omega}{Q} [v] \quad (20.64)$$

where f is the friction force, and $[v]$ is the square wave whose fundamental in a Fourier series expansion is equal to the velocity of the oscillator times $4/\pi$; i.e., for a square wave $\pm h$, the amplitude of the fundamental is $\pm(4/\pi)h$. We see that all the damping types that have been considered in this chapter, when expressed in canonical form, correspond to a fundamental friction force $f = m\omega v/Q$. The simplicity of this result is probably why viscous damping has been viewed by so many physicists as “inviolable.” One must be careful, however, because (as noted in the previous section) only for the case of hysteretic damping is Q constant. For amplitude-dependent damping $Q_f = Q_{f0}(y_0/y)$ and for Coulomb damping

$Q_c = Q_{c0}(y/y_0)$. The time-dependent Q of nonexponential cases will have significant influence on mode development in many-body systems because of elastic nonlinearity (necessary for mode coupling).

There is another important subtlety of Equation 20.64. When only the fundamental of $[v]$ is retained, equivalent to viscous damping, Q is proportional to frequency. When all odd harmonics are included (full square wave), Q becomes proportional to frequency squared. This means that *harmonics in the friction force are responsible for the primary difference between hysteretic damping and viscous damping*. Something being presently considered is how, in an algorithmic sense, to modify Equation 20.52 to Equation 20.54 to provide for “dispersion,” i.e., means for providing Q dependence other than frequency squared. We posit the following: that hysteretic (exponential) damping is the idealized universal form of damping due to secondary creep. When there is an activation process of Zener (Debye) type, such as dislocation relaxation, then additional terms must be added to the hysteretic “background.” It may be that this can be accommodated by a suitable removal of harmonics from the square wave of the hysteretic case, and it may happen that Q is constant for systems that vary continuously. It is conjectured that the PLC effect, responsible for discontinuous changes, plays a role in those cases where Q is not constant. Equations of motion based on the modified Coulomb damping model are summarized in Box 20.3.

Box 20.3

EQUATIONS OF MOTION BASED ON NONLINEAR DAMPING

Equation of motion in terms of energy

$$m\ddot{x} + c m \left[\frac{2E}{k} \right]^2 \text{sgn}(\dot{x}) + kx = 0, \quad E = \frac{1}{2} m \dot{x}^2 + \frac{1}{2} kx^2$$

Hysteretic-only damping (exponential)

$$\ddot{x} + \frac{\pi\omega}{4Q_k} \sqrt{\omega^2 x^2 + \dot{x}^2} \text{sgn}(\dot{x}) + \omega^2 x = 0$$

Velocity-square (fluid) damping

$$\ddot{x} + \frac{\pi}{4y_0 Q_{f0}} (\omega^2 x^2 + \dot{x}^2) \text{sgn}(\dot{x}) + \omega^2 x = 0$$

Coulomb damping

$$\ddot{x} + \frac{\pi\omega^2 y_0}{4Q_{c0}} \text{sgn}(\dot{x}) + \omega^2 x = 0$$

All three damping types simultaneously active

$$\ddot{x} + \left[\frac{\pi\omega^2 y_0}{4Q_{c0}} + \frac{\pi\omega}{4Q_k} \sqrt{\omega^2 x^2 + \dot{x}^2} + \frac{\pi}{4y_0 Q_{f0}} (\omega^2 x^2 + \dot{x}^2) \right] \text{sgn}(\dot{x}) + \omega^2 x = 0$$

Quality factor

$$\frac{1}{Q(t)} = \frac{1}{Q_c} + \frac{1}{Q_k} + \frac{1}{Q_f}$$

20.18 Nonlinearity

20.18.1 General Considerations

Electrical nonlinearity is the type with which most engineers are familiar. It is the very basis for common nondigital forms of communication, such as that of frequency modulation type. A popular form of radio amateur communication is one in which the carrier and one of the two normal sidebands of a signal are suppressed before going to the antenna. At the receiver, the carrier is “regenerated” before going to the demodulator. The demodulator required for ultimate transduction by speaker is also a nonlinear device.

Nonlinearity of mechanical type is encountered throughout nature. The human ear, for example, is not linear, but rather characterized by both quadratic and cubic nonlinearities. If an intense, pure low frequency (inaudible) sound of frequency f is present with a higher frequency audible one of frequency F , then one typically hears (in addition to F) tones at $F \pm f$ due to the quadratic nonlinearity and $F \pm 2f$ due to the cubic nonlinearity.

Very high frequency acoustics (ultrasound) is employed for studies of elasticity. The quasi-linear features of ultrasonic propagation have been the basis for measuring second-order elastic constants (determined by velocity of propagation) and internal friction (by attenuation of the beam, i.e., damping). A commonly employed ultrasonic technique that has been used to study both linear and nonlinear phenomena is the pulse-echo method. By using a thin specimen and extending the pulse width, the overlapped signal can add constructively or destructively and, in the former case, resonance is approached as the width gets very large (Peters, 1973). The pulse-echo method was the basis for this author's Ph.D. dissertation (“Temperature dependence of the nonlinearity parameters of copper single crystals,” The University of Tennessee, 1968). The distinguished career of his professor, M.A. Breazeale, has focused on ultrasonic harmonic generation as a means to determine the shape of the interatomic potential of solids (Breazeale and Leroy, 1991). A longitudinal wave distorts because of the anharmonic potential (acoustic equivalence of optical frequency doubling with lasers in a KdP crystal). In like manner, phonon–phonon interactions are possible only because of nonzero elastic constants of order higher than second (second-order constants determining the harmonic potential). Because phonon–phonon interactions are part of damping, there must be consequences, at least for some cases, from nonlinear damping terms.

The unifying theme for this chapter is that damping is fundamentally nonlinear, in spite of the fact that linear approximations have prevailed in modeling and, for many purposes these linear models appear to be acceptable (Richardson and Potter, 1975). In their paper, Richardson and Potter state that “... an equivalent viscous damping component can always be derived, which will account for all of the energy loss from the system. Thus, in measuring the modal vibration parameters for the linear motion of a system, we don't care what the detailed damping mechanism really is.”

Although their statement may be true for steady state, it is not expected to be true for the transient processes that lead to steady conditions of oscillation. As demonstrated elsewhere in this chapter, mixtures of different damping types are common among oscillators, and only with viscous or hysteretic damping is the Q independent of amplitude. Other cases may result, for example, from the decay being a combination of hysteretic damping and amplitude-dependent damping. An example used to illustrate this combination was an outgassing pendulum oscillating in vacuum. Similarly, a long, “simple” pendulum, oscillating in air, is found to require a pair of terms — viscous damping and “fluid” damping (Nelson and Olssen, 1986). In the Nelson and Olsson experiment, the drag was found, because of the size of the Reynolds number, to involve both first- and second-power velocity terms. Their case can, incidentally, be treated by the modified Coulomb, generalized damping model of this document.

The presence of either amplitude-dependent damping or Coulomb damping is expected to play a role in determining what modes of a multibody system are actually excited by external forcing. Concerning the latter, Coulomb friction is the basis for exciting chaotic vibrations in mechanical systems (Moon, 1987). Without the nonlinear friction, the excitation would be impossible. In similar manner (although chaotic motion may be present but not in an obvious way), friction from rosin on a violin bow is used to

play the violin. Still another example of similar physics is the “singing rod” that was mentioned elsewhere as exhibiting thermoelastic damping.

Whatever combinations of normal modes are initially excited in a linear system are the only ones that can exist thereafter. Such is not the case, however, for many systems and, since nonlinearity is required for mode coupling, there must be nonlinearity in the equations of motion. There is no question about the existence and importance of elastic nonlinearity. Indeed, thermal expansion would be impossible in the absence of higher order elastic constants. The importance of nonlinear damping remains yet to be quantified, since models to include it have been few in number. For those who have found it advantageous to include the oldest and simplest type of nonlinearity in a damping model — Coulomb damping (sliding friction) — the improvements realized by their choice are unlikely to cause them to revisit the problem and try to solve it in terms of a viscous equivalent linear approximation.

There are many examples of damping of a single type other than viscous. In their efforts to improve the knowledge of the Newtonian gravitational constant $G = 6.67 \times 10^{-11} \text{ Nm}^2/\text{kg}^2$ (approx.), Bantel and Newman (2000) discovered a pure form of amplitude-dependent damping of internal friction type. They did their experiments at liquid helium temperature (4.2 K) and noted the following: “A striking feature noted in our data is the linearity of the amplitude dependence of Q^{-1} for the three metal fiber materials,” and also “Linearity implies that Q may depend on frequency but not on amplitude, while in fact Fig.1 displays a significant amplitude dependence (and hence nonlinearity) of internal friction in all fibers tested.” They also considered the temperature dependence of damping and note that there are two independent contributions in Cu–Be. One is linear and temperature-independent and the other amplitude-dependent and independent of temperature. Finally, it is worth noting their statement, “...our results are strongly suggestive of some kind of ‘stick–slip’ mechanism ...,” which lends strong support to the modified Coulomb internal friction damping model of the present document.

Repetition is felt to be warranted — such systems cannot always be reasonably described by an equivalent viscous form! For a case of amplitude-dependent Q , the equivalent form has no meaning unless the amplitude is fixed, i.e., it oscillates at steady state. Unfortunately, the evolution of the system to steady state is expected to depend on the damping form(s). Surely a model (not yet realized) that predicts what modes survive is worth much more than one which only characterizes the modes after they have reached steady state. The author and Prof. Dewey Hodges of Georgia Tech’s Aerospace School are planning projects to try to develop such predictive capability. The present state of the art applied to structures suggests that a truly predictive model cannot ignore damping nonlinearity.

As demonstrated by Bantel and Newman (2000), the mixture of damping types that can co-exist in a system may change with temperature. Early experiments by Berry and Nowick (1958) also showed, as have many investigators subsequently, that damping generally depends on aging. It is naive to believe that aging would not also change the mix of damping types, when there is more than one type. Thus, an adequate damping model must be able to easily accommodate several damping types that are simultaneously active. A variety of engineering techniques have evolved to treat such problems. The most “successful” ones suffer from the fact that an excessive number of parameters or coupled equations must be adjusted by trial and error to yield decent agreement with experiment. This is reminiscent of the state of high-energy (nuclear) physics before the standard model. The hallmark of physics success has always been *simplification*. As noted by Albert Einstein: “All physics is either impossible or trivial. It is impossible until you understand it. Then it becomes trivial.” It is hard to imagine, however, that certain damping physics could ever become trivial. Nevertheless, the simplifying nature of better conceptual understanding is a goal to strive for.

One of the remarkable things about the majority of damping models has been the absence of a direct consideration of energy in describing the dissipation process. After all, the most important quantity transformed by the damping is energy, so its inclusion is natural.

20.18.2 Harmonic Content

When the damping is nonlinear, the waveform of the oscillator in free-decay contains harmonics. The harmonic content is most obvious in the residuals (difference) after fitting a damped sinusoid to the record, as shown in [Figure 20.23](#).

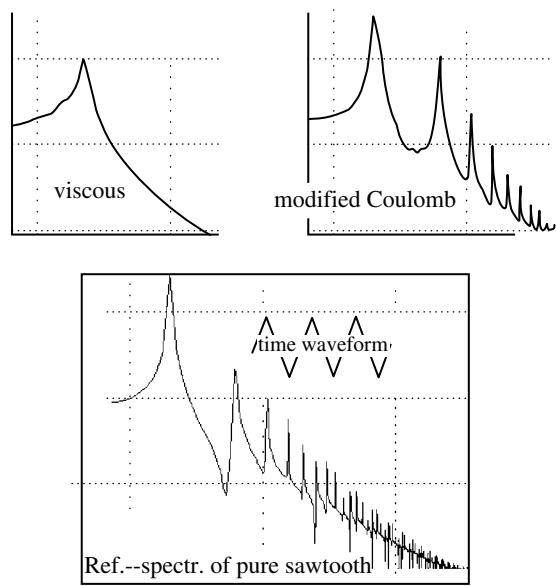

FIGURE 20.23 Harmonic differences between the residuals of the modified Coulomb damping model and the classic viscous damping model. For reference purposes, a pure sawtooth is included in the figure.

Residuals are still present for the viscous case because the equation of motion was integrated numerically and compared against the classic exponentially decaying sinusoid (solution to the equation) that was used for fitting in all cases. There is always some degree of mismatch with the fit because of rounding errors in the computer. In Figure 20.23, the fundamental is smaller for the viscous case because the fit is inherently more perfect by about an order of magnitude in most of the “eye-ball” fits that were performed by Excel after importation of the data.

A test for harmonic content was performed on the seismometer (17-sec period) data displayed in Figure 20.11 illustrating phase noise. The power spectrum of the residuals for that case is shown in Figure 20.24.

The third harmonic is especially noticeable in this case. That the other harmonics are not so “cleanly” displayed may result from the significant phase noise of the record.

FIGURE 20.24 Power spectrum of residuals, Sprengnether vertical seismometer free-decay, showing harmonic content.

By looking at the FFT of residuals, rather than the experimental record itself, one finds evidence for a combination of both mechanical and electronic noise. At lower frequencies, the noise (largely mechanical) is approximately $1/f$, while at higher frequencies the noise (largely electronic) begins to be more nearly “white” (frequency-independent) because of discretization errors of the resolution-limited 12-bit A to D converter.

In general, more spectral information can be gleaned from a consideration of the residuals than from the experimental data alone, particularly as one looks for harmonic distortion of mechanical type. Spectral “fingerprints” may prove ultimately useful in determining to what extent damping models of engineering type need to be implemented in full nonlinear form as opposed to an “equivalent viscous” form that is more convenient mathematically.

The importance of the harmonics observed in Figure 20.24 in determining system evolution is not completely known. It was noted earlier that they are expected to influence the evolution of a multibody system to steady state. Presently, it appears that they may serve to validate damping models. From one model type to another, there can be significant differences in the spectral character of the residuals, as shown in Figure 20.25. As compared with Figure 20.23, the fit with the modified Coulomb (hysteretic case) model has been tweaked to reduce the fundamental somewhat, but the odd harmonics remain significant. Observe that the spectrum of the residuals is almost the same for this model and the simplified structural model (see de Silva, 2000, p. 354). This is true even though the temporal variation of the friction force is dramatically different for the two, as seen from the lower time traces that were used to obtain the residuals (which are too small to be seen in the graphs).

From this author’s perspective, the simplified structural model is unrealistic, since the friction force, given by $f = c|x|\operatorname{sgn}(\dot{x})$, vanishes for zero displacement (the absolute value of the displacement being used to get the hysteretic form of frequency dependence). This is seen in Figure 20.26, which compares hysteresis curves for several models. The modified Coulomb case shown is slightly different from Equation 20.52 that was used to generate Figure 20.25; Figure 20.26 was generated with the A_{prev} shown in Equation 20.10.

More studies of this type are obviously called for. The spectrum of residuals is a powerful means for the study of damping physics, and it needs to be more widely employed.

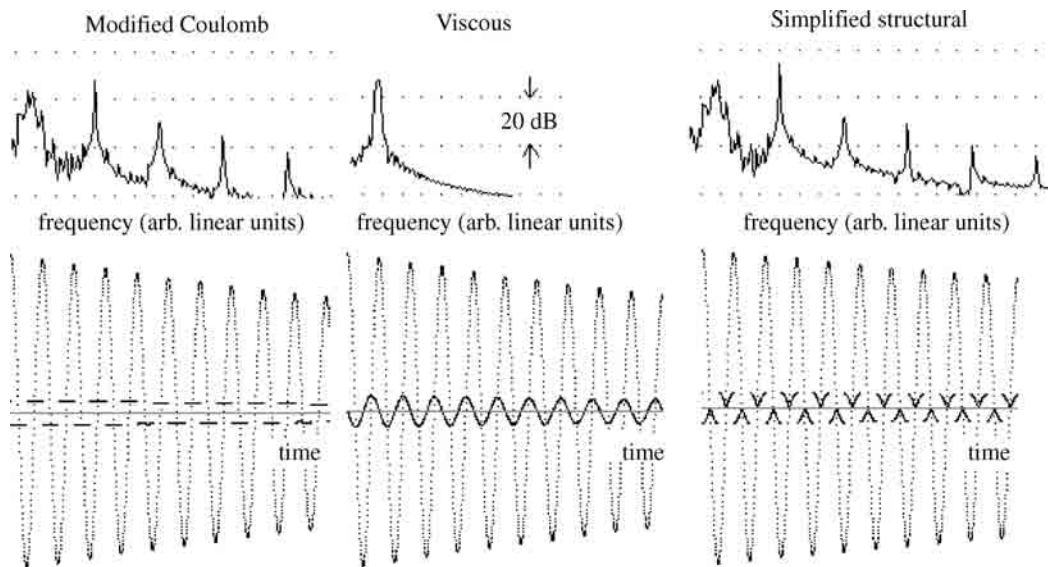

FIGURE 20.25 Illustration of the spectral difference of the residuals for three different damping models. The corresponding temporal records used to generate the spectra are also shown underneath each case.

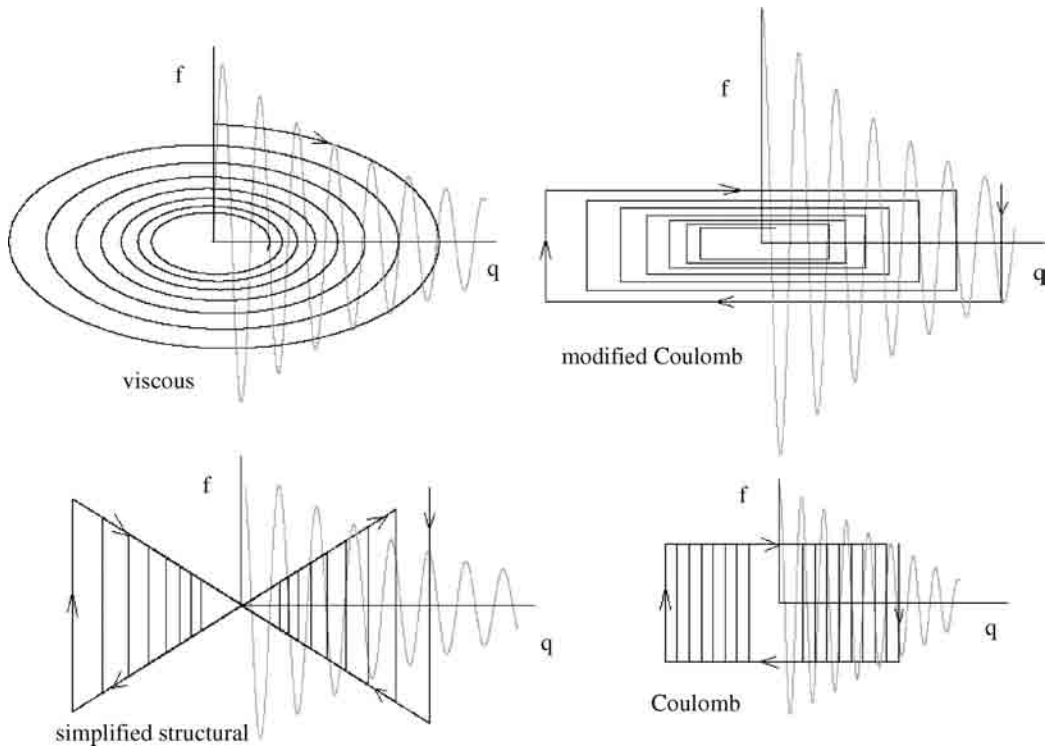

FIGURE 20.26 Comparison of hysteresis curves for some damping models.

20.18.3 Nonlinearity/Complexity and Future Technologies

Nonlinear damping models must improve if we are to overcome various technological barriers. One barrier is in the area of civil engineering. One of the pioneers of finite element modeling (FEM) is Prof. Emeritus Edward L. Wilson, of the University of California Berkeley. In Technical Note 19 (pertaining to “structural analysis programs”) — a document published by his company Computers and Structures Inc — Dr. Wilson says the following:

Linear viscous damping is a property of the computer model and is not a property of a real structure.

Expanding upon the statement, he notes:

the use of linear modal damping, as a percentage of critical damping, has been used to approximate the nonlinear behavior of structures. The energy dissipation in real structures is far more complicated and tends to be proportional to displacements rather than proportional to the velocity. The use of approximate “equivalent viscous damping” has little theoretical or experimental justification...the standard “state of the art” assumption of modal damping needs to be re-examined and an alternative approach must be developed [in reference to Rayleigh damping].

One of the hi-tech areas where modeling improvements are also sorely needed is that involving miniaturized mechanical systems. For example, MEMS devices have already encountered some of the “strange phenomena” of solid-state physics mentioned by Richard Feynman in his famous 1959 talk. To master or compensate for these phenomena, better understanding of the physics will be necessary.

20.18.4 Microdynamics, Mesomechanics, and Mesodynamics

At least three different broad fields of research have focused on problems associated with the structural defects that cause hysteresis. These are as follows.

20.18.4.1 Microdynamics

In the microdynamics world, the emphasis appears to have been primarily on “contact” friction. The 6th Microdynamics Workshop held at the Jet Propulsion Laboratory in 1999 produced the following statements (quoting Marie Levine’s Program Overview): (1) “We have demonstrated that microdynamics exist. The next step is to qualify and quantify microdynamics through rigorous testing and analysis techniques.” (2) Microdynamics is “defined as sub-micron nonlinear dynamics of materials, mechanisms (latches, joints, etc.) and other interface discontinuities.”

In this workshop, it was noted that frequency-based computational methods *cannot* be used to model quasi-static, transient, and nonstationary disturbances. One of the flight operations they have recommended to minimize adverse effects of microdynamics is dithering.

20.18.4.2 Mesomechanics

Ostermeyer and Popov (1999) have the following to say about mesomechanics: “Real physical objects inherently possess discrete internal structures. Great efforts are needed to formulate continuum models of really granular bodies. The history of the last two centuries in a multitude of ways has been marked by highly successful attempts at formulating and analyzing the continuum models of the discrete world. In spite of great advances of continuum mechanics, a number of physical processes are amenable to simulation within the framework of continuum approaches only to a very limited extent. Among these are primarily all the processes whereby the medium continuity is impaired; i.e., those of nucleation and accumulation of damages and cracks and failure of materials and constructions.”

Their paper speaks to one of the difficulties concerning granular materials that was mentioned earlier in this chapter — that the potential energy cannot be defined in the common manner. They introduce a temperature-dependent nonequilibrium interaction potential that is not constant in time due to the relaxation processes occurring in the system.

20.18.4.3 Mesodynamics

The author of this chapter is singlehandedly responsible for the use of the term “mesodynamics” in the context of mechanical oscillators. His research has been conducted independently of those doing mesomechanics; he came only recently to know of the latter. Whereas mesomechanics seems to have been largely concerned with failure, mesodynamics has been concerned with low-level hysteresis. It is probably closely related to the aforementioned microdynamics, except that the latter seems to have focused on surfaces (sliding friction), whereas mesodynamics is concerned with internal friction.

A group of individuals using “mesodynamics” to describe some of their computational physics is part of the Materials Science Division of Argonne National Laboratory. Their description of computational theory includes: (i) atomic-level simulation (using molecular dynamics); (ii) mesoscale simulation, i.e., “mesodynamics” (using FEM); and (iii) macroscale (continuum) simulation (FEM). Like the author of this chapter, they recognize that the mesoscale is not a continuum (meaning, for example, that the foundation of viscoelasticity is, for many cases, on shaky ground). They employ “dynamical simulation methods in which the microstructural elements (grain boundaries and grain junctions) are considered as the fundamental entities whose dynamical behavior determines microstructural evolution in space and time.”

At the Theoretical Division of Los Alamos National Laboratory, Brad Lee Holian has been modeling mesodynamics via nonequilibrium molecular-dynamics (NEMD). In his paper, “Mesodynamics from Atomistics: A New Route to Hall-Petch,” he notes that (i) the mesoscopic nonlinear elastic behavior must agree with the atomistic in compression; and (ii) the mesoscale cold curve in tension represents surface, rather than bulk cohesion, thereby decreasing inversely with grain size (Holian, 2003).

The complexity of mesodynamics, which this author has labeled “mesoanelastic complexity,” is responsible for much of the aforementioned “strange phenomena.” To those familiar with the Barkhausen effect and the PLC effect, they are less strange. It is thought that Richard Feynman, if he were still alive, would identify with mesodynamics because of material in his three-volume series (Feynman, 1970). For example, we have already noted his discussion of the Barkhausen effect, and he included in its entirety a reprint of the Bragg–Nye paper on bubbles which show two-dimensional defect structures such as dislocations, “grains,” and “recrystallization” boundaries after stirring (Bragg et al., 1947).

Another famous individual, whose work related in an unexpected way to the material of this chapter, was Enrico Fermi. In one of the first dynamics calculations carried out on a computer, he and colleagues treated a chain of harmonic oscillators coupled together by a nonlinear term (Fermi, 1940). The continuum limit of their model is the remarkable nonlinear partial differential equation known as the Korteweg–deVries equation, whose solution is a soliton, used to advantage in optical fibers. Damping of solitons, whether of the KdV type or the Sine Gordon (kink/antikink) type, is not to be described by linear mathematics. Incidentally, the Sine Gordon soliton is used in modeling dislocations (Nabarro, 1987). The earliest theory to describe dislocation damping using kink/anti-kink pairs was that of Seeger (1956).

20.18.5 Example of the Importance of Mesoanelastic Complexity

As noted earlier in this chapter, once hysteretic damping was finally recognized to be important to the Cavendish experiment, better agreement with theory and experiment was possible. Curiously, Henry Cavendish may have been the first person to encounter a “strange” phenomenon (which he did not discuss) (Cavendish, 1798). In his first mass swing to perturb the balance, which used a “fiber” made of copper (silvered), there was an anomalously small period of oscillation that was only 55 sec. The period reported for subsequent trials was about 421 sec.

Whereas the Michell–Cavendish apparatus was a torsion balance, the instrument of Figure 20.27 is a physical pendulum. The perturbing masses, M , were hung from a bicycle wheel whose axle was suspended from the ceiling. The long-period pendulum was placed under a bell jar so that the instrument would not be driven by air currents. By rotating the wheel at constant angular

velocity, the driving force on the pendulum was harmonic. (In the figure, the position of each M one-half period later are shown by the dashed circles.) Knowing the amount of damping, as determined from large amplitude free-decay, it was easy to estimate the number of orbits of the bell jar, at the resonance frequency of the pendulum, required to excite motion to a level above noise in the sensor. Surprisingly, if it were initially at rest, no amount of drive by this means was able to get the pendulum oscillating! The reason involves metastabilities of the defect structures. The potential well is not harmonic (parabolic), but is rather modulated by “fine structure.” When located in a deep metastability, the small gravitational force of the drive (in nanoNewtons) is not able to “unlatch” the system. If the pendulum had been dithered (a practice used in engineering) this problem could have been, at least partly, avoided. As it was, the pendulum rested on an isolation table of the type used in optics experiments.

FIGURE 20.27 Physical pendulum used in the late 1980s to try and measure the Newtonian gravitational constant.

More recently, a Hungarian research team has used a similar apparatus and postulated that the anomalies of their experiment derive from gravity being other than prescribed by Newton (Sarkadi and Badonyi, 2001). Although they claim that there is a “strong dependence of gravitational attraction on the mass ratio of interacting bodies,” this author believes that additional experiments must be performed before such a claim has merit. It may be that the anomalous behavior of their pendulum is instead the result of mesoanelastic complexity, i.e., phenomena related to nonlinear damping.

The author’s most recent research on damping complexity is based on the premise that the most important scale for the treatment of internal friction is the mesoscale, and not the atomic scale (Peters 2004). Experiments to support this position center around a study of the SMA NiTiInol.

20.19 Concluding Remark

Much of the material of this part of the chapter on damping is clearly not appropriate to direct engineering application. It was deemed important to present some of the extensive background information responsible for birthing the practical equations of Section 20.17. In [Chapter 21](#), the reader will find practical aids to the measurement of damping.

Summary

This chapter is a continuation of [Chapter 20](#) and is concerned with practical experimental techniques for measuring damping. It begins with a discussion of the requirements placed on electronics. After demonstrating the importance of sensor linearity using a computer simulation, the issues of data acquisition and processing are addressed. The power of the Fast Fourier Transform is illustrated, not just for spectral analysis, but also (in “short time” form) for measuring the damping of each component when a system oscillates with multiple modes. Various sensor types are discussed in relation to their advantages and disadvantages for specific applications through the treatment of seven different systems studied in free decay. These seven cases differ with respect to factors such as (i) eigenfrequency, (ii) material type, and (iii) method of estimating the logarithmic decrement, and thus the Q of the decay. In the case of some solids, damping is shown to result largely from defects in the structures. A powerful test for nonlinear damping is demonstrated: simply looking at a graph of Q to see whether it changes with time. Two examples of driven oscillators are given. The first being very nearly linear, and the second being highly nonlinear, due to an anharmonic restoring force involving magnets plus several simultaneously acting damping mechanisms. The nonlinear system is used to illustrate difficulties in interpretation that can arise in driven systems due to

phenomena such as frequency and/or amplitude jumps involving hysteresis. Then an illustration is given of how elastic-type nonlinearities may couple with damping-type nonlinearities in order to determine which modes of a complex system survive during the transient approach to steady state. Mechanical noise, another important feature of nonlinear damping, is also examined. The magnitude of the $1/f$ character in an evacuated pendulum is shown to decrease with time, as the oscillator is allowed to stabilize against creep. The final sections address the common misconception that viscous air friction is the most important form of mechanical oscillator damping. Cases are chosen to demonstrate that (i) internal friction is nearly always also important, if not the most important, and moreover, that (ii) fluid damping is rarely simple — involving the density as well as the viscosity of the fluid. It is shown that damping has a complicated frequency dependence, as opposed to the simple (overly idealized) form predicted by common theory.

21.1 Electronic Considerations

21.1.1 Sensor Linearity

The importance of sensor linearity is often overlooked (see Chapter 15). It is naively assumed that one can simply employ a lookup table to provide calibration corrections. This assumption can result in serious misinterpretations of spectral data, especially in a multimode system. A classic example of artifacts (nonreal signals) that result from a nonlinear sensor is to be found in the ear. The phenomenon, known as aural harmonics, is well known to musicians and figures in the use of “fortissimo” and “pianissimo” in orchestral music. In this chapter we describe how the artifacts mentioned in Chapter 20 are generated. Figure 21.1 illustrates differences according to the nature of the nonlinearity.

The only “real” signals in Figure 21.1 are at frequencies f_1 and f_2 . The number and type of other “unreal” (artifact) signals depends on the type of nonlinearity. The sensor response for the left graph (quadratic) is of the form $V = ax + bx^2$, whereas for the right graph $V = ax + bx^2 + cx^3$. The influence of terms other than $V = ax$ (ideal, linear output voltage) was generated by (i) simulating the pair of harmonic signals, (ii) inputting these signals to each simulated sensor, respectively, and (iii) performing a Fast Fourier Transform (FFT) on the output.

Although it is possible to understand mathematically the various artifacts using trigonometric identities, the phenomenon is much easier to demonstrate with a computer. For Figure 21.1, all

Simulated harmonic distortion from Sensor Nonlinearity

FIGURE 21.1 Spectral illustration of sum and difference artifact frequencies according to nonlinear sensor type.

numerical operations were performed with code written by the author using QuickBasic. It was used to (i) simulate the harmonic signal that was written to a data file, after which it was (ii) read by the FFT algorithm based on the details supplied in *Numerical Recipes* (Press et al., 1986).

21.1.2 Frequency Issues

The choice of a sensor depends largely on the frequencies to be measured. For higher frequencies an excellent instrument for data collection is a digital (storage) oscilloscope, where a microphone can often be directly connected to the instrument. At lower frequencies, a serial-port analog-to-digital converter (ADC) is generally adequate and user-friendly. Examples of each will be provided. The majority of examples considered in this chapter involve low frequencies, where the eigenmode is typically described not in terms of frequency but rather the period (reciprocal of frequency).

21.1.3 Data Acquisition

In the absence of sophisticated data collection and analysis tools, the true character of damping is not readily discovered. Proper characterization is important, since a crude estimate of the damping, based on a single parameter (such as the viscous linear model), may be inappropriate if the oscillator is driven at places (either frequency or amplitude) other than where the parameter was measured. Some of the examples from the experiment that follows were selected to demonstrate the importance of nonlinearity. The probability that an oscillator, selected at random, might have a Q that varies in time is proving to be more significant than anticipated. Were it not for dramatic improvements in numerical-type technology, this improved understanding of damping would not have been possible.

As with computer technology in general over the last decade, ADCs have become much more powerful. The Dataq model 700, for example, is superior (at lower frequencies) to many of the “plug-in” boards of the previous generation that were several times more expensive. The Dataq ADC operates through the USB port (Windows 98 and later), has 16-bit resolution and the software support is excellent. Especially useful for the present purposes are its ability to (i) easily perform data compression with which to view long records, (ii) quickly compute an FFT according to different, useful options, and (iii) easily output files to a spreadsheet.

21.2 Data Processing

21.2.1 Language Type

The author’s experience with software began with early computers and even included the loading of the Fortran compiler of a PDP-11 using punch-tape. He has programmed computers (or hardware-specific processors) with (i) machine code, (ii) assembly language, (iii) Fortran, and (iv) Basic, and he has acquired a rudimentary knowledge of Pascal and C++. The drudgery of machine coding was a factor in his quest to better understand the Fourier transform (Peters, 1992, 2003a, 2003b, 2003c, 2003d). His philosophy with regard to numerical methods is similar to his view of hardware: choose the simplest package (lowest level of sophistication) consistent with the desired results for the problem at hand. The reader may be surprised to learn that QuickBasic (which some have modernized to Visual Basic for Windows) is his favorite language. Nearly all simulation results presented in this chapter were generated with the DOS version of QuickBasic.

21.2.2 Integration Technique

Too few have discovered the powerful integration scheme in which Cromer (1981) modified the unstable Euler algorithm. The difference between the two methods involves the sequencing (order) of updates to the state vectors in the discrete approximation of the integrals. The method was called the “last point

approximation” (LPA) by Cromer, whereas the Euler technique would be called the “first point approximation” according to this nomenclature. The LPA was discovered by a high school student working for Cromer. She was attempting to simulate planetary motion with the Euler method and accidentally coded the LPA. The author first used the LPA to do intercept analyses for the U.S. antisatellite program — computing, among other things, orbital ephemerides. More recently he has used it in place of Runge Kutta techniques to do all kinds of mechanical system simulations, including nonlinear types with several DoF. A physics theorist at Texas Technical University, Professor Thomas Gibson, now regularly uses the LPA as part of the graduate-level course which he teaches in numerical methods.

21.2.3 Fourier Transform

With the Cooley–Tukey improvement to make it fast, the Fourier transform has become a tool of major software importance. Just as the integrated circuit dramatically changed hardware development, the FFT has had a profound influence on the evolution of scientific code.

Whereas many recognize the value of the FFT for viewing “raw” spectral data, few have discovered other powerful tools based in the FFT. For example, autocorrelation is unrivaled in its ability to uncover low-frequency signals of fairly short duration that are corrupted by noise. The number of cycles is not great enough (Heisenberg effect) for a well-defined line to be observed in the FFT by itself. Through the Wiener–Khinchin theorem, the autocorrelation overcomes this limitation. It is computed by multiplying the transform by its conjugate and then taking the inverse transform. The author has used this technique to study free oscillations of the earth (Peters, 2004).

21.2.3.1 Short Time Fourier Transform

A powerful software tool is one in which the Fourier transform is not computed over the entire length of a record. Instead, the record is subdivided (usually with some degree of overlap between adjacent subsections), and the FFT is computed for each subsection. Because the data are generally of the temporal (rather than spatial) type, the technique is called the short time Fourier transform (STFT). For equivalent processing, where the independent variable has units of meters rather than seconds (as in optics applications), the technique could just as well be called the short space Fourier transform.

The STFT is especially useful when waveforms are not pure harmonic, as from a single-degree-of-freedom (single-DoF) oscillator. For systems with multiple modes, whether they derive from eigenmodes as recognized by most, or from mechanical noise as recognized by a few (generated as part of the internal friction of load bearing members); the STFT is a powerful means for isolating and thus determining the temporal history of individual spectral components.

The most common form of the STFT is the canned programs that are a part of software packages such as LabVIEW. With the Dataq software it is easy to accomplish the same thing manually, since one can readily step in time from place to place of a stored record, computing the FFT at any position. The intensity at a given position is obtained by clicking on the displayed spectral line of interest, which provides the value either in dB (Dataq version) or in volts. The amplitude history in dB of the line is thus obtained (equally spaced-in-time values) with a simple click of the mouse. In this way, the free decay of a single component of the system can be readily extracted from the total system response. For the present purposes, the individual intensities were copied by hand to paper and later typed into a spreadsheet for plotting. The process is not laborious, since the number of necessary points is typically less than two dozen.

An example of a manually generated STFT is provided in [Figure 21.2](#). Unlike the methodology described above (operating on experimental data residing in a Dataq folder), the record of Figure 21.2 was generated by computer and written to an output file. The data correspond to three superposed, exponentially damped sinusoids.

From the upper graph (time record), it is not clear how the individual components are changing with time. The triplet of components becomes obvious in the frequency domain (lower left), and when the

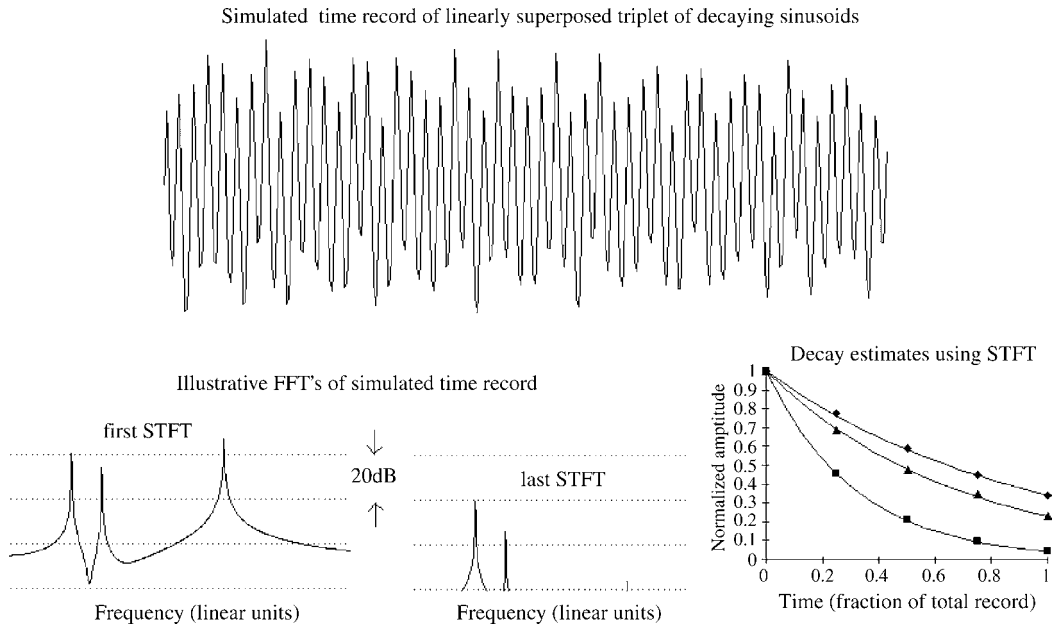

FIGURE 21.2 Example of separating the time decay of superposed components using the STFT.

intensities of each line are plotted *versus* time (lower right) the exponential character of each becomes visible. To test the viability of this method, the individual damping parameters were evaluated from a given STFT graph and found to be in excellent agreement with the values supplied to the simulation.

21.2.3.2 Example Use of the STFT

The majority of the examples given in this chapter avoid low-energy oscillations as space does not allow mesoanelastic regimes to be treated at length. The following case was chosen to illustrate (i) the importance of the Portevin–LeChatelier (PLC) effect on damping (Portevin and Le Chatelier, 1923), and (ii) the power of the STFT in eliminating the influence of clutter. The STFT benefit was expected, since the difference between a noisy record and a multimode case like the previous example is in the number of modes. The PLC effect is significant for high-energy internal friction dissipation even though the jumps for which the effect is known are not obvious at these energies. Evidently, this is a consequence of the large number of events, for which the average effect is a fairly smooth decay.

The scales for the two graphs of Figure 21.3 are different by nearly three orders of magnitude, with the level of the sensor output for each case being indicated (mid-range values). Two features are evident from a direct visual inspection: (i) the change from a smooth to a jerky decay in going from high to low levels, and (ii) a 4% increase in the frequency of oscillation at the lower energy. The latter is recognizable from the vertical lines that have been added (every fifth peak). One of the more interesting (and surprising to most) features of the lower graph is that phase of the oscillation is not significantly altered as the result of mean position jumps.

The following information is provided for those skeptical of the comments concerning the lower trace of Figure 21.3. From the study of hundreds of low-level decays in different mechanical oscillators, the author has become confident that the jumps shown are not sensor (or other electronic) artifacts. Prejudice against this conclusion has been considerable over the last 14 years, in spite of the fact that a similar phenomenon was noted (and accepted) in magnetic materials many years ago, i.e., the Barkhausen effect (Barkhausen, 1919). Unfortunately, the related phenomenon in mechanical systems (PLC effect) is hardly known among physicists.

FIGURE 21.3 Illustration of the character changes in decay in going from high to low energies of a pendulum.

The value of the STFT for the study of data such as that of Figure 21.3 is illustrated in Figure 21.4. Whereas Figure 21.3 showed only the first and the last portions of a long record, here the STFT was applied to the entire record using 27 different FFTs.

As seen in the upper left curve, there is a sharp decrease in the damping in STFT No. 5. Thus, the intensity was replotted in each of the intervals from 0 to 5 and 5 to 27. Both intervals show a near perfect linear trendline fit, indicating exponential decay. Thus the Q was found to quickly change from 78 to 340 at an energy level in the region of 10^{-10} J. Although air damping was a factor in the early part of the record, it is not thought to be capable of causing the rapid change in Q that was observed. A similar sharp

FIGURE 21.4 Example of the use of STFT analysis applied to a dataset, the first and last portions of which are shown in Figure 21.3.

change in the damping of this same pendulum was seen at roughly 10^{-11} J with the pendulum swinging in a high vacuum. The slope change was equally rapid for the vacuum case, but the change in Q was from 120 to 210. It is not known why the damping at low-level energy in a vacuum would have a lower Q than in air. Perhaps the difference derives from a different placement of the knife-edges on the silicon flats. Some of the damping of this pendulum is the result of the knife-edges being fabricated from brass rather than a harder metal such as carbon steel.

21.3 Sensor Choices

Box 21.1 shows some representative sensors for damping measurements. The list is far from exhaustive; for a detailed description of each (plus discussion of other types), the reader is referred to Fraden (1996). Of the transducer types indicated, position sensors are generally the most versatile; but the present chapter also provides examples of the use of (i) velocity, (ii) microphone, and (iii) photogate measurements.

In addition to the need for linearity (discussed in Section 21.1 above), the ideal sensor will be noninvasive. In reality, it is not possible to perform a measurement that does not at some level perturb the system under study. The least perturbative types of direct measurement are optical and electrical — capacitive, followed by inductive.

Some of the advantages and disadvantages of the devices indicated in Box 21.1 are provided below.

Box 21.1

SOME SENSOR TYPES

Representative Sensors for Damping Measurements					
Position	Velocity	Pressure	Time Interval	Acceleration	Force/Strain
Capacitive	Faraday law (electromagnetic)	Microphone	Photogate	Accelerometer	Strain gauge
LVDT		Pressure gauge			
Optical		Capacitive			
Encoder		Optoelectronic			
Shadow		Piezoresistive			
Potentiometric					

21.3.1 Direct Measurement

21.3.1.1 Position Sensors

The inductive linear variable differential transformer (LVDT) is a sensor that is commonly used in engineering applications. Thus, it has been a natural choice for many position-sensing purposes; but it is both more invasive and noisier than capacitive sensors. Wielandt (2001) notes the following concerning the advantage of capacitive over inductive sensors: “Their sensitivity is ... typically a hundred times better than that of the inductive type.”

Optical encoders are also readily available and have been used extensively. Because of their digital nature, based in a finite number of elements, their low-level resolution is poor compared to capacitive devices.

Optical sensing by shadow means is easy to employ — for example, using a solar cell of the type discussed later. The method is afflicted, however, by (i) an offset voltage, and (ii) the degrading influence of background light.

Potentiometers are very easy to use, but compared to other position sensors they are extremely invasive because of Coulomb friction in the slider and also the bearings that support it.

21.3.1.2 Velocity Sensor

The most important velocity sensor is that which functions on the basis of Faraday's law. Using a magnet and a coil, an electromagnetic force is generated in the wire of the coil when it experiences a changing magnetic flux. Prevalent in seismometers before the advent of broadband (feedback) instruments, its primary shortcoming is poor sensitivity at low frequencies.

21.3.1.3 Time Interval

Photogates have become the primary means for kinematic studies in introductory physics laboratories. Combined with compact, user-friendly timers, it is possible to measure both period and velocity. As illustrated later, they can be easily used to measure damping in slowly oscillating systems, but only in a limited amplitude range.

21.3.2 Indirect Measurement

In the cases of (i) pressure, (ii) acceleration, and (iii) force/stress sensing, the measurement is an indirect one. Consider, for example, the Ruchhardt experiment to measure the ratio of heat capacities of a gas (discussed in Chapter 20). The oscillation of the piston could be measured in several different ways. For instance, direct position sensing could be accomplished by attaching a small electrode to the piston and allowing it to move between stationary capacitor plates. Alternatively, a “flag” on the piston could be used to interrupt the light beam of a photogate. Depending on constraints, however, the easiest method might be an indirect measurement in which a pressure sensor monitors the gas through a catheter communicating with the cylinder of the apparatus.

Accelerometers can sometimes be connected directly to an oscillator, but only if the mass of the instrument is very small compared to the system being studied. As with the measurement of velocity, their sensitivity at low frequency is very poor (the second derivative of position yielding a response that is proportional to frequency-squared).

Strain gauges are easy to employ but also lack sensitivity (compared to position measurement), since they communicate with a very small portion of the oscillating sample (if noninvasive).

21.4 Damping Examples

21.4.1 Case 1: Vibrating Bar — Linear with Significant Noise

The simplest means to measure the Q of an oscillator whose frequency is in the range of the human ear is to use a microphone connected to a digital oscilloscope. In this case, the microphone was an inexpensive dynamic type and the oscilloscope was a Tektronix TDS 3054. A better choice, had it been available, would be an electret microphone. The ring-down of a xylophone bar, following a strong (sharp) hammer strike, is shown in Figure 21.5.

The voltage *versus* time of the microphone output was saved to memory in the oscilloscope, from which the digital record was output to a floppy disk, using the CSV format. Data from the disk were read into columns A and B of an Excel spreadsheet using “Open file.” An envelope fit was then performed on the turning points by placement of trial and error data into column C, using “autofill.” A separate graph was generated for each value of the constant b in the expression “ $= 0.04 * \exp(-b * A1)$ ” typed into Cell C1. (The lower turning points were obtained by typing “ $= -b1$ ” into Cell D1 and using autofill.

FIGURE 21.5 Free-decay record of a vibrating bar.

(Additional details concerning the use of Excel in this manner will be provided in the discussion of seismometer damping that follows.)

Although optimizing algorithms could be generated to perform such a fit (with a probable slight increase in accuracy), this visual technique is preferred here as it is more understandable, user-friendly, and its performance is proven. The total time required in Excel to generate Figure 21.5 using a 2K record (2048 points) is typically only a few minutes with a modern Pentium computer.*

Once a satisfactory fit was obtained ($b = 1.6$ in Figure 21.5), the Q was estimated using

$$Q = \frac{\pi}{\Delta} = \frac{\pi f}{b} \quad (21.1)$$

There is a fair amount of electronic noise in Figure 21.5 because the microphone was connected directly to the oscilloscope. The smallest bandwidth of the oscilloscope, at 20 MHz, causes a large amount of Johnson (white) noise. Narrowing the bandpass by means of a preamplifier would improve the quality of the data dramatically. Such is typically true of signal to noise ratio (SNR) improvement by tailoring the electronics to the need.

21.4.2 Case 2: Vibrating Reed — Example of Nonlinear Damping

To illustrate another sensing technique, the system shown in Figure 21.6 was used.

A 90° twist was given to a hacksaw blade after heating with a torch and quenching. One end was clamped to the vertical post shown and a piece of cardboard was taped to the other end. An incandescent lamp is placed above the cardboard, which vibrates horizontally, and a solar panel below the cardboard is used as a sensor. The solar panel in this case is a commercial unit that comes with a cigarette lighter plug for charging automobile batteries. The output from the panel goes to the Tektronix digital scope also in the picture.

Unlike other sensing schemes described in this chapter, the solar panel output is not bipolar but instead has a constant voltage offset corresponding to the equilibrium position of the reed.

The frequency of oscillation is too low to operate the oscilloscope with a.c. coupling. Thus, it is important to make the d.c. offset as small as possible. This was accomplished by shielding nonactive parts

*A disclaimer is in order at this point. Present comments by the author should not be interpreted as an endorsement of Microsoft products in general. Although QuickBasic and Excel have both proven unusually beneficial to the work described in this chapter, they are the only software packages marketed by the company to have received a strong endorsement from the author.

FIGURE 21.6 Setup for measurement of vibrating reed free-decay.

of the solar cell from the lamp. Although the d.c. offset could be removed with a voltage bucking battery, this was found to introduce unacceptable noise spikes. With the offset, the gain of the electronics was limited by the amount of vertical position shift allowed by the scope. The results of this study are illustrated in Figure 21.7.

The nonzero value of b (0.018) in Figure 21.7 indicates the presence of amplitude-dependent damping (refer to Equation 20.61, Chapter 20). The nonlinear damping in this case probably derives from the air, rather than internal friction of the hacksaw blade. Its presence causes the Q of the system to increase with time.

The Q of the system is calculated from the expression

$$Q = \frac{\pi}{(b + ay)\tau} \quad (21.2)$$

where τ is the period of oscillation. At the start of the record ($y = 0.12$) the Q is 390 and it approaches 2700 as the amplitude approaches zero.

21.4.3 Case 3: Seismometer

Since the ability of a seismometer to detect tremors is proportional to the square of the period of the instrument, they require a good low-frequency sensor. The most common sensor for the latest generation commercial instruments is a half-bridge (differential) capacitive type. Because of the greater sensitivity and linearity of the full-bridge symmetric differential capacitive (SDC) sensor mentioned in Chapter 20, it is well suited to these applications, being easy to employ. (The full-bridge character is described in a TEL-Atomic tutorial (Peters, 2002).) A significant advantage of the SDC symmetry (equivalent electrically to the inductive LVDT) is its relative insensitivity to construction imperfections, such as roughness of surface and nonparallelism of electrodes. Thus, construction can be done crudely without serious degradation of performance. For example, electrodes of the first prototype of the SDC sensor were fabricated from sheet

FIGURE 21.7 Vibrating reed decay with amplitude-dependent damping.

FIGURE 21.8 Free-decay record of the Sprengnether vertical seismometer, period 17 sec.

copper that was cut with shears and subsequently flattened by hammer on a hard plane surface. This stands in stark contrast to the optically polished surfaces necessary for the use of some sensors.

The Sprengnether vertical seismometer discussed at several points in [Chapter 20](#) was studied in a configuration for which $Q = 4.9$, as determined by an external $990\ \Omega$ resistor to provide induced-current damping. The resistor was connected across the coil that is part of the original equipment and which moves (with the mass of the instrument) in the field of a stationary magnet, i.e., a Faraday's law (velocity) detector. Excitation to initiate the free-decay study was accomplished by applying an alternating (square wave) current to the coil, reversing the direction of the current at each turning point of the motion of the mass. The fundamental (Fourier series) of a square-drive generated this way is shifted 90° from the mass motion, corresponding therefore to resonance. After cessation of the drive, data as shown in Figure 21.8 were collected with a Dataq DI-700 ADC (16-bit).

The graph in Figure 21.8 was generated with Excel after the Dataq record was saved to floppy disc as an *.dat (CSV) file. It was imported to Excel using "open file" with "comma delimiter." Once in Excel, these data were shifted one place to the right (from the default A column to the B column) to accommodate computer generation of a time-data column. The column of time values was generated according to the sample rate, the value of which is by default saved to the data file. To generate the time column, a 0 was placed in the first row, n corresponding to the start of data. Dropping down one row in the A column, " $= A_n + 1/(\text{sample rate})$ " was typed, to increment the time. Then the lower right hand corner "small solid square" of the box containing this time was grabbed and held with the left button of the mouse to autofill all the way to the last time point of the data. The computer-generated exponentials, which correspond to the turning points, were obtained by generating two additional columns. These were obtained by placing the cursor at a row corresponding to the time A_n (in column C) and then typing " $= A_0 * \exp(-(\omega/2Q) * A_n)$." The value of A_0 is obvious from the data and a first estimate for Q can be quickly obtained from about a dozen turning points (read with the Dataq software before the data are ever saved).

The technique is illustrated in [Table 21.1](#). For example, in the case of Figure 21.8, $Q = 4.8$ from the 13 turning points. Thus the argument of the exponential was set to 0.0385. Using autofill, the columnar (upper) exponential was then quickly produced. Then a second (adjacent) column D was generated in similar manner, by taking the negative of the last point and then autofilling to the top row. (When one autofills downward, the rate with which Excel traverses the rows increases exponentially after the last row of data has been passed; thus, it is much easier to fill upwards rather than downwards.)

Once the pair of exponentials being fitted to the data have been graphed, along with the data, it is simple to adjust the curves by varying the argument (in this case, small changes around 0.0385) until a

average yields $Q = 4.8 (\pi/0.653)$
(final estimate from computerized fit = 4.9)

good fit is obtained (using autofill each time). The fit is rapid and accurate when there are not too many parameters to vary, since the eye is well suited to this operation. Upon obtaining the best-fit by this means, the preliminary value of $Q = 4.8$ was altered to the final value of $Q = 4.9$.

Note that in Table 21.1 a new Excel worksheet was employed (column A no longer the time as in the discussion above). The voltages corresponding to the turning points (maximum and minimum) were each read by placing the cursor at an extremum and manually recording the value displayed in turn by the Dataq software. These values were then typed into Excel, as opposed to the “file open” method for importing large datasets, i.e., as used to generate Figure 21.7.

21.4.4 Case 4: Rod Pendulum with Photogate Sensor

One of the simplest ways to measure damping at larger levels is to use a photogate of the type common to general education physics laboratories. The infrared beam of the photogate is tripped by a “flag” attached

to the oscillator. The rod pendulum pictured in Figure 21.9 was studied by this means. Figure 21.10 shows a closeup of the flag which is attached to the top of the pendulum and which passes through the photogate during oscillation.

As seen in the figures, various parts of the pendulum are clamped to a vertical steel rod. Both upper and lower masses are made of lead, each with a pair of holes drilled in it — one to pass the brass rod of the pendulum through and the other (after tapping) to hold a thumbscrew for securing the mass at different vertical positions on the rod.

This mechanical oscillator is a compound pendulum; the period can be made long as the knife-edge (also clamped to the rod) approaches the center of mass. At long periods, the instrument is not very responsive to external accelerations of the supporting frame; but it is sensitive to internal structural changes. Low-frequency instability is encountered as the upper parts of the instrument experience creep, particularly in the materials just above the knife-edge. The upper pendulum has similarities to an inverted pendulum, except that it is rigidly connected to the lower pendulum, and causes the oscillator to eventually exhibit double-well (Duffing) characteristics. This happens at larger amplitudes as the period is increased toward really long times. The tendency toward mesoanelastic complexity depends on the dimensions of the rod. As expected because of the well-known engineering properties of rods and tubes, a large diameter, thin-wall tube will behave differently from a solid rod made from the same amount of material (same total mass). This will be true if the tube does not experience localized (sharp) deformation prone to creasing.

Damping measurements with a photogate require that the time required for the flag to pass through the beam be fairly small — thus larger amplitudes of motion are required than with other sensors. Of course really large motion would result in a period increase, consistent with long-understood pendulum dynamics. For amplitudes within the acceptable range (which in practice is not overly restrictive), the velocity of the pendulum as it passes through the equilibrium position is inversely proportional to the time

FIGURE 21.9 Rod pendulum in which damping measurements are made with a photogate.

FIGURE 21.10 Top of the pendulum showing the upper mass and “flag” for tripping the photogate.

interval between interrupts of the photogate beam by the two vertical arms of the flag. If the period does not change with amplitude, then there is also an inverse relationship between the gate time and the amplitude. A plot of the inverse of these times *versus* cycle number is, for the constraints indicated, a reasonable approximation of the turning points of the free-decay.

In this case the single gate time interval measurements were made by a Pasco Smart Timer. It is a user-friendly instrument that also permits the period of the pendulum to be accurately measured by the flag (by using two different lengths of the flag arms). For experiments of this type, it may prove more convenient to measure the period with a stopwatch (infrequently as compared to the velocity). The sequentially increasing time intervals are read manually from the Smart Timer and recorded by hand, once per cycle. Of course, to do so requires that the period be long enough to permit these operations. The recorded values are conveniently analyzed by typing to a spreadsheet, which is then used to graph damping curves such as shown in Figure 21.11.

A pure exponential fit is not appropriate to the decay of Figure 21.11, in which the upper mass had been removed and a business card taped to the bottom of the pendulum to cause turbulent air damping (period near 1 sec). The fit shown, however, involving both linear and quadratic dampings, is seen to be quite reasonable. As in the case of the vibrating reed discussed earlier, this system is adequately described by the nonlinear damping equation 20.61 given in Chapter 20. For the data of Figure 21.11, $Q = 25$ initially and increases to 70 at the end of the record.

FIGURE 21.11 Free-decay of a pendulum as determined by photogate measurements.

Without the business card, and with the upper mass in place, the decay of this pendulum was found with the photogate measurement technique to be exponential, as expected for viscous damping with periods of about 5 sec. At periods in excess of about 10 sec, however, internal friction of the rod becomes more important than air damping. Although the decay is then still exponential at larger levels, the frequency dependence is not the same as required by linear air damping.

21.4.5 Case 5: Rod Pendulum Influenced by Material under the Knife-Edge

The data in Figure 21.11 were collected with the knife-edges resting on hard ceramic alumina flats. When supported by other materials, the damping of a rod pendulum can be influenced by anelastic flexure other than that of the rod. Hardness of the material does not guarantee low damping, as will be seen in the following examples. The data that follows were collected with a different pendulum, depicted in Figure 21.12.

The sensor in this case was an SDC unit, connected to the computer through the Dataq DI-700 A/D converter. The upper and lower masses are each approximately 1 kg and their separation distance on the aluminum hunting arrow from which the pendulum was fabricated was about 70 cm.

FIGURE 21.12 Long period rod pendulum used to study the influence of different materials under the knife-edge.

21.4.5.1 Lithium Fluoride Samples

The samples used to collect the data in Figure 21.13 were identical pairs, except that one pair had been irradiated with a huge dose of gamma rays. The resulting changes to the structure of the crystal are responsible not only for color centers as noted in the photograph in Figure 21.14, but also a dramatic change in the internal friction. It is clear from Figure 21.13 that internal friction in the LiF is the dominant source of damping of the rod pendulum that was used (Peters, 2003a, 2003b, 2003c, 2003d).

Lithium fluoride is used in thermoluminescent film badges (radiation monitors). When exposed to energetic radiation, atoms are “knocked” from their crystal lattice sites into metastable states corresponding to interstitial positions of the lattice. Upon ramping the temperature of the sample in an oven fitted with a photomultiplier tube, jumps from the metastable state are accompanied by the release of photons. The amount of light so generated is a measure of the dose that was received by the crystal. Because light flashes are observed with rather small changes in the temperature, it is reasonable to expect that mechanical strains might also cause a significant change to the defect state of such crystals. This postulate is confirmed by the data in Figure 21.13, which show a dramatic difference in the decay character of the pure (clear) crystals (bottom figure) and those which were extensively damaged by gammas (top figure).

In both of the decays in Figure 21.13 there is significant nonlinear damping, as evidenced in the early portions of each of the two records. The top case is nearly pure Coulombic, and the bottom case is partially amplitude dependent. This is revealed from estimates of the Q , shown in Figure 21.15.

The Q values in Figure 21.15 were computed from successive triplet-values of the turning points of the motion, read directly from the decay pattern displayed on the monitor by the Dataq software. The equation used is

$$Q = \frac{\pi}{-2 \ln[1 - (\theta_n - \theta_{n+2})/(\theta_n - \theta_{n+1})]}, \quad n = 0, 1, 2, \dots \quad (21.3)$$

FIGURE 21.13 Illustration of damping difference according to specimen type under the knife-edge.

21.4.6 Hard Materials with Low Q

It is commonly (and mistakenly) thought that hard materials must necessarily also have low damping. The following two examples show that this is not necessarily so. Even though cast iron is very hard, it is also quite dissipative, which makes it an ideal material for engine blocks. Figure 21.16 shows a decay curve for the steel knife-edges of the pendulum resting on cast iron samples.

At the start of the record the damping with cast iron is nearly twice as great as that of steel-on-sapphire or steel-on-silicon, where the Q was found to be of the order of 80. This large damping measurement is consistent with the known excellent properties of cast iron for use in engine blocks, although the frequencies for such applications are much higher.

Figure 21.17 is another very hard material which has large damping — the ceramic piezoelectric wafer formed from lead, zirconium, and titanium (PZT), which by means of a mechanical impulse is commonly used to generate an electric spark to ignite a gas grill. The secular decline of Q based on the short temporal record indicates Coulomb damping. It is consistent with the nearly straight-line turning points for the early part of the long-term record, also shown. The long-term record

FIGURE 21.14 Photograph of LiF single crystals used to obtain the data in Figure 21.13.

FIGURE 21.15 Temporal dependence of the Q, LiF crystal experiments.

FIGURE 21.16 Data collected using cast iron samples.

is labeled as anomalous because it does not appear to be consistent with several simultaneously acting dissipation mechanisms. Instead, the strong Coulomb damping seen early on seems to disappear later, once the amplitude has dropped below a particular level. This suggests activation processes of a quantal type. It would be interesting to study the PZT wafers in a different pendulum configuration, and not operating “open-circuit” as in the present case, but rather with different resistors connected between the top and bottom of the wafers.

21.4.7 Anisotropic Internal Friction

With Polaroid material (H sheet) placed under the knife-edges it was found that the damping depends on the direction of the long-chain polymeric molecules. The direction of the molecules in a sample is readily determined by looking through the Polaroid at reflected light from a polished floor. When the reflection occurs close to the Brewster angle, only the horizontal component of the electric field is significant in the reflected light for unpolarized incident light. The direction of the molecules is thus determined by rotating the sample until the minimum of level of light is found. When this occurs the molecular chains are situated horizontally.

FIGURE 21.17 Data from an experiment involving PZT ceramic wafers.

FIGURE 21.18 Free-decay curves showing anisotropy of the internal friction in polaroid material.

It was reasoned that the molecular properties of Polaroid might result in mechanical as well as optical anisotropies. This postulate proved to be true, as shown in Figure 21.18.

When oscillating on silicon at a period of 10 sec, previous studies have found that the instrument decays consistently with a Q of 80 (uncertainty 3%). In the present study, half a dozen free-decay records were obtained for (i) edges parallel to the chains and (ii) edges perpendicular to the chains. The average Q of oscillation was estimated at 50 for the parallel case and 43 for the perpendicular case. Reproducibility proved slightly better for the parallel case (4%) as compared to the perpendicular case (5%). Additional details are documented elsewhere (Peters, 2003a, 2003b, 2003c, 2003d).

21.4.7.1 Summary, Free-Decay Q Estimation

All of the techniques so far described are methods based on free-decay, which is especially important for nonlinear systems. With linear systems it is also possible to use steady-state methods, as noted in Box 21.2 (last column; de Silva, 2000). Box 21.2 summarizes the techniques used in the present chapter to estimate the logarithmic decrement, βT , from which $Q = \pi/(\beta T)$.

Damping (Q Estimation) Techniques ($Q = \pi/\beta T$, T = Period)					
Logarithmic Decrement (Full-Cycle, N)	Turning Points (Half-Cycle, n)	Nonlinear Fit to Envelope	Time τ to $1/e$ ($0.3679x_0$)	Short Time Fourier Transform	Bandwidth, Magnification Factor, Hysteresis Loop, Step-Response
$\beta T = \frac{1}{N} \ln \frac{x_0}{x_N}$	$\beta T = -2 \ln \left[\frac{1 - (x_{n-1} - x_{n+1})}{(x_{n-1} - x_{n+1})} \right]$	$-\dot{y} = ay^2 + by + c$	$\beta T = T/\tau$	$-\beta T = \frac{T \ln 10}{20}$ [slope(dB/s)]	de Silva (2000), p. 379

The best method is to use a full nonlinear fit; the worst is to measure the time to 1/e. The expression in Box 21.2 for the logarithmic decrement, using the STFT, is equivalent to

$$Q = 27.29 \frac{f}{\left| \frac{\text{dB}}{\text{s}} \right|}$$

(21.4)

where f is the frequency in Hz and the STFT slope is specified in dB per s.

21.5 Driven Oscillators with Damping

This chapter has been mainly concerned with oscillators in free-decay. It is also possible to make quantitative predictions from measurements at steady state. Confidence in predictions, however, depends on the nature of the damping. Such data are of limited value for most nonlinear systems, unless supplemented with free-decay data.

21.5.1 MUL Apparatus

Some of the techniques applicable to driven systems are illustrated by the multipurpose undergraduate laboratory (MUL) apparatus shown in Figure 21.19, that has been used by students in the physics department at Mercer University.

For the purpose of measuring the Lorenz force (basis for defining the current unit, the ampere) a constant current is supplied through the posts to the pivoted-on-points brass wire on which a weight, W , is shown hanging on one of the horizontal arms of the wire. Current enters the wire through one post *via* the banana plug inserted into a drilled hole. It thereafter travels through the lower (invisible) shorter

straight segment of the wire located between the poles of the drive magnet; and it finally exits through the banana plug on the opposite post. When carrying a current, the force on the wire from the part inside the magnet causes vertical deflection, the direction up or down being determined by the direction of the current. This results in a rotation about the pivot points (indented tops of the posts). The position is measured by the capacitive sensor, S (one of several variants of the SDC patent).

The sensitivity of this current balance depends on the location of the center of mass of the oscillatory wire, which is determined in part by the position of the rare earth magnet, M, which hangs from a steel nut on the threaded part of the heavier brass rod having a 90° bend. The upper end of this threaded rod is held by a plexiglass member that also holds the ends of the oscillatory wire.

FIGURE 21.19 Apparatus for studying resonance and the Lorenz force law.

21.5.2 Driven Harmonic Oscillator

The MUL becomes a driven harmonic oscillator when the excitation current is a.c. rather than the d.c. used for the Lorenz force study. The damping is determined primarily by eddy currents in the aluminum ring, R, that lies on the wooden base underneath and in close proximity to magnet M.

The apparatus is useful for studying both free-decay and driven oscillation. Engineering students Brandon R. Bowden and James D. Sipe have programmed LabVIEW to generate both free-decay curves and resonances.

An example Lorentzian (resonance response) is given in Figure 21.20. (Additional information is found in a laboratory writeup (Peters, 1998).)

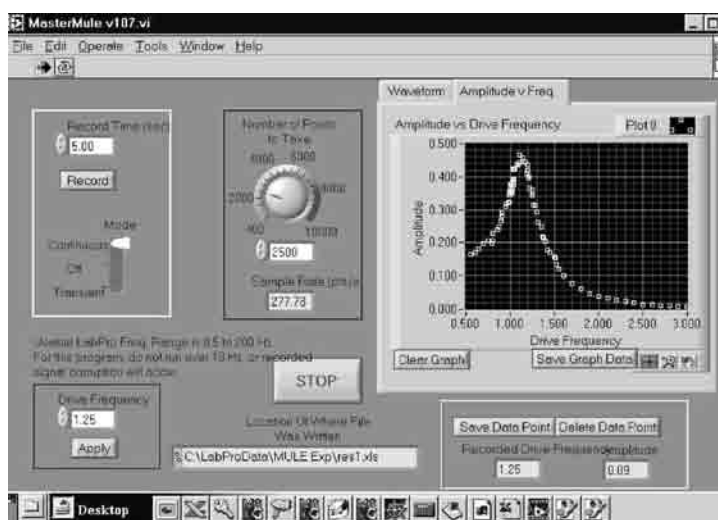

FIGURE 21.20 Screens from the LabVIEW program used with the MUL to study both transient and resonance phenomena.

21.6 Oscillator with Multiple Nonlinearities

An oscillator can have significant nonlinearities of both the elastic and damping types. An example is the mechanical system pictured in Figure 21.21.

The instrument is a modified extensometer that was sold by TEL-Atomic and which was designed around the SDC sensor to measure Young's modulus and thermal expansion coefficients. The wire sample normally used with the instrument (along with a hollow power resistor that fits in the black clamp) has been removed, and two rare earth magnets have been employed. One magnet is superglued to the bottom of the pan where the weights are normally placed, as shown in Figure 21.22; and the other magnet is attached to the bottom of the inductor that is sitting on the top of the oscillator (cased instrument, Pasco) used for drive. The pair of magnets are positioned in close proximity so as to repel each other, thus supporting the mass of the moveable arm of the extensometer.

The study of nonlinear systems requires a linear sensor; i.e., any nonlinear contributions from the detector must be negligible. Figure 21.23 shows the calibration results for the instrument and its linear response for the range of amplitudes used in the study.

The potential energy of this oscillator was assumed to have the following form

$$U(x) = \frac{b}{x^n} + cx \quad (21.5)$$

and the parameters were estimated by measuring x as small masses were placed on the pan. A linear regression fit to a log-log plot (using the sensor calibration constant of 550 V/m) yielded $b = 1.02 \times 10^{-5}$, $n = 1.526$, and $c = 0.304$ (system international units). Anharmonicity of the

FIGURE 21.21 Mechanical oscillator with multiple nonlinearities.

FIGURE 21.22 Closeup picture of the oscillator in [Figure 21.21](#) (nonoperational configuration), showing placement of the rare earth magnets.

potential is readily apparent in the plot shown in [Figure 21.24](#), with the force of restoration being greater in compression (x decreasing) than it is in extension. This feature is reminiscent of interatomic potentials, with anharmonicity being responsible for thermal expansion.

Because of the elastic nonlinearity, the mean position depends on the amplitude of the oscillation, as is evident in the free-decay curve in [Figure 21.25](#).

The damping of this oscillator was also found to be nonlinear, as seen in [Figure 21.26](#).

The oscillator exhibits hysteresis when driven at larger amplitudes, as shown in [Figure 21.27](#), where it can be seen that the location of an amplitude jump depends on which way the oscillator is adjusted, either up or down in frequency. Such jumps (well known with oscillators with nonlinear elasticity) stand in stark contrast with the behavior of a linear oscillator, as can be seen by comparing [Figure 21.27](#) with the screen picture in [Figure 21.20](#).

A surprise from this study involves the frequency of oscillation. In general, the oscillator did not entrain to the drive. Moreover, the preferred frequencies were not necessarily the same as the free-decay frequency of 6.01 Hz. Some of the frequencies (measured with power spectra) are indicated in

FIGURE 21.23 Calibration data for the sensor used with the oscillator having multiple nonlinearities.

FIGURE 21.24 Plot of the potential energy function of the oscillator.

FIGURE 21.25 Free-decay curve showing the mean position shift as a function of oscillator amplitude. (Decreasing sensor voltage corresponds to increasing x .) The frequency of oscillation is 6.01 Hz.

FIGURE 21.26 Free-decay character as determined using the short time Fourier transform.

Figure 21.27. The 3% frequency jumps observed in Figure 21.27 (in going from 5.46 Hz to 6.20 Hz) are not real but rather artifacts of the finite resolution of the 1024 point transforms that were employed.

Figure 21.27 demonstrates why nonlinear damping measurements should be done in free-decay. Figure 21.25 demonstrates how exponential fits make no sense for some oscillators. Fortunately, the STFT can be used to determine the amplitude dependence of the Q .

FIGURE 21.27 Resonance response (steady state) of the driven oscillator.

21.7 Multiple Modes of Vibration

21.7.1 The System

In engineering, multimode oscillations are common. Many, if not most, cases have mode mixing features even though they may in some cases be too small to be readily observed. The importance of nonlinearity to these problems is not widely appreciated, so a case to illustrate salient features is provided here. Free-decay records were obtained with an oscillator in the form of a vertically oriented (hanging) tungsten wire, of length 24 cm and diameter 0.31 mm. It was clamped at the top end, and at the bottom a rectangular plate was attached that was 11.3 cm long, 1.3 cm wide, and 0.8 mm thick. The plate was cut from double-sided copper circuit board. The board was positioned between the stationary plates of a capacitive sensor, as shown in Figure 21.28.

FIGURE 21.28 Photograph of the detector used to monitor the multimode oscillator.

For the picture, the apparatus was disassembled and the plate allowed to rest on the top of the bottom electrode set. Operationally, the plate was positioned midway between the upper and lower static electrode sets (separation distance of 4 mm); and there was no mechanical contact during oscillation. As can be seen, the top of the circuit board containing the upper electrode set contains more than a dozen electronic components; these are of the surface mount technology type. The detector is of the SDC type and this particular embodiment is manufactured in Poland for TEL-Atomic Inc., Jackson, MI, for use in the Computerized Cavendish Balance.

As can be seen in the picture, the wire was rather kinked instead of straight, which is expected to be a significant source of nonlinearity. For this reason, not to mention that it is very difficult to make larger diameter tungsten wires reasonably straight, no serious attempt was undertaken to remove the kinks.

21.7.2 Some Experimental Results

An example decay record generated with this apparatus is illustrated in Figure 21.29.

21.7.3 Short Time Fourier Transform

When multiple modes are present in a decay, as in Figure 21.29, it is not possible to readily estimate Q for all of the various modes using time data. The decays can be estimated using the FFT, in a technique called the short time Fourier transform, which is built-in to various software packages related to acquisition systems, such as LabVIEW (see Appendix 15A). With the versatile software supplied with the Dataq A/D converter, it is straightforward to employ an equivalent manual technique. Using the number of points to define the FFT a value (always a power of 2 total) that is substantially smaller than the number of points in the record, a manual scan is performed in which one simply increments from start to finish, calculating a separate FFT at each position in time along the way. As an illustration of this powerful tool, Figure 21.30 shows spectra corresponding to the start and the finish of the data in Figure 21.29.

All the modes decay in time, and the rate of decay is especially large for those modes that correspond to sum and difference frequencies of the primary modes at 1.19 and 2.19 Hz. Table 21.2 gives the spectral intensities in dB for the two times considered. Where the rows are blank for the end of record case, the values were insignificantly small.

FIGURE 21.29 Example free-decay of a multimode wire oscillator.

FIGURE 21.30 Beginning and end spectra corresponding to the temporal data from Figure 21.29. Ordinate values are spectral intensity in dB, abscissa values are frequency in Hz (linear scale).

The decibel values in the table are referenced to the bit-size (16 corresponding to 65536) of the ADC. In terms of the sensor output voltage, V , it is defined by Dataq as:

$$\text{dB} = 20 \log_{10}(32,768 \times V/\text{FS}) \tag{21.6}$$

where FS is the full-scale voltage as determined by the gain setting.

Elsewhere in this chapter, the decibel is calculated with a different reference. For example, for an FFT spectral line having real and imaginary components R and I , respectively (voltage based), the intensity in dB is calculated using

$$\text{dB} = 20 \log_{10} \left[\sqrt{R^2 + I^2} / \left(\frac{n}{2} \right) \right] \tag{21.7}$$

where n is the number of points in the FFT. This is convenient for determining noise levels. For example, from later graphs showing electronics noise, the floor of the SDC sensor is found to be of the order of -120 dB, corresponding to a microvolt. The position resolution defined by this noise level is about 500 nm, i.e., the wavelength of visible light.

TABLE 21.2 Spectral Intensities for Some of the Lines Shown in Figure 21.30

Frequency (Hz)	Start of Record (dB)	End of Record (dB)
2.19	78.3	63.0
1.19	68.1	55.6
1.00	44.6	
0.19	40.8	
3.38	35.0	6.7
4.34	26.7	
4.53	22.4	
6.53	22.9	
5.53	17.8	

Of the two primary modes of this kinked-wire case study, the higher frequency (2.19 Hz) is the twisting mode and the lower frequency (1.19 Hz) is the swinging mode. The swinging mode is a little higher frequency than that which would result if the wire were completely flexible, yielding a near simple pendulum (1.02 Hz for 24 cm length). The swinging mode is two dimensional (pendulum equivalent called conical), but the sensor only responds (first order) to motion perpendicular to the long axis of the electrodes. It should also be noted that this motion is attenuated, relative to the twisting response, because of the mechanical common-mode rejection feature discussed in [Chapter 20](#).

The manual STFT was used on the data that generated [Figure 21.29](#) to estimate the decay history of three different modes — both of the primary ones (twist and swing) and also the mode whose frequency is the difference between the frequencies of the primaries, i.e., 1 Hz. [Figure 21.31](#) shows the results, where a Hanning window was used, and the total number of points in the record permitted five equally time-spaced FFTs, when working with a 1024 point transform.

Although the decay of the twisting mode is seen to be reasonably exponential, there was large beating between the modes (readily observed in [Figure 21.29](#)). Beating alone would not yield a mix signal whose frequency is 1.0 Hz. However, beating in a linear system can cause amplitude variations in the weaker swinging mode.

21.7.4 Nonlinear Effects — Mode Mixing

At least two signals in the spectra are the result of nonlinearity, i.e., the lines corresponding to the sum and difference of the frequencies of the primary pair — at 3.38 and 1.00 Hz, respectively. If the system of oscillator and detector were completely linear, then no such sum and difference cases would be possible. It is also to be noted that these mixtures are not the result of sensor nonlinearity, which as noted previously one must be careful to avoid.

The amplitude of a mix signal was expected to approximately obey the following relation:

$$A_m \propto A_1 A_2 \quad (21.8)$$

To test this premise, the STFT was used to estimate the amplitudes of each of the three components indicated in Equation 21.8. The amplitudes were all normalized, relative to the starting value for each case, and the results used to generate the graphs in [Figure 21.32](#).

The amplitude of oscillation for a given mode, at the time of the transform, is found by using the peak value in dB of the intensity of the spectral line for that mode, according to

$$A \propto 10^{\text{dB}/20} \quad (21.9)$$

where the factor of 20 is used since the spectral intensities were calculated in terms of voltages. Although calibration constants (in V/m and V/rad) could be used to express the amplitude in meters or in radians, corresponding to the mode, nothing is gained by doing so for the present purposes.

The mixing index for these cases is defined by the expression

$$\text{index} = \frac{A_m}{\sqrt{A_1 A_2}} \quad (21.10)$$

FIGURE 21.31 Decay of modes of the wire oscillator, determined by the manual STFT.

FIGURE 21.32 Evidence in support of nonlinear mixing according to Equation 21.8.

which is similar to expressions encountered in optics. It can be seen that the sum and difference frequencies are approximated reasonably well by theoretical expectation.

21.8 Internal Friction as Source of Mechanical Noise

Chapter 20 claims that internal friction is responsible not only for damping but also for significant mechanical noise of $1/f$ type. Figure 21.33 is provided in support of that claim.

The pendulum in these experiments (lead spheres near the ends of an aluminum tube with a pair of steel-points for the axis) was operated in a high vacuum to eliminate the influence of air. The electronics

FIGURE 21.33 Power spectrum and associated temporal record showing mechanical $1/f$ noise (right pair). For reference, electronics noise is also provided (left pair).

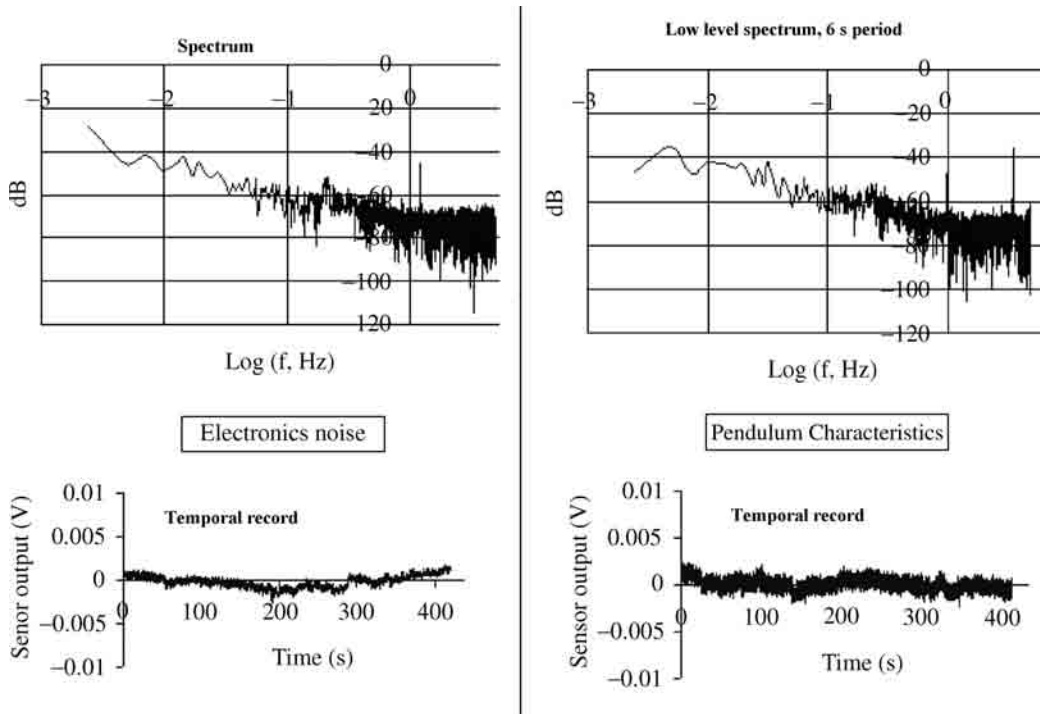

FIGURE 21.34 Same as Figure 21.33, but after the pendulum had stabilized.

noise was obtained by removing the top mass and measuring the motion after oscillation reached a minimum (frequency approximately 1 Hz); some pendulous mode remains because of pump noise transmitted through the vacuum hose. Similarly, the pump vibrations excite a vibratory mode in the long-period pendulum (sharp spectral line at 3.5 Hz, right spectrum). In this vibratory mode the lead masses move in the same direction relative to the stationary axis (similar to the bending mode of the carbon dioxide molecule). It is interesting to note that there is no coherent oscillation to be seen above noise corresponding to the period of 5.7 sec. The mechanical noise is seen to include bistability, which is not uncommon for this type of system before hardening, following a significant force disturbance. The data in Figure 21.33 were collected after replacing the upper mass, which had been removed to measure the electronics noise, and after pumping to the operating pressure (below $5 \mu\text{m Hg}$).

The mechanical noise is seen to be $1/f$ for $f < 1.5$ Hz, which is where electronics begins to contribute noticeably. Everywhere below 1 Hz, the electronics noise is an order of magnitude smaller than the mechanical noise.

After the pendulum had stabilized overnight and been allowed to oscillate through a number of free-decays (initialization by tilting the chamber), the data shown in Figure 21.34 was collected.

It can be seen that the mechanical noise has mostly settled out, leaving the remnant electronics noise.

21.9 Viscous Damping — Need for Caution

Recent experiments have shown important subtleties of viscous damping (Peters, 2003a, 2003b, 2003c, 2003d). It is true that the dissipation at a specified frequency can be adequately modeled by simply multiplying the velocity term in the differential equation by a coefficient. It is not proper, however, to call

this coefficient a constant, since the damping coefficient is frequency dependent and also involves the density as well as the viscosity of the fluid in which oscillation takes place.

Some engineers have known about the history term, which is most simply treated in the case of a sphere executing simple harmonic motion. The friction force acting on the sphere in this case can be reasonably approximated by

$$f_{\text{harmonic}} = 6\pi\eta a \left(1 + C_H \frac{a}{\delta}\right) v, \quad \delta = \sqrt{\frac{2\eta}{\omega\rho}}, \quad (C_H \rightarrow 1 \text{ as } \nu \rightarrow 0) \quad (21.11)$$

where ω is the angular frequency of oscillation, a is the radius of the sphere; and for the fluid, η and ρ are its viscosity and density, respectively. Only in the limit of zero frequency does the damping reduce to the form that one expects on the basis of Stokes' law of viscous friction (steady flow).

Using Equation 21.11 in the equation of motion for a pendulum yields for the Q

$$Q_v = \frac{I\omega}{6\pi\eta a \left(1 + \frac{a}{\delta}\right) L^2}, \quad \delta = \sqrt{\frac{2\eta}{\omega\rho}} \quad (21.12)$$

where I is the moment of inertia, and L is the distance from the axis to the center of the sphere. Typically, the ratio a/δ is significantly greater than unity so that the damping is governed by the surface area of the sphere rather than by its radius. These complexities of viscous damping are summarized in Box 21.3.

Reasonable experimental validation of the estimate for Q was provided, as demonstrated in Figure 21.35.

The instrument in this case was a compound pendulum in which a mass was located above the axis of rotation, as well as the usual situation of mass below the axis. The water damping was provided through a small sphere at the bottom of the pendulum, immersed in water held by a rectangular container.

If the history term in Equation 21.12 is ignored there can be huge errors. For example, in the case of water damping, the damping can be underestimated by 1000 to 3000%, as shown in Figure 21.36.

At low frequencies, it is also important to correct for the influence of hysteretic damping of the pendulum. Figure 21.37 shows the large errors that occur when one fails to do so.

For some cases, buoyancy and added mass of the fluid are also quite significant to the frequency of oscillation, as shown in Figure 21.38.

Box 21.3

COMPLEXITIES OF VISCOUS DAMPING

Friction force is not a function only of viscosity η ; it also depends on density ρ and angular frequency ω

$$f_{\text{harmonic}} = 6\pi\eta a \left(1 + C_H \frac{a}{\delta}\right) v, \quad \delta = \sqrt{\frac{2\eta}{\omega\rho}}, \quad (C_H \rightarrow 1 \text{ as } \nu \rightarrow 0)$$

resulting in a complicated frequency dependence for the Q of viscous damping

$$Q_v = \frac{I\omega}{6\pi\eta a \left(1 + \frac{a}{\delta}\right) L^2}, \quad \delta = \sqrt{\frac{2\eta}{\omega\rho}}$$

FIGURE 21.35 Comparison of theory and experiment for a pendulum damped by water.

21.10 Air Influence

As seen from Figure 21.37, low-frequency motions are likely to be influenced more by internal friction than by any fluids that interact with the oscillator. The most important fluid is of course air, and a true delineation between external and internal effects requires that the oscillator be studied in a high vacuum. It is not enough to just remove most of the air, since the viscosity of gases is surprisingly constant until the mean free path between collisions becomes a significant fraction of chamber dimensions.

Theoretically, it is possible to roughly estimate air influence, although only in the simplest of geometries, such as a sphere. In such cases, Equation 21.11 could be used (with accounts for the history term, using appropriate values for the viscosity and density). It is also possible in some cases to estimate air influence experimentally, as in the example that follows.

21.10.1 Brass and Solder Rod Pendula

Because of its malleability, the internal friction of solder (lead–tin alloy) is large, compared to that of much harder brass. A pendulum of each material was studied, both having a length of about 50 cm and a

FIGURE 21.36 Illustration of how huge errors can occur in damping estimates if one ignores the history term.

FIGURE 21.37 Illustration of significant low-frequency errors that result from a failure to recognize the hysteretic damping component of the pendulum.

diameter of about 3 mm. The technique used was the photogate method described in Section 21.4.4 (Case 4 above). Unlike the previous study, no lead masses were clamped on the rod — but it used the same adjustable knife-edge.

Figure 21.39 clearly shows that the internal friction for the solder pendulum is much greater than that of the brass pendulum.

A nonlinear fit was generated for each decay curve, from which the history of the quality factor was graphed as a function of velocity amplitude, as shown in Figure 21.40.

Consider the pair of brass curves in Figure 21.40. The large difference in Q at 10 cm/sec (387 compared to 266) is in stark contrast with their near equality at 50 cm/sec. This is primarily a consequence of air drag that is quadratic in the velocity at the larger amplitude. It is more important to brass than to solder because of the small internal friction of the brass.

From the large difference in internal friction of the two materials, a first order correction for air influence on the solder pendulum is to simply subtract $1/Q$ of the brass from $1/Q$ (raw data) of the solder, to yield the reciprocal Q (corrected) due to internal friction of the solder. This has been done in Figure 21.41.

FIGURE 21.38 Example of how fluid properties influence the frequency as well as damping of an oscillator.

FIGURE 21.39 Free-decay curves for brass and solder pendula at two different frequencies, showing the larger internal friction of solder. The velocity is that of the peak value (amplitude) at the top of the pendulum, approx. 22 cm above the axis.

From [Figure 21.41](#) it can be seen that the internal friction damping is not simply hysteretic (constant Q); rather it is a function of amplitude. It can also be seen, from the close proximity of the solid and dashed curves, that the air influence on the solder pendulum is much less than that of the internal friction. By contrast, air influence is of comparable magnitude to the internal friction in the case of the brass pendulum (or even larger, at large amplitude).

A minimum of two frequencies was considered for the study, since the frequency variation of the damping is different for external and internal frictions. (Note: although the period is a function of amplitude, the amount of nonisochronism is small compared to the damping changes and is ignored here.) The periods were matched for the two pendula at each of 2.03 and 2.51 sec. For hysteretic-only (internal friction) damping, the Q at the shorter period should in theory be 1.53 times that of the longer period, for both brass and solder. If the damping were viscous only, the factor should be 1.24. In the case of solder at 10 cm/sec (corrected), the ratio is $1.66 = 131/71$, and for brass it is $1.46 = 387/266$. Although the ratio for solder is greater than the expected 1.53, the difference is within experimental

FIGURE 21.40 Illustration of amplitude-dependent damping in a rod pendulum made of (i) brass and (ii) solder. The two different matched periods of oscillation are indicated in seconds.

FIGURE 21.41 Amplitude dependence of the estimated quality factor due only to internal friction in the solder pendulum. Dashed lines show the Q before correction for air damping.

uncertainty for individual Q values, which from other, more detailed experiments were in the neighborhood of 5 to 10%.

The ratio for brass (1.46) is between 1.24 and 1.53, as expected, because of the comparable influence of air and internal friction.

Summary

In this chapter, a brief review will be given of the concept of isolation for suppressing the vibrations in structures and equipment subjected either to harmonic or seismic ground excitations. The mechanism of various isolation devices, including the elastomeric bearing, sliding bearing, resilient-friction base isolator, and Electricite de France system, will first be described in Section 22.2, together with their mathematical models. In Section 22.3, a closed form solution will be derived for the dynamic response of a structure–equipment system isolated by bearings of the elastomeric type, subjected to harmonic motions. Such a solution enables us to interpret the various behaviors of the structure and equipment under excitation. The elastomeric bearings can help increase the fundamental period of the structure, thereby, reducing the accelerations transmitted to the superstructure. In Section 22.4 and Section 22.5, the seismic behavior of a structure–equipment system isolated by a sliding support, with and without resilient force, will be studied using a state-space incremental-integration approach. With the introduction of a frictional sliding interface, the motion of the structure–equipment system will be uncoupled from the ground excitation, and the influence of the latter will be mitigated. The residual base displacement caused by the sliding isolator can be reduced

through inclusion of a resilient mechanism in the isolator. Nevertheless, the resilient mechanism can make the system more sensitive to the low-frequency components of excitation. In Section 22.6, issues related to design of base isolators will be discussed, along with the concepts underlying some design codes and guidelines. The notation used is listed at the end of the chapter.

22.1 Introduction

Conventionally, structural designers are concerned about the safety of buildings, bridges, and other civil engineering structures that are subjected to earthquakes. The recent history of earthquakes reveals that strong earthquakes, such as the 1994 Northridge earthquake (U.S.A.), 1995 Kobe earthquake (Japan), and 1999 Chi-Chi earthquake (Taiwan), can cause some badly designed structures or buildings to fail or collapse, and also cause some well-designed structures to malfunction due to the damage or failure of the equipment housed in the structure or building. Both the failures of structures and equipment, also known as *structural* and *nonstructural* failures, respectively, can cause serious harm to the residents or personnel working in a building. For the case where the equipment is part of a key service system, such as in hospitals, power stations, telecommunication centers, high-precision factories, and the like, the lives and economic losses resulting from the malfunctioning of the equipment can be tremendous. Thus, the maintenance of the safety of structures and attached equipment during a strong earthquake is a subject of high interest in earthquake engineering (also see Chapter 29 to Chapter 31). In this regard, *base isolation* has been proved to be an effective means for protecting the structures and attached equipment, which is made possible through reduction of the seismic forces transmitted from the ground to the superstructure (Yang et al., 2002).

For light secondary systems mounted on heavier primary systems, it was concluded that the response of the light secondary system, that is, the equipment, is affected by four major dynamic characteristics in earthquakes (Igusa and Der Kiureghian, 1985a, 1985b, 1985c; Yang and Huang, 1993). The first issue is *tuning*, which means that the natural frequency of the equipment is coincident with that of the structure. Such an effect may amplify the response of the equipment due to the fact that the light secondary system behaves as if it were a vibration absorber of the heavier primary system. The second issue is *interaction*, which is related to the feedback effect between the motions of the primary and secondary systems. Ignoring the feedback effect of interaction may result in an overestimation of the true response of the combined system. The third issue is *non-classical damping*, which may occur when the damping properties of the two systems are drastically different, such that the natural frequencies and mode shapes of the combined system can only be expressed in terms of complex numbers. Under such a circumstance, the conventional response spectrum analysis, based on modal superposition, becomes inapplicable. The last issue is *spatial coupling*, which relates to the effect of multiple support motions when the secondary system of interest is mounted at multiple locations. By considering the inelastic effect, Igusa (1990) proposed an equivalent linearization technique for investigating the response characteristics of an inelastic primary–secondary system with two degrees of freedom (DoF) under random vibrations. His results indicated that the existence of small nonlinearity is helpful for reducing the coupling system responses. With the concept of equivalent linearization, Huang et al. (1994) explored the response and reliability of a linear secondary system mounted on a yielding primary structure under white-noise excitations. It was concluded that the response of the secondary system could be reduced by increasing the equipment damping or by locating equipment at higher levels of the primary structure.

Owing to the fact that the mass and stiffness of a secondary system are much smaller than those of the primary structure, the interaction effect of the combined system, as well as the ill-conditioning in system matrices, may take place when one performs the dynamic analysis. To deal with this problem, some researchers chose to evaluate the response of the secondary systems from the floor motions. To avoid solving large eigenvalue problems and to account for the interaction between the building and equipment components, Villaverde (1986) applied the response spectrum technique to the analysis of a combined building–equipment system, by which the maximum response of light equipment mounted on the building under the earthquake is expressed in terms of the natural frequencies and mode shapes of

the building and equipment. To take into account the equipment–structure interactions, Suarez and Singh (1989) proposed an analytical scheme for computing the dynamic characteristics of the combined system, using the modal properties to compute the floor spectra. Lai and Soong (1990) presented a statistical energy analysis technique for evaluating the response of coupling primary–secondary structural systems, based on the concept of power-balance equation, that is, the power input to the primary system is equal to the dissipated energy of the primary system plus the transferred energy to the secondary system. Using a mean-square condensation procedure, Chen and Soong (1994) considered the effect of interaction by calculating the multi-DoF response of a primary–secondary system under random excitations. Later on, Chen and Soong (1996) derived an exact solution for the mean-square response of a structure–equipment system under dynamic loads, indicating that there exists an optimal damping ratio for reducing the vibration of equipment attached to the primary structure. Gupta and coworkers investigated the response of a secondary system with multiple supports on a primary structure subjected to earthquakes, taking into account the interaction effect between the equipment and structure (Dey and Gupta, 1998, 1999; Chaudhuri and Gupta, 2002). Their results indicated that when the soil–structure interaction (SSI) is taken into account, the response of the equipment–structure system will be affected by the SSI, unless a very stiff soil condition is considered.

On the other hand, a number of research works have been conducted by implementing isolation systems at the base of the equipment–structure system, aiming to reduce the earthquake forces transmitted from the ground. Based on a theoretical and experimental investigation, Kelly and Tsai (1985) showed that seismic protection can be achieved effectively for lightweight equipment mounted on an isolated structure installed with elastic bearings at the base. A hybrid isolation system with base-isolated floors was proposed by Inaudi and Kelly (1993), for the protection of highly sensitive devices mounted on a structure subjected to support motions. Considering the effects of torsion and translation, Yang and Huang (1998) studied the seismic response of light equipment items mounted on torsional buildings supported by elastic bearings. Their results indicated that the response of an equipment–structure system can be effectively reduced through installation of base isolators, and that there exists an optimal location for mounting the equipment. Juhn et al. (1992) presented a series of experimental results for the secondary systems mounted on a sliding base-isolated structure. They concluded that the acceleration response of the secondary system may be amplified when the input motions are composed of low-frequency vibrations. In this case, the sliding bearings are not considered to be an effective isolation device, which implies that the base-isolated structure is not suitable for a construction site with soft soil.

Concerning the use of sliding bearings (supports) as base isolators, Lu and Yang (1997) investigated the response of an equipment item attached to a sliding primary structure under earthquake excitations. Their results showed that the response of the equipment can be effectively reduced through the installation of a sliding support at the structural base, in comparison with that of a structure with fixed base. To overcome the discontinuous nature of the sliding and nonsliding phases of a structural system with sliding base, a fictitious spring model was proposed by Yang and coworkers for simulating the mechanism of sliding and nonsliding (Yang et al., 1990, 2000; Yang and Chen, 1999). Such a model will be described in a later section of this chapter. Agrawal (2000) adopted the same fictitious spring model in studying the response of an equipment item mounted on a torsionally coupled structure with sliding support. His results indicated that sliding supports could effectively reduce the equipment response, compared to that of a fixed-base structure. However, in the tuning region, where the natural frequency of the equipment coincides with the fundamental frequency of the structure, the equipment response may be adversely amplified due to the increase in eccentricity of the torsionally coupled structure.

The problem of building isolation has recently received more attention than ever from researchers and engineers, due to the construction of high-precision factories worldwide. More and more stringent requirements have been employed in this regard for removing the ambient or man-made vibrations (Rivin, 1995; Steinberg, 2000). To allow sensitive electronic equipment to operate in a harsh environment, Veprik and Babitsky (2000) proposed an optimization procedure for the design of vibration isolators aimed at minimizing the response of the internal components of electronic equipment. As for the protection of high-tech equipment from micro- or ambient

vibrations, Yang and Agrawal (2000) showed that passive hybrid floor isolation systems are more effective in mitigating the equipment response than passive or hybrid base isolation systems. Xu and coworkers studied the response of a batch of high-tech equipment mounted on a hybrid platform, which in turn is mounted on a building floor (Xu et al., 2003; Yang et al., 2003). Both their theoretical and experimental studies showed that the hybrid platform, which is composed of leaf springs, oil dampers, and an electron-magnetic actuator with velocity feedback control, is more effective in mitigating the velocity response of the high-tech equipment than the passive platform.

The objective of this chapter is to give an overview on the seismic behavior of various base isolators. The organization of this chapter can be summarized as follows. In Section 22.2, the mechanisms of various seismic isolators that are currently in use are introduced and explained. In Section 22.3, a structure–equipment system isolated by bearings of the elastomeric type is modeled by a three-DoF system composed of a spring and dashpot unit, for which a closed-form solution is obtained for the dynamic response of the isolated system subjected to harmonic earthquakes; remarks on the dynamic response of the system components are also made. In Section 22.4 and Section 22.5, the seismic behaviors of a structure–equipment system isolated by a sliding support, with and without resilient capability, will be investigated. Also presented are numerical methods based on the incremental-integration procedure for the analysis of structural systems with sliding-type isolators. Further information on seismic behavior and isolation of structures and equipment is found in [Chapter 29](#) to [Chapter 31](#).

22.2 Mechanisms of Base-Isolated Systems

Figure 22.1 shows a simplified model for a structural system subjected to a support motion.

For this single-DoF system, the equation of motion can be written as

$$m\ddot{x} + c\dot{x} + kx = -m\ddot{x}_g \quad (22.1)$$

where m denotes the mass, c the damping, k the stiffness, x the displacement of the system, and \ddot{x}_g the ground acceleration. By assuming the system to be linearly elastic, the response $x(t)$ can be obtained using Duhamel's integral (also see [Chapter 2](#) and [Chapter 14](#)), as

$$x(t) = \frac{1}{\Omega_d} \int_0^t \ddot{x}_g(\tau) e^{-\zeta\Omega_d(t-\tau)} \sin \Omega_d(t-\tau) d\tau \quad (22.2)$$

where the natural angular frequency, Ω , damped natural frequency, Ω_d , and damping ratio, ζ , of the system are defined as follows:

$$\Omega = \sqrt{\frac{k}{m}} \quad (22.3a)$$

$$\Omega_d = \Omega \sqrt{1 - \zeta^2} \quad (22.3b)$$

$$\zeta = \frac{c}{2m\Omega} \quad (22.3c)$$

Correspondingly, the natural period, T , and damped period, T_d , of the structure are

$$T = \frac{2\pi}{\Omega} = 2\pi \sqrt{\frac{m}{k}} \quad (22.4a)$$

FIGURE 22.1 Model of a single-DoF system.

$$T_d = \frac{2\pi}{\Omega_d} = \frac{T}{\sqrt{1 - \zeta^2}} \quad (22.4b)$$

For a given support acceleration, \ddot{x}_g , the displacement, x , and acceleration, \ddot{x} , of the single-DoF system can be related to the natural period, T , and damping ratio, ζ , of the system. Thus, for a specific earthquake, by first selecting a damping ratio, ζ , and using Equation 22.2, one can compute the peak displacement x , for a structure with a period of vibration, T , with given values of m , c , and k . Repeating the above procedure for a wide range of periods, T , while keeping the damping ratio, ζ , constant, one can obtain response curves similar to those shown in Figure 22.2. By varying the damping ratio, ζ , one can construct the *displacement response spectra* and *pseudo-acceleration response spectra* for all single-DoF structures under a given earthquake, as schematically shown in Figures 22.2 and 22.3, respectively.

A general impression that is gained from Figure 22.2 and Figure 22.3 is that a structure with a shorter natural period has less displacement response when subjected to an earthquake, but it also has a larger acceleration response. Specifically, let us consider a structure of a constant damping ratio, ζ , with its period increased from T_1 to T_2 . As can be observed from the figures, the displacement of the structure increases from D_1 to D_2 , while the acceleration decreases from A_1 to A_2 . Such a feature is known as the *period shift* effect. On the other hand, by increasing damping ratio of the structure, the displacement of the structure decreases significantly, as can be seen from Figure 22.2. The same is also true with the acceleration response, as can be seen from Figure 22.3. Moreover, a larger damping ratio also makes the structure less sensitive to the variation in ground vibration characteristics, as indicated by the smoother response curves for structures having higher damping ratios, in both figures. From the aforementioned two response spectra, one observes that the philosophy of base isolation is to lengthen the vibration period of the structure to be protected, using base isolators of some kind, by which the earthquake force transmitted to the structure can be greatly reduced. In the meantime, some additional damping must be introduced on the base isolators in order to control the relative displacements across the base isolators with tolerable limits.

To fulfill the function of lengthening the period of vibration of the structure to be protected, the base isolators that are inserted between the structure and its foundation must be flexible in the horizontal direction, but stiff enough in the vertical direction so as to carry the heavy loads transmitted from the superstructure. With such devices, the natural period of vibration of the structure will be significantly lengthened and shifted away from the dominant frequency range of the expected earthquakes. The following is a summary of the fundamental features of four types of isolators frequently used in engineering practice.

FIGURE 22.2 Schematic of displacement response spectra.

FIGURE 22.3 Schematic of pseudo-acceleration response spectra.

22.2.1 Elastomeric Isolation System

Elastomeric bearing is the type of base isolator most commonly known to researchers and engineers working on base isolation. It is usually composed of alternating layers of steel and hard rubber and, for this reason, it is also known as the *laminated rubber bearing*. This type of bearing is stiff enough to sustain the vertical loads, yet flexible under the lateral forces. The ability to deform horizontally enables the bearing to reduce significantly the structural base shear transmitted from the ground. While the major function of elastomeric bearings is to reduce the transmission of shear forces to the superstructure by lengthening the vibration period of the entire system, they must also provide sufficient rigidity under vertical loads. Let us consider a structure installed with elastomeric bearings, which is subjected to a support acceleration, \ddot{x}_g , as in Figure 22.4. By representing the isolated structure as a single-DoF system, based on the assumption that the superstructure is rigid in comparison with the stiffness of the elastic bearings, the equation of motion for the entire system can be written as

FIGURE 22.4 Model for base-isolation systems with elastic bearing.

$$\begin{bmatrix} m & 0 \\ 0 & m_b \end{bmatrix} \begin{Bmatrix} \ddot{x} \\ \ddot{x}_b \end{Bmatrix} + \begin{bmatrix} c & -c \\ -c & c + c_b \end{bmatrix} \begin{Bmatrix} \dot{x} \\ \dot{x}_b \end{Bmatrix} + \begin{bmatrix} k & -k \\ -k & k + k_b \end{bmatrix} \begin{Bmatrix} x \\ x_b \end{Bmatrix} = - \begin{Bmatrix} m\ddot{x}_g \\ m_b\ddot{x}_g \end{Bmatrix} \quad (22.5)$$

where m , c , and k denote the mass, damping, and stiffness of the superstructure, respectively, m_b , c_b , and k_b denote the mass, damping, and stiffness of the base raft, respectively, and x and x_b denote the displacements of the superstructure and the base, respectively.

In reality, the reduction in the seismic forces transmitted to a superstructure through the installation of laminated rubber bearings is achieved at the expense of large relative displacements across the bearings. If substantial damping can be introduced into the bearings or the isolation system, then the problem of large displacements can be alleviated. It is for this reason that the laminated rubber bearing with a central lead plug inserted has been devised (Yang et al., 2002). To simulate the dynamic properties of the lead-rubber bearing (LRB) system, an equivalent linearized system has been proposed, for which the equation of motion is

$$\begin{bmatrix} m & 0 \\ 0 & m_b \end{bmatrix} \begin{Bmatrix} \ddot{x} \\ \ddot{x}_b \end{Bmatrix} + \begin{bmatrix} c & -c \\ -c & c + c_{eq} \end{bmatrix} \begin{Bmatrix} \dot{x} \\ \dot{x}_b \end{Bmatrix} + \begin{bmatrix} k & -k \\ -k & k + k_{eq} \end{bmatrix} \begin{Bmatrix} x \\ x_b \end{Bmatrix} = - \begin{Bmatrix} m\ddot{x}_g \\ m_b\ddot{x}_g \end{Bmatrix} \quad (22.6)$$

where c_{eq} and k_{eq} respectively represent the equivalent linearized damping and stiffness coefficients of the LRB system. The dynamic behavior of a structure-equipment system isolated by elastomeric bearings with linearized damping and stiffness coefficients, when subjected to harmonic and earthquake excitations, will be investigated analytically and numerically, respectively, in Section 22.3.

22.2.2 Sliding Isolation System

Another means for increasing the horizontal flexibility of a base-isolated structure is to insert a *sliding* or *friction surface* between the foundation and the base of the structure. The shear force transmitted to the superstructure through the sliding interface is limited by the static frictional force, which equals the product of the coefficient of friction and the weight of the superstructure. The coefficient of friction is usually kept as low as is practical. However, it must be high enough to provide a frictional force that can sustain strong winds and minor earthquakes without sliding. Since the sliding system has no dominant

natural period, it is generally frequency-independent when the structure is subjected to earthquakes with a wideband frequency content. As mentioned previously, when a sliding structure is subjected to a ground motion, transitions may occur repeatedly between the sliding and nonsliding phases. To take into account such a phase transition, Yang et al. (1990) proposed the use of a fictitious spring between the structural base raft and the underlying ground to simulate the static–dynamic frictional force of the sliding device. With reference to Figure 22.5, the equation of motion for the structure with sliding base can be written as follows:

FIGURE 22.5 Model for base-isolation systems with sliding support.

$$\begin{bmatrix} m & 0 \\ 0 & m_b \end{bmatrix} \begin{Bmatrix} \ddot{x} \\ \ddot{x}_b \end{Bmatrix} + \begin{bmatrix} c & -c \\ -c & c \end{bmatrix} \begin{Bmatrix} \dot{x} \\ \dot{x}_b \end{Bmatrix} + \begin{bmatrix} k & -k \\ -k & k \end{bmatrix} \begin{Bmatrix} x \\ x_b \end{Bmatrix} + \begin{Bmatrix} 0 \\ f_r \end{Bmatrix} = - \begin{Bmatrix} m\ddot{x}_g \\ m_b\ddot{x}_g \end{Bmatrix} \quad (22.7)$$

where k_f is the stiffness of the fictitious spring and the frictional force, f_r , can be represented as

$$f_r = \begin{cases} k_f(x_b - x_{b0}) & \text{for non-sliding phase,} \\ \pm \mu(m + m_b)g & \text{for sliding phase} \end{cases} \quad (22.8)$$

with x_{b0} indicating the initial elongation of the fictitious spring in the current nonsliding phase, μ the coefficient of friction, and g the acceleration of gravity. The fictitious spring concept will be incorporated in the analysis of sliding structures in Section 22.4 of this chapter, when considering both harmonic and seismic excitations.

22.2.3 Sliding Isolation System with Resilient Mechanism

One particular problem with a sliding structure is the occurrence of residual displacements after earthquakes. To remedy such a drawback, the sliding surface is often made concave, so as to provide a recentering mechanism for the isolated structures. This is the idea behind the *friction pendulum system* (FPS), shown in Figure 22.6, which utilizes a spherical concave surface to produce a recentering force for the superstructure under excitations. To guarantee that a sliding structure can return to its original position, other mechanisms, such as high-tension springs and elastomeric bearings, can be used as an auxiliary system for providing the restoring forces. Previously, the sliding isolation systems have been successfully applied in the protection of important structures, such as nuclear power plants, emergency fire water tanks, large chemical storage tanks, and so on, from the damaging actions of severe earthquakes.

FIGURE 22.6 Friction pendulum system.

To improve the performance of sliding isolators under strong earthquakes, Mostaghel (1984) and Mostaghel and Khodaverdian (1987) proposed the *resilient-friction base isolator* (RFBI) for

controlling the transmission of shear force to the superstructures, while keeping the residual displacements within an allowable level. The RFBI device is basically made of a central rubber core and Teflon-coated steel plates, and offers a friction resistance for keeping the system in the nonsliding mode under wind excitations and small earthquakes, and a restoring force by the rubber ingredient for limiting the maximum sliding displacements. The equation of motion for a structure installed with RFBI, as shown in Figure 22.7, can be written as

$$\begin{bmatrix} m & 0 \\ 0 & m_b \end{bmatrix} \begin{Bmatrix} \ddot{x} \\ \ddot{x}_b \end{Bmatrix} + \begin{bmatrix} c & -c \\ -c & c + c_b \end{bmatrix} \begin{Bmatrix} \dot{x} \\ \dot{x}_b \end{Bmatrix} + \begin{bmatrix} k & -k \\ -k & k + k_b \end{bmatrix} \begin{Bmatrix} x \\ x_b \end{Bmatrix} + \begin{Bmatrix} 0 \\ f_r \end{Bmatrix} = - \begin{Bmatrix} m\ddot{x}_g \\ m_b\ddot{x}_g \end{Bmatrix} \quad (22.9)$$

The interfacial frictional force, f_r , existing in the RFBI and appearing in Equation 22.9 serves as the outlet for energy dissipation. The behavior of a structure–equipment system supported by sliding isolators with resilient mechanism subjected to both harmonic and earthquake excitations will be investigated in Section 22.5.

22.2.4 Electricite de France System

To limit effectively the acceleration of base-isolated structures and internal secondary systems, such as those of nuclear power plants, when subjected to strong earthquakes, the *Electricite de France* (EDF) system was proposed by Gueraud et al. (1985). The design concept of an EDF system is to arrange the elastomeric bearing and sliding device at the base of a structure in series. For low-level ground motions, the EDF system will behave as an elastomeric bearing and return to the original position after support motions, while for strong earthquakes, the EDF system will behave as a sliding device. The EDF system may have a residual displacement after some major earthquakes. Because of the sliding mechanism of the EDF system, the maximum horizontal acceleration of the superstructure is kept within a certain range (Gueraud et al., 1985; Park et al., 2002), while the shear force transmitted to the superstructure through the frictional interface is smaller than the static frictional force. For the mathematical model shown for the EDF system in Figure 22.8, the equations of motion for the nonsliding and sliding phases can be written as

(a) nonsliding phase:

$$\begin{Bmatrix} m\ddot{x} \\ m_b\ddot{x}_b \\ 0 \end{Bmatrix} + \begin{bmatrix} c & -c & 0 \\ -c & c & 0 \\ 0 & 0 & c_{EDF} \end{bmatrix} \begin{Bmatrix} \dot{x} \\ \dot{x}_b \\ \dot{x}_{EDF} \end{Bmatrix} + \begin{bmatrix} k & -k & 0 \\ -k & k + k_f & -k_f \\ 0 & -k_f & k_f + k_{EDF} \end{bmatrix} \begin{Bmatrix} x \\ x_b \\ x_{EDF} \end{Bmatrix} = \begin{Bmatrix} -m\ddot{x}_g \\ -m_b\ddot{x}_g \\ 0 \end{Bmatrix} \quad (22.10a)$$

FIGURE 22.7 Model for base-isolation systems with RFBI device.

FIGURE 22.8 Model for base-isolation systems with EDF device.

(b) sliding phase:

$$\begin{aligned} & \begin{Bmatrix} m\ddot{x} \\ m_b\ddot{x}_b \\ 0 \end{Bmatrix} + \begin{bmatrix} c & -c & 0 \\ -c & c & 0 \\ 0 & 0 & c_{\text{EDF}} \end{bmatrix} \begin{Bmatrix} \dot{x} \\ \dot{x}_b \\ \dot{x}_{\text{EDF}} \end{Bmatrix} + \begin{bmatrix} k & -k & 0 \\ -k & k & 0 \\ 0 & 0 & k_{\text{EDF}} \end{bmatrix} \begin{Bmatrix} x \\ x_b \\ x_{\text{EDF}} \end{Bmatrix} \\ &= \begin{Bmatrix} -m\ddot{x}_g \\ -m_b\ddot{x}_g \mp \mu(m + m_b)g \\ \pm \mu(m + m_b)g \end{Bmatrix} \end{aligned} \quad (22.10b)$$

where c_{EDF} and k_{EDF} , respectively, denote the damping and stiffness of the EDF system, and x_{EDF} denotes the displacement of the system.

22.2.5 Concluding Remarks

To mitigate the transmission of earthquake forces to a structure, and the potentially earthquake-induced damage to the equipment attached to the structure, base isolation is an effective structural design philosophy. With the installation of base isolators, the natural period of vibration of the structure will be significantly lengthened and shifted away from the dominant frequency range of the expected earthquakes. In accordance, the earthquake force transmitted to the structure can be significantly reduced. In this section, the mechanisms of four types of base isolator frequently used in engineering practice are introduced. Since the base isolators, such as the elastomeric bearings or sliding isolations, have relatively flexible stiffness in the horizontal direction, the occurrence of residual displacements after earthquakes may cause certain problems on the structure to be protected. To remedy such a drawback and to further guarantee that a base-isolated structure can return to its original position, the RFBI is implemented for controlling the transmission of shear force to the superstructure, while keeping the residual displacement within an allowable level. On the other hand, to limit the acceleration level of internal secondary systems housed in a base-isolated structure under strong earthquakes, such as those of the nuclear power plants, the EDF system can be used as an alternative device for base isolation, even though some residual displacements may be induced after the earthquakes.

22.3 Structure–Equipment Systems with Elastomeric Bearings

Owing to the stringent requirements for normal functioning of high-tech facilities, such as printed circuit boards, semiconductor factories, and sensitive medical devices, the need to suppress excessive vibrations in sensitive structure–equipment systems has become an issue of great concern to structural designers. Besides, these high-tech facilities may suffer significant damages during a major earthquake. Using elastomeric isolation systems to reduce the earthquake forces transmitted from the ground is one of the most popular ways adopted by structural designers. In this section, the performance of elastomeric bearings in protecting structure–equipment systems against horizontal ground motions will be investigated.

22.3.1 Formulation of Base Isolation Systems with Elastic Bearing

By modeling the structure, internal equipment and the base of an isolated structure–equipment system as a lumped mass system, one can construct the mathematical model for the structure–equipment isolation system supported by an elastic bearing in [Figure 22.9](#). The following is the

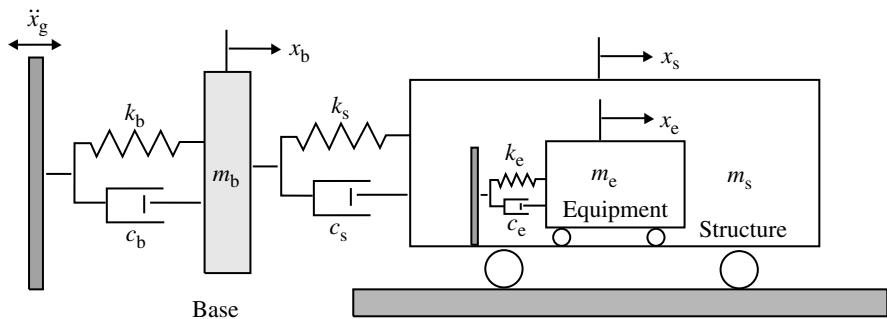

FIGURE 22.9 Model of a structure–equipment isolation system with elastic bearing.

equation of motion for the base-isolated structure–equipment system when it is subjected to a ground acceleration, \ddot{x}_g :

$$\begin{aligned} & \begin{Bmatrix} m_e \ddot{x}_e \\ m_s \ddot{x}_s \\ m_b \ddot{x}_b \end{Bmatrix} + \begin{bmatrix} c_e & -c_e & 0 \\ -c_e & c_s + c_e & -c_s \\ 0 & -c_s & c_s + c_b \end{bmatrix} \begin{Bmatrix} \dot{x}_e \\ \dot{x}_s \\ \dot{x}_b \end{Bmatrix} + \begin{bmatrix} k_e & -k_e & 0 \\ -k_e & k_s + k_e & -k_s \\ 0 & -k_s & k_s + k_b \end{bmatrix} \begin{Bmatrix} x_e \\ x_s \\ x_b \end{Bmatrix} \\ &= - \begin{Bmatrix} m_e \\ m_s \\ m_b \end{Bmatrix} \ddot{x}_g \end{aligned} \tag{22.11}$$

where m represents the mass, c the damping coefficient, and k the stiffness of the system. Also, the subscripts ‘e’, ‘s’, and ‘b’ are associated with the DoF of the equipment, structure, and base, respectively. The notations employed in Figure 22.9 have been defined in Table 22.1. It should be mentioned that the elastic bearing stiffness, k_b , appearing in Equation 22.11, is a parameter relating to the boundary conditions of the system considered here. A small value of k_b relative to the structural stiffness, k_s , means that the system is isolated by a set of soft bearings. In contrast, a large value of k_b means that the structure is rigidly supported.

TABLE 22.1 Definition of Symbols

Symbol	Definition
c_e, c_s	Damping coefficients of equipment and superstructure
k_e, k_s	Stiffness of equipment and superstructure
k_b	Stiffness of elastic bearing or resilient stiffness of isolation system
m_e, m_s, m_b	Masses of equipment, superstructure and base mat
$x_e(t), x_s(t), x_b(t)$	Relative-to-the-ground displacements of equipment, superstructure and base mat
$\ddot{x}_g(t)$	Ground acceleration
μ	Frictional coefficient of sliding isolation system
ω_b	Frequency of isolation system
ω_e, ω_s	Frequencies of equipment and superstructure
ω_g	Frequency of ground excitation
ζ_e, ζ_s	Damping ratios of equipment and structure

22.3.2 Free Vibration Analysis

By neglecting the damping and forcing terms in Equation 22.11, the equation of motion for free vibration can be written as

$$\begin{Bmatrix} m_e \ddot{x}_e \\ m_s \ddot{x}_s \\ m_b \ddot{x}_b \end{Bmatrix} + \begin{bmatrix} k_e & -k_e & 0 \\ -k_e & k_s + k_e & -k_s \\ 0 & -k_s & k_s + k_b \end{bmatrix} \begin{Bmatrix} x_e \\ x_s \\ x_b \end{Bmatrix} = \begin{Bmatrix} 0 \\ 0 \\ 0 \end{Bmatrix} \quad (22.12)$$

By solving the preceding equation, one can obtain the natural frequencies and vibration modes of the structure–equipment system with elastic bearings. As for the present problem, the horizontal stiffness of the elastic bearing is designed to be quite low compared with that of the superstructure. It follows that the superstructure in its entirety behaves essentially as a *rigid body* for the fundamental vibration mode shape of the combined system, which implies that the displacement responses for the equipment, structure, and base under free vibration can be approximately taken as the same, that is, $x_e = x_s = x_b = x$. By introducing such a condition into Equation 22.12, the equation of motion for the equivalent single-DoF base-isolated system can be written as

$$(m_e + m_s + m_b)\ddot{x} + k_b x = 0 \quad (22.13)$$

Equation 22.13 indicates that the fundamental frequency, ω_1 , of the base-isolated system can be approximated by $\omega_1 \approx \sqrt{k_b/(m_e + m_s + m_b)}$. Further, if the condition of fixed base is considered, that is, by letting the responses of the base be equal to zero, $x_b = \ddot{x}_b = 0$, the structure–equipment isolation system will be reduced to the case of a fixed-base system, such that the equation of motion becomes

$$\begin{Bmatrix} m_e \ddot{x}_e \\ m_s \ddot{x}_s \end{Bmatrix} + \begin{bmatrix} k_e & -k_e \\ -k_e & k_s + k_e \end{bmatrix} \begin{Bmatrix} x_e \\ x_s \end{Bmatrix} = \begin{Bmatrix} 0 \\ 0 \end{Bmatrix} \quad (22.14)$$

as is well known.

22.3.3 Dynamics of Structure–Equipment Isolation Systems to Harmonic Excitations

The advantage of a closed-form solution is that it allows us to examine the key parameters involved in the problem considered. This is what will be sought herein. For the case of a harmonic ground excitation, x_g , with amplitude, X_g , that is, with $x_g = X_g e^{i\omega t}$, one may derive from Equation 22.11 the following:

$$\begin{Bmatrix} m_e \ddot{x}_e \\ m_s \ddot{x}_s \\ m_b \ddot{x}_b \end{Bmatrix} + \begin{bmatrix} k_e & -k_e & 0 \\ -k_e & k_s + k_e & -k_s \\ 0 & -k_s & k_s + k_b \end{bmatrix} \begin{Bmatrix} x_e \\ x_s \\ x_b \end{Bmatrix} = \begin{Bmatrix} m_e \\ m_s \\ m_b \end{Bmatrix} X_g \omega^2 e^{i\omega t} \quad (22.15)$$

Correspondingly, the steady-state responses of the system can be expressed as

$$\begin{Bmatrix} x_e \\ x_s \\ x_b \end{Bmatrix} = \begin{Bmatrix} X_e \\ X_s \\ X_b \end{Bmatrix} e^{i\omega t} \quad (22.16)$$

where (X_e , X_s , and X_b) represent the amplitudes of the equipment, structure, and base, respectively.

Substituting Equation 22.16 into Equation 22.15 yields

$$\begin{bmatrix} k_e - m_e \omega^2 & -k_e & 0 \\ -k_e & k_s + k_e - m_s \omega^2 & -k_s \\ 0 & -k_s & k_s + k_b - m_b \omega^2 \end{bmatrix} \begin{Bmatrix} X_e \\ X_s \\ X_b \end{Bmatrix} = \begin{Bmatrix} m_e \\ m_s \\ m_b \end{Bmatrix} X_g \omega^2 \quad (22.17)$$

from which the amplitudes (X_e , X_s , and X_b) for the system can be solved as follows:

$$X_e = \frac{X_s + X_g f_e^2}{1 - f_e^2} \quad (22.18a)$$

$$X_b = \frac{X_s + \varepsilon_b f_s^2 X_g}{1 + k_b/k_s - \varepsilon_b f_s^2} \quad (22.18b)$$

$$X_s = \frac{\left[m_s + \frac{m_e}{1 - f_e^2} + \frac{m_b}{1 + k_b/k_s - \varepsilon_b f_s^2} \right] X_g \omega^2}{\frac{k_b - m_b \omega^2}{1 + k_b/k_s - \varepsilon_b f_s^2} - \left(m_s + \frac{m_e}{1 - f_e^2} \right) \omega^2} \quad (22.18c)$$

where the amplitudes of the equipment and base, that is, X_e and X_b , have been expressed in terms of the amplitude of the base, X_s . The parameters in Equation 22.18 are defined as

$$f_e = \omega/\omega_e \quad (22.19a)$$

$$f_s = \omega/\omega_s \quad (22.19b)$$

$$\varepsilon_b = m_b/m_s \quad (22.19c)$$

$$\omega_e = \sqrt{k_e/m_e} \quad (22.19d)$$

$$\omega_s = \sqrt{k_s/m_s} \quad (22.19e)$$

Finally, the state-steady absolute acceleration responses of the structure, equipment, and base can be expressed in terms of the ground acceleration \ddot{x}_g as

$$a_s = \ddot{x}_s + \ddot{x}_g = -(X_s + X_g) \omega^2 e^{i\omega t} = \frac{k_b \ddot{x}_g}{D(\omega)} \quad (22.20a)$$

$$a_e = \ddot{x}_e + \ddot{x}_g = -\frac{(X_s + X_g) \omega^2 e^{i\omega t}}{1 - f_e^2} = \frac{k_b \ddot{x}_g}{(1 - f_e^2) D(\omega)} \quad (22.20b)$$

$$a_b = \ddot{x}_b + \ddot{x}_g = \frac{[-X_s + X_g + (k_b/k_s) X_g] \omega^2 e^{i\omega t}}{1 + k_b/k_s - \varepsilon_b f_s^2} = \frac{(D^{-1}(\omega) + k_s^{-1}) k_b \ddot{x}_g}{1 + k_b/k_s - \varepsilon_b f_s^2} \quad (22.20c)$$

$$D(\omega) = (k_b - m_b \omega^2) - (1 + k_b/k_s - \varepsilon_b f_s^2) \left(m_s + \frac{m_e}{1 - f_e^2} \right) \omega^2 \quad (22.20d)$$

As can be seen, the acceleration response of each component in the structure–equipment system depends mainly on the stiffness of the elastic bearing, k_b . In particular, the use of a smaller bearing stiffness, k_b , can result in significant reduction of the shear forces transmitted to the superstructure, as indicated by Equation 22.20a. This explains why an elastic bearing can be effectively used as an isolator for reducing the base shear of the structure–equipment system. In contrast, if the bearing stiffness, k_b , is made to be infinitely large, that is, by letting $k_b \rightarrow \infty$, the acceleration responses in Equation 22.20, reduce to

$$a_s = \frac{(1 - f_e^2) \ddot{x}_g}{(1 - f_e^2)(1 - f_s^2) - \varepsilon_e f_s^2} \quad (22.21a)$$

$$a_e = \frac{\ddot{x}_g}{(1 - f_e^2)(1 - f_s^2) - \varepsilon_e f_s^2} \quad (22.21b)$$

$$a_b = \ddot{x}_g \quad (22.21c)$$

with the use of L'Hospital's Rule, where $\varepsilon_e = m_e/m_s$. As can be seen from Equation 22.21c, the acceleration of the structural base is equal to the ground acceleration. Clearly, the present problem has been reduced to a two-DoF system with a rigid base, for which the solutions have been given in Equation 22.21a and Equation 22.21b.

Some important high-tech facilities, such as semiconductor factories and medical devices, are very sensitive to vibrations, especially to those caused by resonance. To consider the effect of resonance, we shall let the ground excitation frequency, ω , coincide with the equipment frequency, ω_e , that is, by letting $f_e = 1$ or $\omega_e = \omega$. For this case, the acceleration responses of the system in Equation 22.20 reduce to

$$a_s = 0 \quad (22.22a)$$

$$a_e = \frac{-k_b \ddot{x}_g}{k_e[1 + (k_b - m_b \omega_e^2)/k_s]} \quad (22.22b)$$

$$a_b = \frac{k_b \ddot{x}_g}{k_s + k_b - m_b \omega_e^2} \quad (22.22c)$$

Because of the coincidence of the ground excitation frequency with the equipment frequency, the equipment behaves like a vibration absorber of the structure. For this reason, the response of the equipment is greatly amplified, as implied by Equation 22.22b, while the response of structure is completely suppressed, as indicated by Equation 22.22a. Moreover, if the frequency of the equipment is equal to the fundamental frequency of the structure–equipment isolation system, that is, $\omega_e (\approx \omega_1) = \sqrt{k_b/(m_e + m_s + m_b)}$, then the responses of the system in Equation 22.22 can further be expressed as follows:

$$a_s = 0 \quad (22.23a)$$

$$a_e = \frac{-k_b \ddot{x}_g}{k_e[1 + (m_s + m_e)\omega_e^2/k_s]} \quad (22.23b)$$

$$a_b = \frac{k_b \ddot{x}_g}{k_s + (m_s + m_e)\omega_e^2} \quad (22.23c)$$

Since the equipment mass is generally much smaller than the structural mass, the preceding equation can be further reduced to

$$a_s = 0 \quad (22.24a)$$

$$a_e = \frac{-k_b \ddot{x}_g}{k_e(1 + \omega_e^2/\omega_s^2)} \quad (22.24b)$$

$$a_b = \frac{k_b \ddot{x}_g}{k_s(1 + \omega_e^2/\omega_s^2)} \quad (22.24c)$$

As indicated by Equation 22.24b, the acceleration response of the equipment depends on the stiffness ratio, k_b/k_e , of the base to the equipment.

For the resonance condition of $\omega_e = \omega$, mentioned previously, let us consider the case when the structural frequency is equal to the equipment frequency, that is, $\omega_e = \omega_s$. For this case, the responses of the system in Equation 22.22 reduce to

$$a_s \approx 0 \quad (22.25a)$$

$$a_e \approx \frac{-k_b \ddot{x}_g}{\varepsilon_e[k_s(1 - \varepsilon_b) + k_b]} \quad (22.25b)$$

$$a_b = \frac{k_b \ddot{x}_g}{k_s(1 - \varepsilon_b) + k_b} \quad (22.25c)$$

which indicates that the acceleration response of the equipment may be greatly amplified, as implied by the relatively small mass ratio $\varepsilon_e (= m_e/m_s)$ and large stiffness ratio, k_b/k_s , in Equation 22.25b. Such a phenomenon has been referred to as the *tuning of equipment*.

On the other hand, when the excitation frequency, ω , coincides with the fundamental frequency, ω_1 , of the isolated system, that is, $\omega (\approx \omega_1) = \sqrt{k_b/(m_e + m_s + m_b)}$, resonant response may be induced on the structure–equipment isolation system. Considering that the first priority in design of high-tech

equipment is to reduce the vibrations of the equipment, rather than the structure, by comparing the denominators in Equation 22.20a and Equation 22.20b, one may assume that the condition $|1 - f_e^2| \geq 1$ or $f_e = \omega/\omega_e \geq \sqrt{2}$ remains satisfied for a good design, which is equivalent to

$$\frac{\omega_e}{\omega_s} \leq \sqrt{\frac{k_b/k_s}{2[1 + (m_b + m_e)/m_s]}} \tag{22.26}$$

Since the fundamental frequency, ω_s , of a base-isolated structure is generally low in practice, the horizontal stiffness of the equipment attached to the structure must be designed to be soft enough such that Equation 22.26 can be satisfied. Certainly, this is one of the guidelines to be obeyed in the design of equipment for the sake of vibration reduction.

22.3.4 Illustrative Example

The forgoing formulations have been made by neglecting the damping of the structural system and by assuming the ground motion to be of the harmonic type. In practice, there is always some damping with the structural system, while the ground motion may be random in nature. To deal with such problems, the only recourse is to use numerical methods that are readily available. In this section, the Newmark β method, proposed by Newmark (1959), with $\gamma = 1/2$ and $\beta = 1/4$, will be adopted for solving the second-order differential equation presented in Equation 22.11, which has the advantage of being numerically stable.

The example considered is the structure–equipment system isolated by elastomeric bearings, shown in Figure 22.9, with the data given in Table 22.2. As can be seen, the equipment has a frequency equal to five times the structural frequency, that is, $\omega_e = 5\omega_s$ ($= 8.34$ Hz). The 1940 El Centro earthquake (NS component) with a peak ground acceleration (PGA) of 341.55 gal is adopted as the ground excitation, as given in Figure 22.10. By an eigenvalue analysis, the natural frequencies solved for the base-isolated system are 2.46, 21.41, and 52.74 rad/sec. Because of the installation of elastic bearings on the structure–equipment system, the fundamental frequency of the system decreases significantly and is approximately equal to $\omega_1 \approx \sqrt{k_b(m_e + m_s + m_b)} = 2.51$ rad/sec, according to Section 22.3.2. From this example, one observes that the use of a single-DoF system to model a base-isolated system can give a generally good result for the first frequency of vibration.

As can be seen from Figure 22.11, for the structural acceleration of the system, the main-shock response of the fixed-base structure has been effectively eliminated due to installation of the elastic bearings. However, as indicated by Figure 22.12, because of the installation of soft bearings, the base displacement response of the isolated system is much larger and decays much slowly, even after the main shocks.

In Figure 22.13 the acceleration response of the equipment for the isolated and fixed-base cases are compared. As can be seen, the main-shock response of the fixed-base structure has been effectively suppressed through the installation of the elastic bearings. Furthermore, the equipment response appears to be almost identical to the structure response shown in Figure 22.11, due to the fact that the equipment

TABLE 22.2 System Parameters Used in Simulation (Section 22.3.4)

Equipment		Superstructure		Isolation System	
Parameter	Value	Parameter	Value	Parameter	Value
Mass m_e	3 t ($= m_s/100$)	Mass m_s	300 t	Mass m_b	100 t ($= m_s/3$)
Horizontal stiffness k_e	8258 kN/m	Horizontal stiffness k_s	33,030 kN/m	Horizontal stiffness k_b	2546 kN/m
Damping	15.74 kN m/s	Damping	314.79 kN m/s	Damping	50.46 kN m/s
Frequency $\omega_e = \sqrt{k_e/m_e}$	52.47 rad/sec	Frequency $\omega_s = \sqrt{k_s/m_s}$	10.46 rad/sec	Frequency $\omega_b = \sqrt{k_b/m_b}$	5.05 rad/sec

FIGURE 22.13 Comparison of equipment accelerations.

is rigidly attached to the structure, as implied by the relatively higher frequency of the equipment. As for the present example, the effectiveness of the elastic bearings in reducing the equipment response is ascertained.

For high-tech equipment, engineers may be concerned about the effect on equipment tuning induced by external excitations, such as earthquakes and traffic-induced vibrations. To investigate this effect on the structure–equipment isolation system considered, the maximum equipment acceleration was plotted as a function of the frequency ratio, ω_e/ω_s , in Figure 22.14. As can be seen, the response of the equipment is greatly amplified when it has a frequency close to the fundamental frequency of the structure–equipment isolation system, that is, when $\omega_e = 2.51$ rad/sec or $\omega_e/\omega_s = 0.24$. To avoid such a situation, it is suggested that isolators be mounted at both the structure base and equipment base. From Figure 22.14, one observes that the use of a small horizontal stiffness for the equipment will generally lead to greater equipment response due to tuning effect. However, as the stiffness of the equipment is further reduced, the equipment will reach another isolation state, in which the equipment response will be substantially suppressed, as indicated by the region with relatively small values of ω_e/ω_s . The margin for such a frequency ratio of ω_e/ω_s can be obtained by substituting the parameters in Table 22.2 into

FIGURE 22.14 Maximum accelerations of structure–equipment isolation systems.

Equation 22.26, which yields a critical ratio of $\omega_c/\omega_s = 0.168$, very close to the value of 0.16 marked in Figure 22.14.

22.3.5 Concluding Remarks

This section investigates the dynamic response of a mathematical model of a structure–equipment system isolated by elastomeric bearings and subjected to ground excitations. Based on the closed-form solution of a structure–equipment isolation system subjected to harmonic support motions, one observes that the coincidence of the ground excitation frequency with the equipment frequency will make the equipment behave like a vibration absorber of the structure, of which the acceleration response will be greatly amplified. For the case that the first priority in design is to reduce the vibration of the equipment rather than that of the structure, Equation 22.26 provides a guideline for the design of equipment, which has been verified in the numerical example.

22.4 Sliding Isolation Systems

Sliding isolation can be an effective means for the seismic protection of structural systems. By implementing sliding isolators under the base mat of a structure, the transmission of ground excitation to the structure can be greatly reduced. Currently, applications of sliding isolation systems can be found elsewhere (Naeim and Kelly, 1999). A *sliding isolator* usually consists of a slider with frictional surfaces. For this reason, it is also referred to as a *friction isolator*. When subjected to an earthquake, the slider will slide along the frictional contact surfaces whenever the horizontal seismic force exceeds the maximum frictional force of the support, which, by Coulomb's theory, is equal to the normal contact force multiplied by the static (or dynamic) coefficient of friction of the sliding surfaces. Because of this, the seismic force transmitted to the superstructure is generally less than the maximum frictional force of the isolator. Obviously, the maximum frictional force is an important parameter for the design of a sliding isolation system, because it decides when the system starts to slide and how large the shear force is to be transmitted to the superstructure.

The motion of a sliding structure consists of two different states, namely, the sliding state and the stick (or nonsliding) state. At any instant of motion, the structure can only belong to one of the two states. Although in each state the sliding structure can be modeled as a linear system, the governing equations of motion for the two states are different. As a result, the overall behavior of the sliding structure is nonlinear. Such nonlinearity has resulted in the occurrence of subharmonic resonance in the frequency response of a sliding structure (Mostaghel et al., 1983; Westermo and Udawadia, 1983), making the dynamic response much more complicated. In some applications, a sliding isolation system has been designed with an automatic recentering mechanism (or resilient mechanism), so that the structure can slide back to its original position after the earthquake (Mokha et al., 1991). This type of sliding systems has been called the *resilient sliding isolation system*, which will be investigated in Section 22.5. The implementation of a recentering mechanism offers some advantages, but will inevitably introduce some disadvantages, as will be discussed in Section 22.5.

The purpose of this section is to investigate the seismic behavior of a sliding isolated structure and also the behavior of an equipment item mounted on the structure. No consideration will be made for the recentering mechanism. The nonlinear dynamic equation for a structure with an underneath friction element is first formulated. Next, two numerical approaches will be presented for solving the nonlinear equation, the *shear balance method* and *fictitious spring method*. Finally, using some assumed data, the harmonic response and seismic behavior of a sliding structure, together with the equipment mounted on it, will be presented. In this section, the frictional coefficient of the sliding system is assumed to be of the Coulomb type, that is, a time-invariant constant. For simplification, no distinction will be made between the static and dynamic frictional coefficients, or between the dynamic and maximum static frictional force.

22.4.1 Mathematical Modeling and Formulation

22.4.1.1 Equation of Motion

A sliding isolated structure with an attached equipment item, as schematically shown in Figure 22.15, can be represented as a mass–spring–dashpot system of three DoF, as shown in Figure 22.16, for which the notations employed have been defined in Table 22.1. When the structural system is excited by an earthquake, the equation of motion can be written as

$$\mathbf{M}\ddot{\mathbf{x}}(t) + \mathbf{C}\dot{\mathbf{x}}(t) + \mathbf{K}\mathbf{x}(t) = -\mathbf{M}\mathbf{L}_1\ddot{x}_g(t) + \mathbf{L}_2f(t) \quad (22.27)$$

where the vector \mathbf{x} denotes the dynamic responses of the whole structural system

$$\mathbf{x}(t) = \begin{Bmatrix} x_e(t) \\ x_s(t) \\ x_b(t) \end{Bmatrix} \quad (22.28)$$

The mass, damping, and stiffness matrices in Equation 22.27 are defined as

$$\mathbf{M} = \begin{bmatrix} m_e & 0 & 0 \\ 0 & m_s & 0 \\ 0 & 0 & m_b \end{bmatrix},$$

$$\mathbf{C} = \begin{bmatrix} c_e & -c_e & 0 \\ -c_e & c_e + c_s & -c_s \\ 0 & -c_s & c_s \end{bmatrix}, \quad (22.29)$$

$$\mathbf{K} = \begin{bmatrix} k_e & -k_e & 0 \\ -k_e & k_e + k_s & -k_s \\ 0 & -k_s & k_s \end{bmatrix}$$

and the force distribution vectors as

$$\mathbf{L}_1 = \begin{Bmatrix} 1 \\ 1 \\ 1 \end{Bmatrix}, \quad \mathbf{L}_2 = \begin{Bmatrix} 0 \\ 0 \\ 1 \end{Bmatrix} \quad (22.30)$$

Note that in Equation 22.27, the isolator frictional force, $f(t)$, which is not a constant, is moved to the right-hand side of the equation. This nonlinear force requires a special treatment in an analysis procedure, as will be explained later on.

For a systematic treatment, the above equation of motion can be further written in a state space form as shown below (Meirovitch, 1990):

$$\dot{\mathbf{z}}(t) = \mathbf{A}\mathbf{z}(t) + \mathbf{E}\ddot{x}_g(t) + \mathbf{B}f(t) \quad (22.31)$$

FIGURE 22.15 Schematic for an isolated structure–equipment system with sliding bearing.

FIGURE 22.16 Model for an isolated structure–equipment system with sliding support.

where the state vector $\mathbf{z}(t)$ and the system matrix \mathbf{A} are defined as

$$\mathbf{z}(t) = \begin{bmatrix} \dot{\mathbf{x}}(t) \\ \mathbf{x}(t) \end{bmatrix}, \quad \mathbf{A} = \begin{bmatrix} -\mathbf{M}^{-1}\mathbf{C} & -\mathbf{M}^{-1}\mathbf{K} \\ \mathbf{I} & \mathbf{0} \end{bmatrix} \quad (22.32)$$

and the excitation and friction distribution vectors as

$$\mathbf{E} = \begin{bmatrix} -\mathbf{L}_1 \\ \mathbf{0} \end{bmatrix}, \quad \mathbf{B} = \begin{bmatrix} \mathbf{M}^{-1}\mathbf{L}_2 \\ \mathbf{0} \end{bmatrix} \quad (22.33)$$

22.4.1.2 Conditions for Stick and Sliding States

As mentioned above, the motion of a sliding structure at any instant has two possible states, namely, the stick (or nonsliding) and sliding states. The following are the conditions that must be satisfied by the sliding structure:

- (1) In stick state

$$|f(t)| < f_{\max} = \mu W \quad (22.34a)$$

$$\dot{x}_b(t) = 0 \quad (22.34b)$$

where μ is the coefficient of friction and W is the total weight of the structure. According to the preceding equations, the frictional force in the stick state is an unknown with a magnitude less than the maximum frictional force, f_{\max} , which equals the product of μ and W , while the sliding velocity of the structure is simply zero. Whenever the frictional force satisfies Equation 22.34a, the sliding system remains in the stick state, otherwise it changes into the sliding state.

- (2) In sliding state

$$f(t) = -\text{sgn}(\dot{x}_b(t))f_{\max} = -\text{sgn}(\dot{x}_b(t))\mu W \quad (22.35a)$$

$$\dot{x}_b(t) \neq 0 \quad (22.35b)$$

where the function $\text{sgn}(x)$ denotes the sign of the variable x . According to Equation 22.35a and Equation 22.35b, the frictional force in the sliding state has a magnitude equal to the maximum frictional force, but directed in a sense opposite to that of the sliding velocity. On the other hand, the sliding velocity of the isolator remains as an unknown.

22.4.2 Methods for Numerical Analysis

Two numerical methods commonly used for the analysis of sliding isolated structural systems, the shear balance method and fictitious spring method, will be introduced in this section. By employing the discrete-time state-space formula, both methods can be cast in an incremental form that is suitable for the analysis of sliding systems with multiple DoF.

22.4.2.1 Shear Balance Method

Consider the state-space equation, Equation 22.31, and assume that both the ground acceleration and frictional force vary linearly within each time interval, as shown in Figure 22.17. Equation 22.31 may be written in the following incremental form (Meirovitch, 1990)

$$\mathbf{z}[k+1] = \mathbf{A}_d\mathbf{z}[k] + \mathbf{E}_0\ddot{x}_g[k] + \mathbf{E}_1\ddot{x}_g[k+1] + \mathbf{B}_0f[k] + \mathbf{B}_1f[k+1] \quad (22.36)$$

where the symbol $x[k]$ denotes that the variable x is evaluated at the k th time step. The other coefficient

matrices in equation 22.36 are defined as

$$\mathbf{A}_d = e^{\mathbf{A}\Delta t} = \sum_{i=0}^{\infty} \frac{(\Delta t)^i}{i!} \mathbf{A}^i \quad (22.37)$$

$$\mathbf{B}_0 = \left[(\mathbf{A})^{-1} \mathbf{A}_d + \frac{1}{\Delta t} (\mathbf{A})^{-2} (\mathbf{I} - \mathbf{A}_d) \right] \mathbf{B} \quad (22.38a)$$

$$\mathbf{B}_1 = \left[-(\mathbf{A})^{-1} + \frac{1}{\Delta t} (\mathbf{A})^{-2} (\mathbf{A}_d - \mathbf{I}) \right] \mathbf{B} \quad (22.38b)$$

where Δt denotes the size of the time step considered for analysis. The matrices \mathbf{E}_0 and \mathbf{E}_1 can be computed in a way similar to \mathbf{B}_0 and \mathbf{B}_1 , except that the matrix \mathbf{B} in Equation 22.38a and Equation 22.38b should be replaced by the matrix \mathbf{E} . In some applications, the system matrix \mathbf{A} may not be invertible, that is, \mathbf{A}^{-1} does not always exist. If this is the case, one may compute \mathbf{B}_0 and \mathbf{B}_1 (and similarly \mathbf{E}_0 and \mathbf{E}_1) by the following formulas:

$$\mathbf{B}_0 = \mathbf{A}_d^* \mathbf{B}, \quad \mathbf{B}_1 = (\hat{\mathbf{A}}_d - \mathbf{A}_d^*) \mathbf{B} \quad (22.39)$$

where

$$\mathbf{A}_d^* = \sum_{i=0}^{\infty} \frac{(\Delta t)^{i+1}}{i!(i+2)} \mathbf{A}^i, \quad \hat{\mathbf{A}}_d = \sum_{i=0}^{\infty} \frac{(\Delta t)^{i+1}}{(i+1)!} \mathbf{A}^i \quad (22.40)$$

Note that, on the right-hand side of Equation 22.36, the only unknown at the k th time step is the frictional force $f[k+1]$; therefore, $f[k+1]$ must be determined before the next time step response $\mathbf{z}[k+1]$ is computed. Wang et al. (1998) proposed the shear balance method for computing the frictional force $f[k+1]$. By this method, the sliding structure is first assumed to be in the stick state at the $(k+1)$ th step, for which the condition given in Equation 22.34b must be satisfied

$$\dot{\mathbf{x}}_b[k+1] = \mathbf{D}\mathbf{z}[k+1] = 0 \quad (22.41)$$

where \mathbf{D} is a relation matrix, equal to $\mathbf{D} = [0 \ 0 \ 1 \ 0 \ 0 \ 0]$ for the model shown in Figure 22.16. Substituting $\mathbf{z}[k+1]$ in Equation 22.36 into Equation 22.41, one may solve for the *estimated frictional force* at the $(k+1)$ th time step as

$$\bar{f}[k+1] = -(\mathbf{D}\mathbf{B}_1)^{-1} \mathbf{D}(\mathbf{A}_d \mathbf{z}[k] + \mathbf{B}_0 f[k] + \mathbf{E}_0 \ddot{\mathbf{x}}_g[k] + \mathbf{E}_1 \ddot{\mathbf{x}}_g[k+1]) \quad (22.42)$$

where $\bar{f}[k+1]$ with an overbar signifies that the frictional force is an estimate obtained by assuming the sliding structure to be at the stick state. Such a value may not be the actual one if the system is not in the stick state. The physical meaning for $\bar{f}[k+1]$ is that it represents the *balanced shear force* required at the $(k+1)$ th time step for the structure to remain in the stick state. Therefore, the sign of $\bar{f}[k+1]$ indicates the direction of the resistant force provided by the isolation system. In spite of the fact that $\bar{f}[k+1]$ may not be the actual frictional force, it plays an important role for determining the actual state (stick or sliding) and the actual frictional force of the sliding isolated structure, as will be described below based on Equation 22.34a and Equation 22.35a.

- (1) The system is in the “stick state” if $|\bar{f}[k+1]| < f_{\max}$ and the frictional force is

$$f[k+1] = \bar{f}[k+1] \quad (22.43)$$

- (2) The system is in the “sliding state” if $|\bar{f}[k+1]| \geq f_{\max}$ and the frictional force is

$$f[k+1] = \text{sgn}(\bar{f}[k+1])f_{\max} \quad (22.44)$$

FIGURE 22.17 Force integration scheme with linear interpolation.

As can be seen, the term $-\text{sgn}(\dot{x}_b[k+1])$ in Equation 22.35a is replaced by $\text{sgn}(\tilde{f}[k+1])$ in Equation 22.44. Such a replacement is justified since the sign of $\tilde{f}[k+1]$ indicates the direction of the resistant force at the $(k+1)$ th time step. Once the correct frictional force, $f[k+1]$, is determined by using either Equation 22.43 or Equation 22.44, it can be substituted into Equation 22.36 to obtain the response $\mathbf{z}[k+1]$ for the next time step. The computational flow-chart for the shear balance method has been given in Figure 22.18.

22.4.2.2 Fictitious Spring Method

The fictitious spring method was first proposed by Yang et al. (1990) for the analysis of a sliding structure. Later, Lu and Yang (1997) reformulated the method into a state-space form for the analysis of equipment

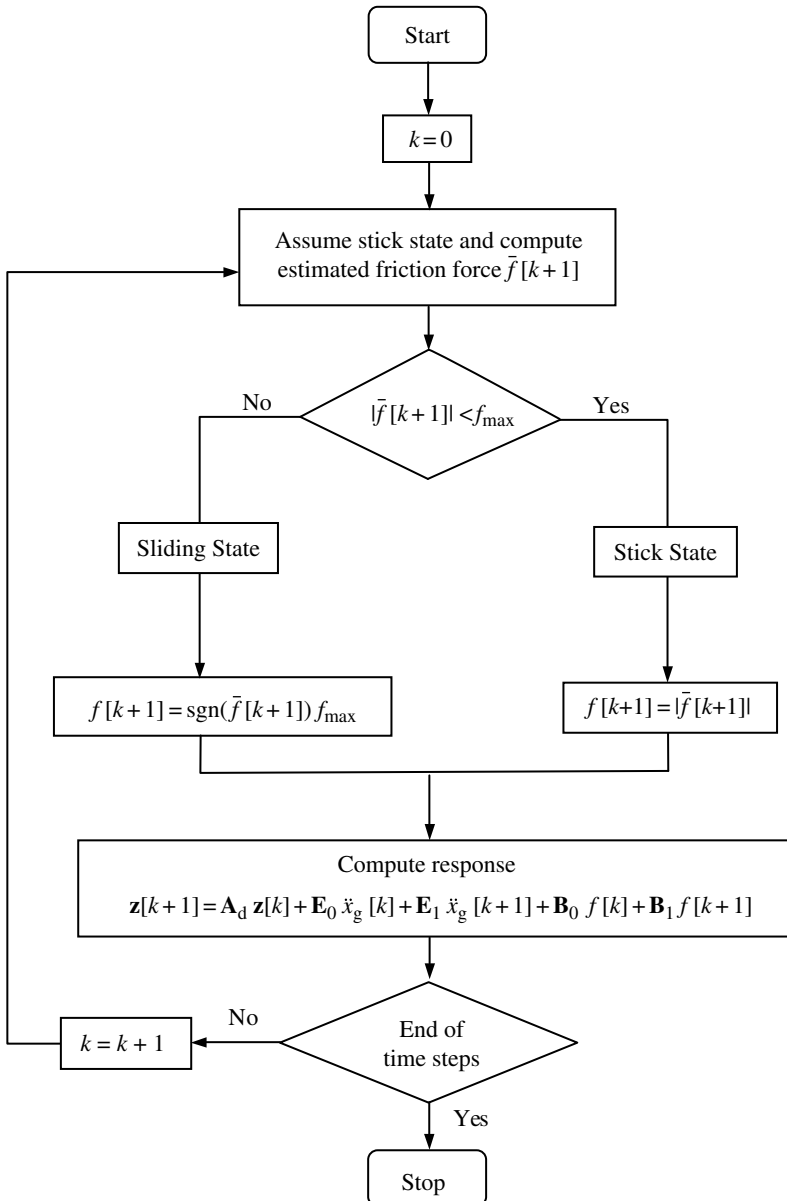

FIGURE 22.18 Computational flow-chart for shear balance method.

mounted on a sliding structure. By this method, a fictitious spring, k_f , is introduced between the base mat and the ground, as in Figure 22.19, to represent the mechanism of sliding or friction. The stiffness, k_f , of the fictitious spring is taken as zero for the sliding state and as a very large value for the stick state. With the introduction of the fictitious spring, the stiffness matrix, \mathbf{K} , in Equation 22.29 should be modified as follows:

$$\mathbf{K} = \mathbf{K}(k_f) = \begin{bmatrix} k_e & -k_e & 0 \\ -k_e & k_e + k_s & -k_s \\ 0 & -k_s & k_s + k_f \end{bmatrix} \quad (22.45)$$

FIGURE 22.19 Model for isolated structures with fictitious spring.

Accordingly, the state-space dynamic equation, Equation 22.31, should be modified as

$$\dot{\mathbf{z}}(t) = \mathbf{A}(k_f)\mathbf{z}(t) + \mathbf{E}\ddot{x}_g(t) + \mathbf{B}\tilde{f}(t) \quad (22.46)$$

where

$$\mathbf{A} = \mathbf{A}(k_f) = \begin{bmatrix} -\mathbf{M}^{-1}\mathbf{C} & -\mathbf{M}^{-1}\mathbf{K}(k_f) \\ \mathbf{I} & \mathbf{0} \end{bmatrix} \quad (22.47)$$

Depending on the current state of the sliding system, the fictitious stiffness, k_f , and the modified friction term, $\tilde{f}(t)$, in Equation 22.46 may take one of the following two sets of values:

- (1) In the stick state

$$k_f = \alpha k_s, \quad \tilde{f}(t) = k_f x_{b0} \quad (22.48)$$

- (2) In the sliding state

$$k_f = 0, \quad \tilde{f}(t) = -\text{sgn}(\dot{x}_b(t))\mu W \quad (22.49)$$

In Equation 22.48, the symbol α represents a constant of very large value, and x_{b0} the initial elongation of the fictitious spring in the current stick state (computation of x_{b0} will be explained later). Note that the modified friction term, $\tilde{f}(t)$, may not be the actual frictional force. The actual frictional force can be determined as follows:

- (1) In the stick state

$$f(t) = k_f(x_b(t) - x_{b0}) \quad (22.50)$$

- (2) In the sliding state

$$f(t) = \tilde{f}(t) \quad (22.51)$$

According to Equation 22.50 and Equation 22.51, the actual frictional force of the isolation system in the stick state is equal to the internal force of the fictitious spring, while in the sliding state it is equal to the modified frictional force, $\tilde{f}(t)$. The frictional force computed from the preceding two equations should obey the conditions given in Equation 22.34a and Equation 22.35a as well.

With the conditions imposed for the stick and sliding states in Equation 22.48 and Equation 22.49, respectively, the equation of motion in Equation 22.46 actually represents two different sets of equations.

Specifically, Equation 22.46 and Equation 22.48 collectively describe the motion of the structure in the stick state, while Equation 22.46 and Equation 22.49 represent the motion of the structure in the sliding state. Owing to the fact that a sliding system may switch between the two states at certain instants, the behavior of the entire system should undoubtedly be regarded as a nonlinear one. Nevertheless, within each particular state, the behavior of the system as represented either by Equation 22.46 and Equation 22.48 or Equation 22.46 and Equation 22.49 is a linear one.

In the following, a numerical solution scheme based on the concept of fictitious spring will be introduced. Let Δt denote a time increment, which is usually taken as a very small value, and assume that the ground excitation and frictional force are constant within each time increment, Δt (see Figure 22.20). Accordingly, the discrete-time solution of Equation 22.46 can be rewritten in an incremental form (Meirovitch, 1990) as

FIGURE 22.20 Constant force integration scheme.

$$\mathbf{z}[k+1] = \mathbf{A}_d \mathbf{z}[k] + \mathbf{E}_d \ddot{x}_g[k] + \mathbf{B}_d \tilde{f}[k] \quad (22.52)$$

where

$$\mathbf{A}_d = \mathbf{A}_d(k_f) = e^{\mathbf{A}(k_f)\Delta t} = \sum_{i=0}^{\infty} \frac{\Delta t^i}{i!} \mathbf{A}(k_f)^i \quad (22.53)$$

$$\mathbf{E}_d = \mathbf{E}_d(k_f) = \mathbf{A}(k_f)^{-1} (\mathbf{A}_d(k_f) - \mathbf{I}) \mathbf{E} \quad (22.54a)$$

$$\mathbf{B}_d = \mathbf{B}_d(k_f) = \mathbf{A}(k_f)^{-1} (\mathbf{A}_d(k_f) - \mathbf{I}) \mathbf{B} \quad (22.54b)$$

For the case where the system matrix \mathbf{A} is invertible, \mathbf{B}_d and \mathbf{E}_d may be computed instead using the following formulas:

$$\mathbf{E}_d = \mathbf{E}_d(k_f) = \left[\sum_{i=0}^{\infty} \frac{\Delta t^i}{i!} \mathbf{A}(k_f)^{i-1} \right] \mathbf{E} \quad (22.55)$$

$$\mathbf{B}_d = \mathbf{B}_d(k_f) = \left[\sum_{i=0}^{\infty} \frac{\Delta t^i}{i!} \mathbf{A}(k_f)^{i-1} \right] \mathbf{B} \quad (22.56)$$

Equation 22.52 is the solution of the sliding system given in incremental form, because the response, $\mathbf{z}[k+1]$, can be computed from the solution of the previous step, $\mathbf{z}[k]$. Note that, in Equation 22.53 and Equation 22.54, the coefficient matrices \mathbf{A}_d , \mathbf{E}_d , and \mathbf{B}_d have two possible sets of values, as the fictitious spring constant, k_f , may take different values for the sliding and stick states. Nevertheless, once the time step size, Δt , is chosen, the coefficient matrices \mathbf{A}_d , \mathbf{E}_d , and \mathbf{B}_d , remain constant for each state. As such, they need only be calculated once at the beginning of the incremental procedure. The computational flow-chart for the fictitious spring method described above has been given in Figure 22.21.

The dynamic equation and its discrete-time solution for the sliding structure in the two states have been presented above. In the following, we shall describe how to determine the *transition time* for the sliding structure to switch from one state to the other. Once the transition time is determined, the original step size should be scaled down accordingly to reflect the transition point (Yang et al., 1990).

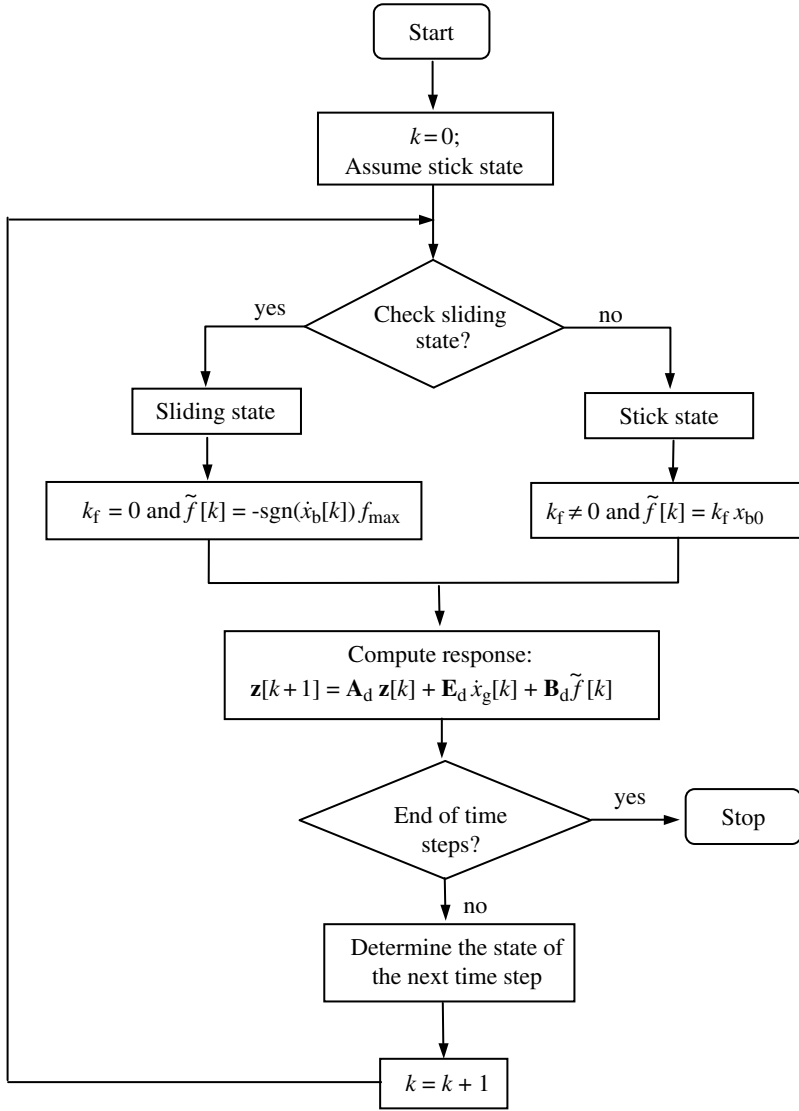

FIGURE 22.21 Computational flow-chart for fictitious spring method.

Transition from stick to sliding state. As stated in Equation 22.34a, the condition for a sliding isolated structure to remain in the stick state is that the static frictional force under the base mat be less than its maximum value, f_{\max} . Once the frictional force exceeds this maximum value, the system starts to slide. With the fictitious spring method, the static frictional force is computed as the internal force of the fictitious spring, as in Equation 22.50. Based on the above considerations and Equation 22.50, the condition for the sliding system to transfer from the stick to the sliding state is

$$|f(t_0)| = |k_f(x_b(t_0) - x_{b0})| = f_{\max} = \mu W \quad (22.57)$$

where t_0 denotes the transition time at which the structure starts to slide and k_f is the spring constant given in Equation 22.48 for the stick state. Because a very large value has been used for the fictitious spring constant, k_f , in the stick state, the deviation in base displacement due to spring elongation is very small in this state, which can just be neglected. In practice, the transition time, t_0 may not occur precisely

at the discrete points of time considered. It is likely that the spring force is less than f_{\max} at the current time step, say, the k th step, but exceeds f_{\max} at the following time step. If this is the case, numerical methods such as the bisection method should be employed to locate the transition time, t_0 within the time interval $(k\Delta t, (k+1)\Delta t)$ considered based on Equation 22.57.

Transition from sliding state to stick state. The structure in the sliding state may return to the stick state whenever the following two conditions are satisfied. (1) The relative velocity of the base mat to the ground reaches zero, that is, $\dot{\xi}_b(t_0) = 0$ where t_0 is the transition time; (2) the estimated static frictional force, denoted by $\tilde{f}(t_0)$, is less than the maximum static frictional force, that is, $\tilde{f}(t_0) < f_{\max}$. Here, the estimated static frictional force, $\tilde{f}(t_0)$, is defined as the shear force required to balance the motion of the superstructure if the system is assumed to be in the stick state, similar to the one given in Equation 22.42 for $\tilde{f}[k+1]$. By letting the relative velocity and relative acceleration between the base mat and the ground be equal to zero, that is, $\ddot{\xi}_b(t_0) = \dot{\xi}_b(t_0) = 0$, the estimated frictional force can be calculated from the free-body diagram of the base mat as

$$\tilde{f}(t_0) = m_b \ddot{x}_g(t_0) - k_s(x_s(t_0) - x_b(t_0)) - c_s \dot{x}_s(t_0) \quad (22.58)$$

For the sliding structure to transfer from the sliding to the stick state, both the aforementioned conditions must be satisfied simultaneously. Once the structure enters the stick state, the term $f(t_0)$ should be set equal to $\tilde{f}(t_0)$ and used as the initial frictional force. For the sake of equilibrium, the initial base mat displacement, x_{b0} , should be computed as

$$x_{b0} = x_b(t_0) - (\tilde{f}(t_0)/k_f) \quad (22.59)$$

where the value of k_f is the one given for the stick state in Equation 22.48.

Concerning the two conditions mentioned above, it may happen that only the first condition, $\dot{\xi}_b = 0$ is satisfied, while the computed $\tilde{f}(t_0)$ is still larger than f_{\max} . If this is the case, the sliding system should not be regarded as a transition to the stick state. Rather, the situation should be regarded as an indication for reversing the direction of sliding in the next time step. Correspondingly, the frictional force, $f(t_0)$, should be set equal to the sliding frictional force, rather than the estimated one, $\tilde{f}(t_0)$.

22.4.3 Simulation Results for Sliding Isolated Systems

22.4.3.1 Numerical Model and Ground Excitations

In this section, the dynamic behavior of the sliding isolated structure–equipment system shown in Figure 22.16 will be analyzed using the shear balance method. Although the sliding structure and equipment considered are both of single-DoF, there exists no difficulty for use of the method to solve problems with multi-DoF systems. In Table 22.3, the material properties adopted for the present model have been listed, which are intended to simulate a small, five-story, reinforced concrete frame. For the present purposes, two types of ground excitation are considered, namely, harmonic and earthquake excitations. The harmonic excitation is considered primarily for studying the frequency response of the sliding system, while the earthquake excitation is considered for the effect of earthquake intensity. For the

TABLE 22.3 System Parameters Used in Simulation (Section 22.4.3)

Equipment		Superstructure		Isolation System	
Parameter	Value	Parameter	Value	Parameter	Value
Mass m_e	3 t ($= m_s/100$)	Mass m_s	300 t	Mass m_b	100 t ($= m_s/3$)
Frequency ω_e	$5\omega_s$ or a variable	Frequency ω_s	1.67 Hz	Frictional coefficient μ	0.05, 0.1, 0.25
Damping ratio ζ_e	5%	Damping ratio ζ_s	5%	—	—

harmonic excitation, a sinusoidal ground acceleration of the following form is adopted:

$$\ddot{x}_g(t) = 0.5g \sin \omega_g t \quad (22.60)$$

where ω_g denotes the excitation frequency and g is the gravitational acceleration. For the earthquake excitation, the 1940 El Centro earthquake (NS component) is considered, for which the waveform has been given in Figure 22.10. The PGA level of the earthquake will be adjusted for reasons of research. Concerning the effectiveness of response reduction, three quantities are chosen as the indices, namely, the base displacement (base drift), structural acceleration, and equipment acceleration. For all the figures shown in Section 22.4.3 below, the symbol μ in the legend is used to denote the frictional coefficient of the sliding isolation system and the word “fixed” denotes the response of the corresponding fixed-base structure.

22.4.3.2 Harmonic Response of Structure

Time history. For the isolated system subjected to a harmonic excitation of $\omega_g = 1$ Hz, the base displacements computed for different coefficients of friction were plotted in Figure 22.22 and Figure 22.23. As can be seen, the base displacements quickly reach the steady-state response within the first few cycles. Meanwhile, the use of a smaller frictional coefficient results in a larger permanent displacement before the steady state is reached. From the structural accelerations plotted in Figure 22.24, one observes that, for a sliding structure with a smaller coefficient of friction, the steady-state response is achieved in a faster way, accompanied by a larger reduction on structural acceleration. Of interest in Figure 22.24 is that the response of the fixed-base case shows a clear period of 1 sec, while in the sliding case, the response is contaminated by high-frequency signals caused by the sliding-stick transitions.

Hysteretic behavior. In order to understand the mechanical characteristics of a nonlinear device used for vibration control, it is common to present a diagram showing the force–deformation relation of the device, also referred to as the *hysteretic diagram* (Soong and Dargush, 1997). Figure 22.25 shows the hysteresis loops of the sliding isolation system (the sliding layer) for $\mu = 0.1$ and 0.25, when the system is subjected to a harmonic excitation of $\omega_g = 1$ Hz. In the figure, the horizontal and vertical axes, respectively, represent the base displacement and shear force, that is, the frictional force, under the mat. Just like many other frictional elements or devices, the shape of the hysteresis loop of a sliding bearing is rectangular. The height of the rectangle is equal to the maximum frictional force that depends on the coefficient of friction, while the width of the hysteresis loop is determined by the base-sliding displacement. As the coefficient of friction decreases, the height of the loop decreases, while the width increases. The total area of the hysteresis loop is equivalent to the portion of the energy dissipated by the sliding bearing.

FIGURE 22.22 Comparison of base displacements ($\omega_g = 1$ Hz; $\omega_e = 5\omega_s$).

FIGURE 22.23 Comparison of base displacements ($\omega_g = 1$ Hz; $\omega_e = 5\omega_s$).

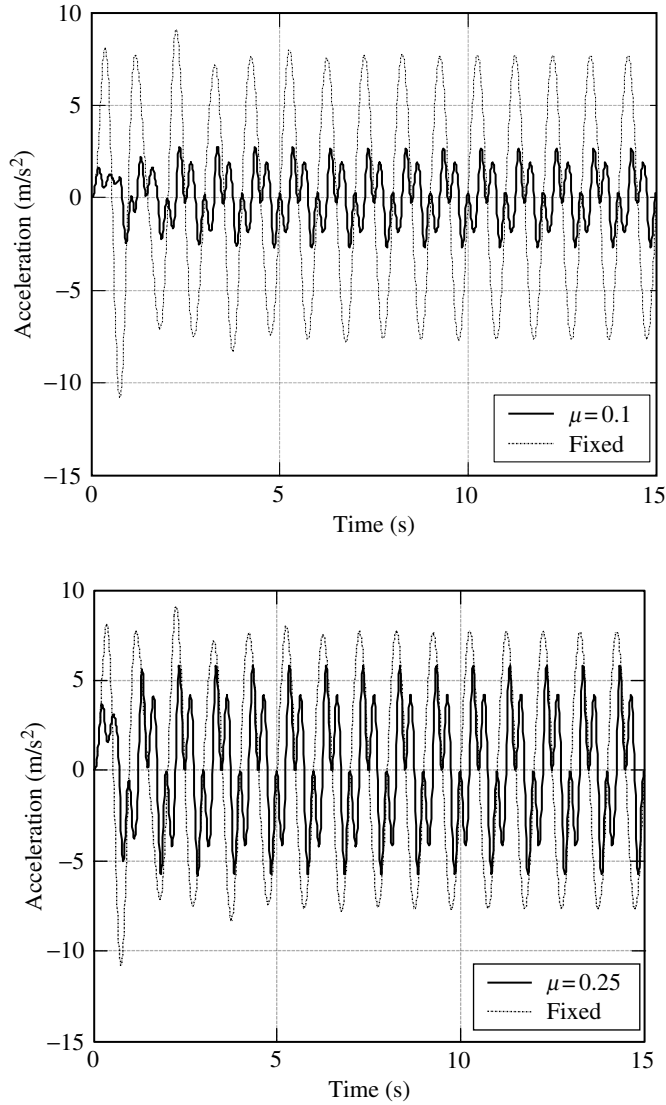

FIGURE 22.24 Comparison of structural accelerations ($\omega_g = 1$ Hz; $\omega_e = 5\omega_g$).

Frequency response. Figure 22.26 shows the maximum structural acceleration with respect to the excitation frequency for four different frictional coefficients, $\mu = 0.05, 0.1, 0.25$ and ∞ (for the fixed-base case). Here, the maximum acceleration means the steady-state acceleration response. The following observations can be made from Figure 22.26: (1) Compared with the fixed-base case, the use of a smaller frictional coefficient can reduce the structural acceleration for the frequency range considered. (2) The sliding mechanism can effectively suppress the main resonant response, associated with the natural frequency of 1.67 Hz of the superstructure system. (3) As the coefficient of friction, μ , decreases from ∞ to 0.05, the main resonant frequency associated with the structural natural frequency drifts from the fixed-base frequency of 1.67 Hz toward a higher value. (4) For the sliding cases of $\mu = 0.05, 0.1, 0.25$, there exist some minor peaks in the range of lower excitation frequencies, besides the main resonant peak. Such a phenomenon is called the *subharmonic resonance*. For a large frictional coefficient, say, with $\mu = 0.25$, the subharmonic resonant response may be even larger than that of the main resonance.

FIGURE 22.25 Hysteresis loops of a sliding bearing ($\omega_g = 1 \text{ Hz}$; $\omega_e = 5\omega_s$).

FIGURE 22.26 Maximum structural acceleration vs. ground excitation frequency ($\omega_e = 5\omega_s$).

Figure 22.27 shows the frequency responses of the maximum base displacement for various frictional coefficients. The following are observed: (1) The larger the frictional coefficient, the smaller the base drift is. (2) The base displacement has very large magnitudes in the lower excitation frequencies and decreases monotonically as the excitation frequency increases. (3) The extremely large base drift exhibited in the lower excitation frequency range is due to the initial permanent displacement observed in Figure 22.22.

22.4.3.3 Harmonic Response of Equipment

Time history. Consider an equipment item of a natural frequency equal to five times of the structural frequency, that is, $\omega_e = 5\omega_s$. For the case of a harmonic excitation of $\omega_g = 1 \text{ Hz}$, the accelerations solved for the equipment mounted on the structure with $\mu = 0.1$ and 0.25 , along with the fixed-base case, have

FIGURE 22.27 Maximum base displacement vs. ground excitation frequency ($\omega_e = 5\omega_s$).

been plotted in Figure 22.28. As can be seen, the equipment quickly reaches the steady state within a few cycles of oscillation. The equipment response is effectively suppressed for the case with a smaller frictional coefficient. Additionally, the waveforms shown in Figure 22.28 for the equipment appear to be marginally higher than those of the primary structure shown in Figure 22.24, which can be attributed to the use of a relatively stiff equipment, that is, with $\omega_e = 5\omega_s$.

Frequency responses. For an equipment item of the frequency $\omega_e = 5\omega_s$ ($= 8.34$ Hz), the maximum acceleration response has been plotted as a function of the excitation frequency in Figure 22.29. By comparing Figure 22.29 with Figure 22.26, one observes that the frequency response curves of the equipment and primary structure are generally similar, except that a secondary resonant peak occurs around the equipment natural frequency of 8.34 Hz in Figure 22.29. The other observations from Figure 22.29 are as follows: (1) In comparison with the fixed-base case, the sliding isolation alleviates both the structural and equipment resonant peaks around the frequencies of 1.67 and 8.34 Hz, respectively. However, the level of alleviation is more apparent for the former than for the latter. (2) The equipment also exhibits the same subharmonic resonance behavior as that of the primary structure, in terms of the resonance peaks and frequencies. (3) As the frictional coefficient μ decreases from ∞ (for the fixed-base case) to 0.05, the main resonant frequency associated with the structure drifts toward a higher value. However, the resonant frequency associated with the equipment remains the same.

Effect of equipment tuning. The effect of equipment tuning refers to the case when the equipment frequency is tuned to the structural frequency, that is, $\omega_e = \omega_s$. Figure 22.30 shows the frequency response of the equipment when the equipment tuning occurs. Compared with Figure 22.29, this figure shows the following: (1) When equipment tuning occurs, the sliding isolation system can still mitigate the main resonant peak of the equipment, but the effectiveness of mitigation is drastically reduced. (2) Although the subharmonic resonance can still be observed, the relevant frequencies of the equipment are different from those of the primary structure. (3) The frequency of the maximum resonant response remains equal to the tuned equipment's natural frequency of 1.67 Hz, regardless of the change in the frictional coefficient, μ , from ∞ to 0.05.

22.4.3.4 Earthquake Response of Structure

Time history. For the isolated system subjected to the El Centro earthquake with a PGA of 0.5g, the structural acceleration and base displacement of the sliding system have been plotted in Figure 22.31 and Figure 22.32, respectively, together with the response for the fixed-base case in Figure 22.31. As can be

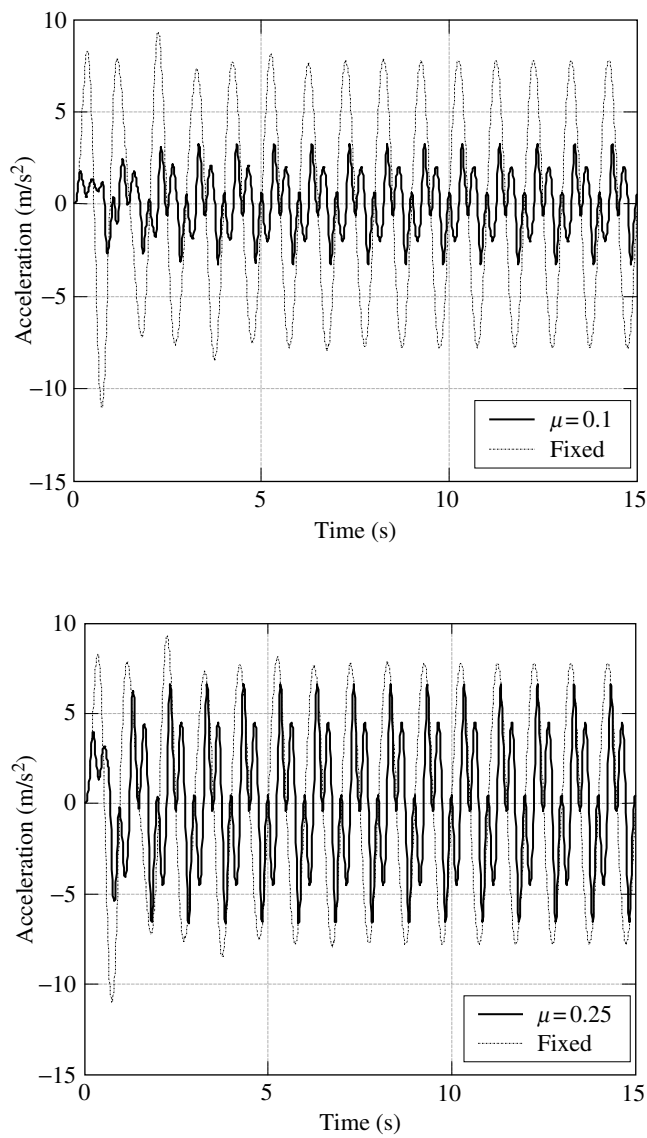

FIGURE 22.28 Comparison of equipment accelerations ($\omega_g = 1$ Hz; $\omega_e = 5\omega_s$).

seen from Figure 22.31, the main-shock response occurring between 0 and 10 sec for the fixed-base structure has been effectively suppressed by the sliding isolators with $\mu = 0.1$ and 0.25. About 80 and 60% of the maximum structural acceleration have been suppressed by the isolators with $\mu = 0.1$ and 0.25, respectively. On the other hand, Figure 22.32 demonstrates that the better suppression effect for the case with $\mu = 0.1$ is achieved at the expense of a larger base displacement. It is interesting to note that the horizontal segments in the curves of Figure 22.32 actually represent the stick state of the sliding system, which is useful for unveiling the sliding-stick mechanism involved.

Effect of earthquake intensity. The maximum structural acceleration and base displacement vs. the PGA have been plotted in Figure 22.33 and Figure 22.34, respectively. As can be seen from Figure 22.33, the maximum structural acceleration for the fixed-base case is proportional to the earthquake intensity, while in all the sliding cases it remains essentially as a constant after the PGA reaches a certain level. In other words, the reduction in structural maximum response and the efficiency of isolation have increased

FIGURE 22.29 Maximum equipment acceleration vs. ground excitation frequency ($\omega_e = 5\omega_s$).

FIGURE 22.30 Maximum equipment acceleration vs. ground excitation frequency for equipment tuning ($\omega_e = \omega_s$).

with the increase in earthquake intensity. For example, for the case of $\mu = 0.1$, Figure 22.33 shows that the structural acceleration is reduced by around 60% at $\text{PGA} = 0.2g$, while it is reduced by more than 90% at $\text{PGA} = 1.0g$. However, as indicated by Figure 22.34, the above reduction in structural response has been achieved at the expense of increased base displacements. For the same PGA level, a sliding system with a smaller frictional coefficient has a better effect of vibration reduction, but this is accompanied by a larger base displacement.

Residual base displacement. The residual base displacement is defined as the permanent base displacement of the structure after it stops vibrating. This quantity is important in the study of sliding structures. Figure 22.35 shows the residual base displacement as a function of the earthquake PGA level. A first look at the figure reveals that no clear relation exists between the earthquake intensity and residual

FIGURE 22.31 Comparison of structural accelerations ($\omega_c = 5\omega_s$, PGA = 0.5g).

displacement, because a larger PGA may lead to a smaller residual base displacement. Nevertheless, after taking the average of the residual displacements over the PGA range of 0.1 to 1g, we obtain $x_{res} = 0.083, 0.084, 0.084$ m for the case of $\mu = 0.05, 0.1, 0.25$, respectively. These values indicate that a smaller frictional coefficient leads to a larger residual base displacement in general. However, when the frictional coefficient, μ , approaches zero, the residual displacement approaches a constant equal to the permanent ground displacement.

22.4.3.5 Earthquake Response of Equipment

Time history. Consider an equipment item with a natural frequency equal to five times the structural frequency, that is, $\omega_c = 5\omega_s$ ($= 8.34$ Hz). For the isolated system subjected to the El Centro earthquake

FIGURE 22.32 Comparison of base displacements ($\omega_e = 5\omega_s$, PGA = 0.5g).

FIGURE 22.33 Maximum structural acceleration vs. PGA ($\omega_e = 5\omega_s$).

with PGA = 0.5g, the time histories computed for the equipment acceleration for the cases with $\mu = 0.1$ and 0.25, along with the fixed-base case, have been plotted in Figure 22.36a and b. As can be seen, the main-shock response of the fixed-base structure occurring for the first 10 sec has been effectively suppressed through installation of the sliding isolator with $\mu = 0.1$ and 0.25. A higher level of reduction can be achieved if a smaller frictional coefficient is chosen.

Effect of earthquake intensity. Figure 22.37 shows the maximum equipment acceleration as a function of the PGA level. Because of the use of a relatively stiff equipment ($\omega_e = 5\omega_s$), the curves shown in Figure 22.37 are similar to those for the primary structure in Figure 22.33, but with slightly higher values. Therefore, the observations made previously for Figure 22.33 are applicable to Figure 22.37. The maximum response of equipment items with other frequencies will be discussed below.

FIGURE 22.34 Maximum base displacement vs. PGA ($\omega_c = 5\omega_s$).

FIGURE 22.35 Residual base displacement vs. PGA ($\omega_c = 5\omega_s$).

Effect of equipment tuning. In order to study the equipment tuning effect, the maximum equipment acceleration has been plotted as a function of the equipment frequency in Figure 22.38. As can be seen, for all the values of μ considered, the equipment response is amplified when the equipment frequency moves close to the structural frequency of 1.67 Hz for the fixed-base case. Note that, since the resonant frequency of a sliding structure shifts to a higher value as the frictional coefficient decreases (see Figure 22.26), the frequency for which the most severe tuning effect occurs in Figure 22.38 also shifts from 1.67 Hz to a higher value as μ decreases. Nevertheless, it is concluded that, by choosing a smaller μ , the amplification of the equipment response due to tuning effect can be effectively suppressed.

22.4.4 Concluding Remarks

The dynamic behavior of a sliding isolated structural system with an attached equipment item was investigated in this section. A sliding isolated structure is classified as a nonlinear dynamic system, as the

FIGURE 22.36 Comparison of equipment accelerations ($\omega_c = 5\omega_s$, PGA = 0.5g).

frictional forces induced on the sliding surface do not remain constant. To deal with such nonlinear systems, two analysis methods were formulated, the shear balance method and the fictitious spring method, both of which were presented in an incremental form that is suitable for direct implementation. Through the selection of a sliding isolated structure–equipment model, the responses of the structure and equipment subjected to both harmonic and earthquake excitations were analyzed. For the case of harmonic excitation, the results showed that the resonant responses of both the structure and attached equipment can be effectively suppressed, which remains good even when the equipment frequency is tuned to the structural frequency. For the case of seismic excitation, the results indicated that the level of reduction on the structural and equipment responses increases as the PGA level of the earthquake increases. Moreover, a sliding system with a smaller frictional coefficient has a higher isolation efficiency, at the expense of a larger base displacement.

22.5 Sliding Isolation Systems with Resilient Mechanism

In Section 22.4, the relevant equations of analysis have been presented for a sliding isolated structural system, with no consideration made for the resilient (or recentering) mechanism. Because of this, rather large residual displacements may occur on the sliding isolation system, as have been numerically illustrated. If the concept of sliding isolators is to be applied to a real structure, it is important that the residual base displacements be controlled within certain limits, since they are not tolerable for some

FIGURE 22.39 Schematic for a structure–equipment system isolated by a sliding bearing with resilience capability: (a) combined isolation system; (b) friction pendulum system (FPS).

engineering applications. For example, residual base displacements may distort the networking of water and power lines, change the space between the isolated structure and adjacent buildings, and widen the gaps at building entrances. Therefore, in practice, a sliding isolation system is usually enhanced through inclusion of mechanisms that can provide some resilient force. However, for certain ground motions, the added resilient force may also present some negative effects not readily transparent to structural designers, as will be illustrated in the numerical studies later on.

As shown in Figure 22.39, there are at least two ways of implementing the resilient mechanism in a sliding isolation system. Figure 22.39a shows an isolation system that combines the elastomeric bearings with sliding bearings (Chalhoub and Kelly, 1990), in which the elastomeric bearings are used to provide the resilient force, and the sliding bearings to uncouple the structural system from the ground motion. On the other hand, the resilient mechanism can also be incorporated into each single sliding bearing, in a way similar to that in the RFBI described in Section 22.2.3 (Mostaghel and Khodaverdian, 1987) or the FPS shown in Figure 22.39b (Mokha et al., 1991). The FPS isolation system has been implemented in many existing buildings and bridges. A typical FPS bearing consists a spherical sliding surface and a slider, which usually has a smooth coating of very low friction. When an FPS device is implemented under a structure, the slider will slide on the spherical surface during an earthquake, and the gravitational load of the structure, together with the curved sliding surface, will provide the resilient force for the system to return to its original position. The resilient stiffness of an FPS bearing depends on the radius of curvature of the sliding surface and the structural weight carried by the bearing.

This section is aimed at investigating the behavior of a structure–equipment system isolated by a sliding system with resilient device. For convenience of discussion, a system with resilient device will be referred to as the *resilient sliding isolation* (RSI), and a sliding system without resilient device, as the one studied previously, as the *pure sliding isolation* (PSI).

22.5.1 Mathematical Modeling and Formulation

Both the RSI systems shown in Figure 22.39 can be represented by the mathematical model given in Figure 22.40, for which the symbols used have been defined in Table 22.1. The RSI model shown in Figure 22.40 differs from the PSI model shown Figure 22.16 in that a linear spring of stiffness, k_b , is added to simulate the resilient force of the isolator. Obviously, an RSI model can be considered as the composition of a friction element and a spring element in parallel. Owing to addition of resilient stiffness, the number of vibration frequencies of the system is increased by one. The newly introduced frequency, which depends on the resilient stiffness, is called the *isolation frequency*, which can be approximated by

$$\omega_b = \sqrt{k_b/(W/g)} \quad (22.61)$$

where W is the total weight of the isolated structure–equipment system. The isolation frequency commonly used in design is between 0.33 and 0.5 Hz, which implies a period of 2 to 3 sec (Naeim and Kelly, 1999).

For the type of combined sliding system shown in Figure 22.39(a), the actual value of resilient stiffness, k_b , is decided by the total horizontal stiffness of the elastomeric bearings implemented. On the other hand, for the FPS shown in Figure 22.39(b), the resilient stiffness, k_b , is approximated by the following equation for small isolator displacements:

$$k_b = \frac{W}{R} \quad (22.62)$$

where R denotes the radius of curvature of the sliding surface. By substituting Equation 22.62 into Equation 22.61, one can verify that the isolation period of an FPS is equal to the oscillation period of a pendulum; that is

$$T_b = \frac{2\pi}{\omega_b} = \frac{2\pi}{\sqrt{k_b/(W/g)}} = 2\pi\sqrt{R/g} \quad (22.63)$$

When the sliding isolated system of Figure 22.40 is excited by a ground motion, its equation of motion may be written in exactly the same form as that of Equation 22.27; that is

$$\mathbf{M}\ddot{\mathbf{x}}(t) + \mathbf{C}\dot{\mathbf{x}}(t) + \mathbf{K}\mathbf{x}(t) = -\mathbf{M}\mathbf{L}_1\ddot{x}_g(t) + \mathbf{L}_2f(t) \quad (22.64)$$

All the variables used in the preceding equation are the same as those defined in Equation 22.28 to Equation 22.30, except that the stiffness matrix, \mathbf{K} , should be modified as

$$\mathbf{K} = \begin{bmatrix} k_e & -k_e & 0 \\ -k_e & k_e + k_s & -k_s \\ 0 & -k_s & k_s + k_b \end{bmatrix} \quad (22.65)$$

Note that, in Equation 22.64, the frictional force, $f(t)$, which does not remain constant, is placed on the right-hand side, while the resilient stiffness, k_b , which remains constant, is absorbed by the stiffness matrix, \mathbf{K} , as in Equation 22.65. However, if the total shear force, $s(t)$ of the isolation system is of interest, it should be computed as the summation of the frictional force and resilient force (see Figure 22.40); that is

$$s(t) = k_b x_b(t) + f(t) \quad (22.66)$$

The equation of motion as given in Equation 22.64 can be recast in the following form of the first-order state-space equation:

$$\dot{\mathbf{z}}(t) = \mathbf{A}\mathbf{z}(t) + \mathbf{E}\ddot{x}_g(t) + \mathbf{B}f(t) \quad (22.67)$$

The definitions of the matrices $\mathbf{z}(t)$, \mathbf{E} , \mathbf{A} , and \mathbf{B} are the same as those defined in Equation 22.32 and Equation 22.33, except that the system matrix, \mathbf{A} , should be modified to account for the addition of the resilient stiffness k_b in the stiffness matrix, \mathbf{K} .

22.5.2 Methods for Numerical Analysis

If one compares the equation of motion for the RSI system in Equation 22.67 with that for the PSI system in Equation 22.31, one will conclude that the only source of nonlinearity in both equations comes from

FIGURE 22.40 Model for a structure–equipment system isolated by a sliding bearing with resilience capability.

the same term, namely, the frictional force, $f(t)$. As a result, the two methods of solution mentioned in Section 22.4.2, the shear balance method (Wang et al., 1998) and fictitious spring method (Yang et al., 1990), remain valid for the analysis of the RSI systems, with no modification required. Moreover, owing to inclusion of the resilient stiffness, k_b , in the structural stiffness matrix, \mathbf{K} , the system matrix, \mathbf{A} , becomes nonsingular and invertible. This introduces some advantage in computation of relevant coefficient matrices, including the \mathbf{B}_0 and \mathbf{B}_1 matrices in Equation 22.38a and Equation 22.38b. In Section 22.5.3, the shear balance method will be employed to simulate the response of an RSI system.

22.5.3 Simulation Results for Sliding Isolation with Resilient Mechanism

22.5.3.1 Numerical Model and Ground Excitations

In this section, the dynamic behavior of a sliding system represented by the model shown in Figure 22.40 will be investigated. The data adopted in the analysis for the equipment, structure, and the isolator have been listed in Table 22.4. To facilitate comparison, some of the data are selected to be the same as those in Table 22.3. In particular, the isolation frequency chosen is $\omega_b = 0.4$ Hz, falling in the common range of 0.33 to 0.5 Hz. Again, two types of ground excitations are considered, namely, the harmonic and earthquake excitations. For the harmonic excitation, a waveform of ground acceleration identical to the one given in Equation 22.60 is used. And for the earthquake excitation, the 1940 El Centro earthquake with different levels of PGA will be used, of which the acceleration waveform has been given in Figure 22.10. The harmonic excitation is adopted mainly for studying the frequency response of the sliding isolated system, while the earthquake excitation is for studying the effect of earthquake intensity. The dynamic responses computed for the RSI system, including the structure and equipment, will be presented, with emphasis placed on comparison with the PSI system of the same parameters. Similar to what was done in Section 22.4.3, the symbol μ will be used to denote the frictional coefficient of the sliding isolation system in all figures, and the word “fixed” denotes the fixed-base structure.

22.5.3.2 Harmonic Response of Structure

Time history. Consider an RSI system subjected to a harmonic excitation of $\omega_g = 1$ Hz. The base displacement and structural acceleration of the RSI system have been plotted in Figure 22.41 and Figure 22.42, respectively. Clearly, both the base displacement and structural acceleration of the RSI system reach their steady-state harmonic responses in the first few cycles. Moreover, a smaller sliding frictional coefficient ($\mu = 0.1$) is more effective for suppressing the structural acceleration, as indicated by Figure 22.42. However, this is achieved only at the expense of a larger base displacement, as indicated by Figure 22.41. By comparing the result for the RSI system in Figure 22.41 with those for the PSI system in Figure 22.23, the effect of resilient mechanism in eliminating the permanent base displacement for the case with a small frictional coefficient of $\mu = 0.1$ can be clearly appreciated. In spite of the large difference in base displacement, the structural accelerations for the RSI and PSI systems shown in Figure 22.42 and Figure 22.24, respectively, appear to be quite similar, when interpreted in terms of the waveform and response amplitude. This implies that, for the harmonic excitation considered, the resilient mechanism in RSI has little influence on the isolation effectiveness.

Hysteretic behavior. In Figure 22.43, the hysteresis loops for RSI systems with $\mu = 0.1$ and 0.25 subjected to a harmonic excitation of $\omega_g = 1$ Hz have been plotted, in which the vertical axis represents

TABLE 22.4 System Parameters Used in Simulation (Section 22.5.3)

Equipment		Superstructure		Isolation System	
Parameter	Value	Parameter	Value	Parameter	Value
Mass m_e	3 t ($= m_s/100$)	Mass m_s	300 t	Mass m_b	100 t ($= m_s/3$)
Frequency ω_e	$5\omega_s$ or a variable	Frequency ω_s	1.67 Hz	Frictional coefficient μ	0.05, 0.1, 0.25
Damping ratio ζ_e	5%	Damping ratio ζ_s	5%	Isolation frequency ω_b	0.4 Hz

FIGURE 22.41 Comparison of base displacements ($\omega_g = 1$ Hz, $\omega_c = 5\omega_s$).

the total shear, $s(t)$, of the bearing computed from Equation 22.66. It is interesting to note that, for an RSI system, the hysteresis loop is a parallelogram, of which the slope of the inclined upper and lower sides exactly represents the total resilient stiffness, k_b , and the height and width, respectively, are decided by the maximum frictional force and maximum base displacement. As the frictional coefficient decreases, the height of the parallelogram decreases, but the width increases. The total area of the hysteresis loop represents the portion of energy dissipated by the RSI system. Noteworthy is the fact that, when the resilient stiffness, k_b , reduces to zero, the hysteresis parallelogram reduces to a square as well, identical to the one shown in Figure 22.25 for the PSI system.

Frequency responses. The maximum accelerations of the steady-state response of the structure for four different frictional coefficients, that is, $\mu = 0.05, 0.1, 0.25$ and ∞ (fixed-base), have been plotted in Figure 22.44. From this figure, the following observations can be made: (1) Compared with the fixed-base case, the resonant peak occurring around the structural frequency, ω_s , of 1.67 Hz was effectively suppressed by the RSI system, but a resonance of higher amplitude was induced in the lower frequency range (with frequencies lower than 0.6 Hz for the case studied). A further investigation reveals that the newly induced resonance is associated with the isolation frequency, ω_b , of 0.4 Hz. Such an observation remains valid for all values of frictional coefficients, μ . (2) The use of a lower frictional coefficient, μ , will result in a smaller response in the high-frequency range for the RSI system, for example, with frequencies higher than 0.6 Hz, but a larger response for the low-frequency range. (3) Although both the RSI and PSI systems can effectively remove the resonant peak around the structural frequency of 1.67 Hz, the RSI system has the side effect of creating a low-frequency resonant peak at the isolation frequency, ω_b . This implies that the RSI system is more sensitive to the excitation frequency.

The frequency responses of the maximum base displacement for the RSI system with various frictional coefficients have been plotted in Figure 22.45. When compared with the results for the PSI system in Figure 22.27, it is clear that the resilient mechanism of the RSI system considerably reduces the base displacement in the nonresonant excitation range, but it also amplifies the base displacement in the region when the excitation frequency is close to the isolation frequency, ω_b . From Figure 22.44 and Figure 22.45, we observe that both the structural acceleration and base displacement of an RSI system may resonate at the isolation frequency, which is usually designed to be less than 0.5 Hz. This implies that an RSI system may be ineffective or unsafe for a ground motion with enriched low-frequency

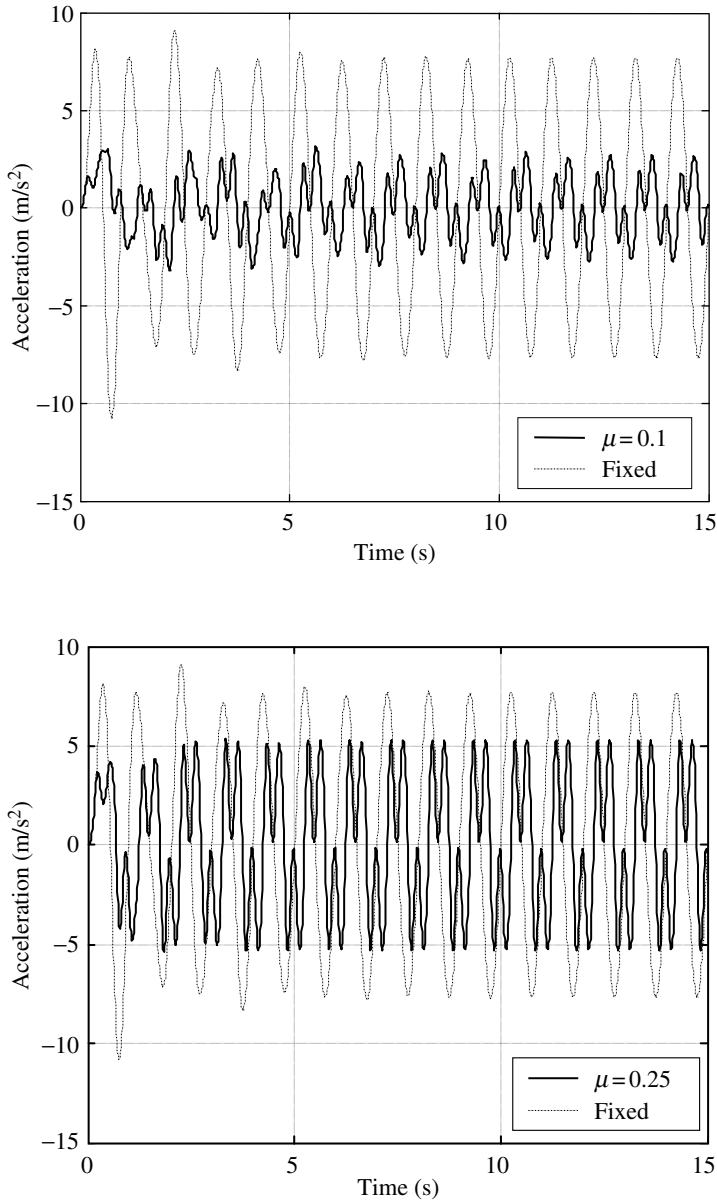

FIGURE 22.42 Comparison of structural accelerations ($\omega_g = 1$ Hz, $\omega_e = 5\omega_g$).

(long-period) vibrations, such as the case with a near-fault earthquake containing a long-period, pulse-like waveform (Jangid and Kelly, 2001; Lu et al., 2003). Structural designers should be aware of such a side effect when designing an RSI system.

22.5.3.3 Harmonic Response of Equipment

Time history. Consider an equipment item with a frequency of $\omega_e = 5\omega_g$ ($= 8.34$ Hz), attached to the RSI system. The harmonic acceleration responses of the equipment for the case with $\mu = 0.1$ and 0.25 have been plotted in Figure 22.46a and b, respectively, together with those for the fixed-base case. As can be seen, the equipment acceleration has been effectively suppressed by the RSI with the smaller frictional coefficient ($\mu = 0.1$). Moreover, the acceleration waveforms shown in Figure 22.46 are similar to those of

FIGURE 22.43 Hysteresis loops of a sliding bearing with resilience capability ($\omega_g = 1$ Hz, $\omega_e = 5\omega_s$).

FIGURE 22.44 Maximum structural acceleration vs. ground excitation frequency ($\omega_e = 5\omega_s$).

the PSI system shown in Figure 22.28. This implies that for the given excitation, the behavior of the equipment was not altered by introduction of the resilient mechanism in the RSI system.

Frequency responses. Figure 22.47 shows the acceleration frequency response curve of the attached equipment with a frequency of $\omega_e = 5\omega_s$ (8.34 Hz). A comparison of Figure 22.47 with Figure 22.44 indicates that the frequency responses of the equipment and primary structure are generally similar, except that a resonant peak associated with the equipment frequency around 8.34 Hz appears in Figure 22.47. Owing to such a similarity, the observations made previously for Figure 22.44 are applicable to Figure 22.47 for the attached equipment.

Effect of equipment tuning. Figure 22.48 shows the frequency response of the attached equipment for the case when the equipment frequency is tuned to the structural frequency, that is, with $\omega_e = \omega_s$. Similar to

FIGURE 22.45 Maximum base displacement vs. ground excitation frequency ($\omega_e = 5\omega_s$).

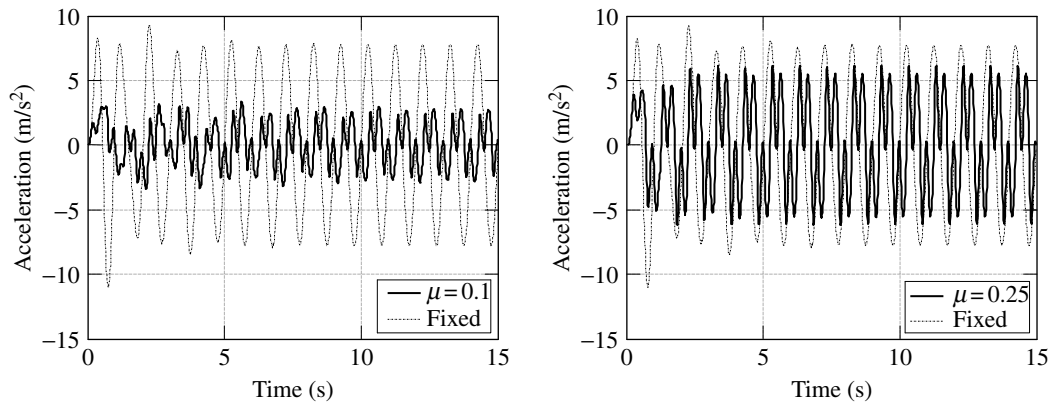

FIGURE 22.46 Comparison of equipment accelerations ($\omega_b = 1$ Hz, $\omega_e = 5\omega_s$).

the structural frequency response shown in Figure 22.44, the equipment attached to the RSI system also resonates at the isolation frequency ω_b of 0.4 Hz. Such a resonance does not occur for the equipment attached to the PSI system (see Figure 22.30). Through comparison of the tuned case in Figure 22.48 with the detuned case in Figure 22.47, the following observations can be made: (1) Even when the equipment tuning occurs, an RSI system mitigates the equipment's resonant peak associated with the structural frequency at 1.67 Hz, although the effectiveness of isolation has been reduced. (2) The tuning effect has no influence on the resonant response associated with the isolation frequency of 0.4 Hz.

22.5.3.4 Earthquake Response of Structure

Time history. For an RSI system subjected to the El Centro earthquake with $\text{PGA} = 0.5g$, the structural acceleration and base displacement have been shown in Figure 22.49 and Equation 22.50, respectively. By comparing Figure 22.49 with Figure 22.31 for the corresponding PSI system, one observes that the structural accelerations of the RSI and PSI systems are generally similar, in terms of the response waveform and the response magnitude. Both systems reduce the maximum structural acceleration quite effectively, for example, by about 80% for $\mu = 0.1$. However, significant difference does exist between the

FIGURE 22.47 Maximum equipment acceleration vs. ground excitation frequency ($\omega_e = 5\omega_s$).

FIGURE 22.48 Maximum equipment acceleration vs. ground excitation frequency under tuning condition ($\omega_e = 5\omega_s$).

base displacements for the RSI system in [Figure 22.50](#) and those for the PSI system in [Figure 22.32](#). For example, for $\mu = 0.1$, the maximum base displacement experienced by the RSI system has been reduced by about 30%, while the residual base displacement has been reduced by about 70%, as can be seen by comparing [Figure 22.50](#) with [Figure 22.32](#). This implies that the resilient mechanism of the RSI system plays an important role in reducing the maximum and residual base displacements, especially the latter.

In spite of the observations made above, one should not forget that the frequency content of one earthquake may be different from another. As was demonstrated in [Figure 22.44](#) and [Figure 22.45](#), an RSI system is generally sensitive to low-frequency excitations and may resonate at the isolation frequency.

FIGURE 22.49 Comparison of structural accelerations ($\omega_c = 5\omega_s$, PGA = 0.5g).

Therefore, if the RSI system is subjected to an earthquake containing more low-frequency components, unlike the El Centro earthquake, it is likely that the maximum structural responses induced exceed those of the PSI system.

Effect of earthquake intensity. The maximum structural acceleration and base displacement of the RSI system have been plotted with respect to the PGA in Figure 22.51 and Figure 22.52, respectively. These figures indicate that as the earthquake intensity increases from 0.1 to 1g, the structural acceleration is reduced by an increasing amount by the RSI system, while the maximum base displacement also increases. By comparing Figure 22.51 and Figure 22.52 with Figure 22.33 and Figure 22.34 for the PSI system, one observes that both the RSI and PSI systems perform equally well for the El Centro earthquake, although the PSI system induces a slightly larger base displacement. On the other hand, unlike the response for the PSI system, the use of a smaller frictional coefficient for the RSI system does not always lead to a lower structural acceleration, as can be verified by comparing the responses for $\mu = 0.1$ and 0.05 with a PGA greater than 0.8g in Figure 22.33 and Figure 22.51. This can be attributed to the large resilient force induced by the large base displacement under higher PGA levels.

FIGURE 22.50 Comparison of base displacements ($\omega_e = 5\omega_s$, $\text{PGA} = 0.5g$).

FIGURE 22.51 Maximum structural acceleration vs. PGA ($\omega_e = 5\omega_s$).

Residual base displacement. Figure 22.53 shows the residual base displacement of the RSI system vs. the PGA of the earthquake. For a given μ , it is difficult to establish a relation between the earthquake intensity and residual displacement, because a larger PGA may result in a smaller residual base displacement in some cases. However, if one takes the average of residual displacements over the PGA range from 0.1 to 1g, the following can be computed: $x_{\text{res}} = 0.0065, 0.011$, and 0.014 m for $\mu = 0.05, 0.1$, and 0.25 , respectively. These values indicate that a smaller frictional coefficient leads to a smaller residual base displacement, which can be attributed to the fact that for a SRI system with a smaller coefficient of friction, it is easier for the resilient mechanism to return the structure to its initial position after an earthquake. On the other hand, a comparison of Figure 22.53 with Figure 22.35 for the PSI system indicates that for the same value of μ , the residual displacement was reduced substantially by the RSI system. This is certainly an advantage offered by the resilient mechanism of the RSI system.

FIGURE 22.52 Maximum base displacement vs. PGA ($\omega_e = 5\omega_s$).

FIGURE 22.53 Residual base displacement vs. PGA ($\omega_e = 5\omega_s$).

22.5.3.5 Earthquake Response of Equipment

Time history. Let us consider an equipment item of natural frequency equal to five times the structural frequency, that is, $\omega_e = 5\omega_s$ ($= 8.34$ Hz). The acceleration responses of the equipment mounted on the RSI system that were subjected to the El Centro earthquake with a PGA of $0.5g$ for $\mu = 0.1$ and 0.25 have been plotted in Figure 22.54a and b, respectively, along with those for the fixed-base cases. As can be seen, the main-shock response of the equipment appearing during the first 10 sec for the fixed-base system was effectively suppressed by the RSI system with $\mu = 0.1$ or 0.25 . The level of reduction is more pronounced for the case with a smaller frictional coefficient, that is, with $\mu = 0.1$. By comparing Figure 22.54 with Figure 22.36 for the PSI system, one concludes that the effect of the resilient mechanism of the RSI system on the equipment response is insignificant for the earthquake and equipment frequency considered.

Effect of earthquake intensity. Figure 22.55 shows the maximum equipment acceleration vs. the PGA of the earthquake. This figure illustrates that for all values of the frictional coefficient, μ , considered, an

FIGURE 22.54 Comparison of equipment accelerations ($\omega_e = 5\omega_s$, PGA = 0.5g).

increasing amount of reduction can be achieved by the RSI system as the earthquake intensity increases from 0.1 to 1g. Because relatively stiff equipment (i.e., with $\omega_e = 5\omega_s$) was assumed in the simulation, the curves shown in Figure 22.55 are similar to those of Figure 22.51 for the primary structure. Therefore, the observations made previously for Figure 22.51 apply here. The maximum response of equipment items with other natural frequencies will be discussed below. Moreover, a comparison of Figure 22.55 with Figure 22.37 (for the PSI system) reveals that the resilient mechanism can have some minor effect on the equipment response, but only when a smaller frictional coefficient (i.e., $\mu = 0.05$ or 0.1) is used and when the PGA level is high.

Effect of equipment tuning. In order to study the effect of equipment tuning, the maximum acceleration of the equipment has been plotted in Figure 22.56 for equipment frequencies ranging from 0.1 to 10 Hz.

FIGURE 22.55 Maximum equipment acceleration vs. PGA ($\omega_e = 5\omega_s$).

FIGURE 22.56 Maximum equipment acceleration vs. equipment frequency (PGA = 0.5g).

As can be seen, for all the values of μ considered, the equipment response is amplified when the equipment frequency is close to the structural frequency, ω_s , of 1.67 Hz, which means that the tuning effect tends to enlarge the equipment response. However, the use of a smaller μ can help in reducing the amplification of the equipment response resulting from the tuning effect. Finally, a comparison between Figure 22.56 and Figure 22.38 (for the PSI system) shows that the two diagrams are quite similar for an equipment item with a frequency higher than 1 Hz, but are different for that with a lower frequency. This implies that for the earthquake considered, the resilient mechanism of the RSI system has little effect on the response of the equipment with a higher stiffness.

22.5.4 Concluding Remarks

In this section, the behavior of a structure–equipment system isolated by an RSI system under both the harmonic and earthquake excitations has been investigated. Both the responses of the structure and equipment were studied, with special attention given to the effect of the resilient mechanism that characterizes an RSI system. The numerical results demonstrated that when subjected to a harmonic excitation, an RSI system is able to effectively suppress the resonant peaks associated with the structural frequency for both the structure and equipment, but it may also induce some resonant response near the isolation frequency due to the presence of resilient stiffness. Therefore, an RSI system is more sensitive to the frequency content of the ground excitation than a PSI system, especially to excitations of low-frequency components. As for the earthquake responses, the numerical results showed that the resilient mechanism of an RSI system can considerably reduce the residual base displacement. The resilient mechanism has a minor effect on the acceleration response of the structure and equipment, as long as no resonance is induced by the RSI system at the isolation frequency. By and large, both the RSI and PSI systems can be used as effective devices for reducing the acceleration responses of a structure and equipment.

22.6 Issues Related to Seismic Isolation Design

22.6.1 Design Methods

Having been developing for over 30 years, the technology of seismic isolation has matured. Many earthquake-prone countries, including the U.S., Japan, New Zealand, Taiwan, China, and European countries, have developed their own design codes, regulations, or guidelines (Fujita, 1998; Kelly, 1998; Martelli and Forni, 1998). Although most of the codes were developed based on the theory of structural dynamics, the design details outlined in the codes vary from one country to another. While a comprehensive explanation of the various design codes is not the purpose of this section, a brief overview of the concept underlying the design codes will be given. For more details, interested readers should refer to each code or to the books by Naeim and Kelly (1999) or Skinner et al. (1993). The design concept introduced herein is based on the series of Uniform Building Code (UBC, 1994, 1997).

Given the fact that base isolation devices are diverse, most design codes or regulations have been written in such a way as not to be specific with respect to the isolation systems. For instance, in the UBC (1997), no particular isolation system is identified as being acceptable; rather, it requires that every isolation system is stable for required displacement, has properties that do not degrade under repeated cyclic loadings, and provides increasing resistance with increasing displacement.

The design methods for base isolation can be classified as static analysis and dynamic analysis. The static analysis is applicable for stiff and regular buildings (in vertical and horizontal directions) that are constructed on soil of a relatively stiff condition. On the other hand, dynamic analysis is usually required for isolation systems with an irregular or long-period superstructure, or constructed on relatively soft soils. For a sophisticated design case, static analysis may be used in the preliminary design phase in order to draft or initiate the isolation design parameters, while dynamic analysis is employed in the final design phase for tuning or finalizing the design details of the isolation system. For simple design cases, static analysis alone is considered sufficient.

22.6.2 Static Analysis

For static analysis, a number of formulas have been specified in the design codes, so that engineers can easily calculate the following design parameters (shown in the design sequence): maximum isolator displacement, D ; isolator total shear, V_b ; total base shear, V_s , of superstructure; and seismic load, F_i , applied on each floor. These formulas were usually derived based on a simplified isolation model,

assuming the isolation system can be linearized (even though most isolation systems are nonlinear) and the superstructure can be modeled as a rigid block. Such a simplified model is considered reasonable, since the displacements of an isolated structure are concentrated at the isolation level, which implies that the superstructure behaves as a rigid block. Based on such a model, only the first vibration mode with the superstructure treated as a rigid body has been considered in deriving the formulas. This explains why static analysis is suitable only for rigid and regular structures.

22.6.2.1 Computation of Maximum Isolator Displacement

An isolation design by static analysis usually starts with the calculation of the maximum isolator displacement, D , which depends on several factors:

$$D = D(Z, N, S, T_{\text{ef}}, \zeta_{\text{ef}}) \quad (22.68)$$

where Z denotes the earthquake zone factor, N the near-fault factor, S the soil condition factor, T_{ef} the effective isolation period, and ζ_{ef} the effective isolation damping. For example, in the UBC (1994), the formula derived from the constant-velocity spectra over the period range of 1.0 to 3.0 sec has been given in the following form:

$$D = \frac{0.25ZNST_{\text{ef}}}{B} \quad (22.69)$$

where B is the damping factor, given as

$$B = B(\zeta_{\text{ef}}) \approx 0.25(1 - \ln \zeta_{\text{ef}}) \quad (22.70)$$

In the above equations, the factors Z , N , and S depend on conditions of the construction site of the isolated structure; however, the factors T_{ef} and ζ_{ef} depend solely on the properties of the chosen isolation system. The factors T_{ef} and ζ_{ef} are called the “effective” period and damping of the isolation system, because they are frequently obtained by linearizing a nonlinear isolation system. The way to linearize an isolation system will be explained below, along with the formulas for computing T_{ef} and ζ_{ef} . Suppose that for a nonlinear isolation system, the force-displacement relation (hysteresis loop) obtained from a component test is shown in Figure 22.57. The effective stiffness of this isolation system can be computed by

$$K_{\text{ef}} = \frac{F^+ - F^-}{2D} \quad (22.71)$$

where F^+ and F^- , respectively, denote the largest positive and negative forces in the test. After the linearized stiffness is obtained from Equation 22.71, the corresponding effective quantities T_{ef} and ζ_{ef} can be computed from the dynamic theory for a single DoF oscillation system; that is

$$T_{\text{ef}} = 2\pi\sqrt{\frac{W}{K_{\text{ef}}g}} \quad (22.72)$$

$$\zeta_{\text{ef}} = \frac{1}{2\pi} \left(\frac{A}{K_{\text{ef}}D^2} \right) \quad (22.73)$$

where W is the structural weight, g the gravitational acceleration, and A the total area enclosed by the hysteresis loop in Figure 22.57.

FIGURE 22.57 Typical force-displacement diagram for an isolation system.

22.6.2.2 Computation of Maximum Isolator Shear

After the maximum isolator displacement, D , is obtained, the maximum isolator shear, V_b , can be estimated by the following formula:

$$V_b = K_{ef}D \quad (22.74)$$

Obviously, the above equation represents an equivalent static force exerted on the isolation system, when the system is displaced by an amount, D . In some design codes, V_b has also been referred to as the design force beneath the isolation system.

22.6.2.3 Computation of Total Base Shear

The total base shear, V_s , of the superstructure can be given as

$$V_s = \frac{K_{ef}D}{R_1} \quad (22.75)$$

where R_1 is a reduction factor (ductility factor) to account for structural ductility, which will be developed when the structure is subjected to an earthquake with intensity above the design level. In some codes, V_s has also been referred to as the design force above the isolation system.

22.6.2.4 Computation of Shear Force for Each Floor

Having computed the above total base shear, V_s , a formula is employed to distribute this total shear to each floor of the isolated structure. For instance, in the, UBC (1997), the shear force, F_i , exerted on each floor is computed by

$$F_i = V_s \frac{h_i w_i}{\sum_{j=1}^n h_j w_j} \quad (22.76)$$

where n denotes the number of floors, w_i the weight of the i th floor, and h_i the height of the i th floor above the isolation level. Note that the sum of F_i ($i = 1$ to n) must be equal to V_s .

The general procedure for static analysis was illustrated in [Figure 22.58](#). Once the design parameters, D , V_b , V_s , and F_i , are all determined according to the code, they can be used in the detailed design of structural elements as well as of isolator elements. Nevertheless, in most applications, because the test data of the isolation system may not be available in the beginning of design, the values of K_{ef} , T_{ef} , and ζ_{ef} , which are required in computing D , are not known to the designer. If this is the case, the design can begin with assumed values of K_{ef} , T_{ef} , and ζ_{ef} , which may be obtained from experience or previous test data on similar isolators. After the preliminary design is completed, prototype isolators will be fabricated and tested. The actual values of K_{ef} , T_{ef} , and ζ_{ef} , obtained from the tests will be used in the aforementioned code formulas to update the design parameters D , V_b , V_s . Moreover, one observes from Equation 22.71 that the linearized isolator stiffness, K_{ef} , is a function of the design parameter, D , itself, and so are T_{ef} , and ζ_{ef} , obtained from Equation 22.72 and 22.73. In order to obtain K_{ef} , as well as T_{ef} , and ζ_{ef} , an initial guess of D is required at the beginning of design. As a result, the design procedure may have to be repeated iteratively until the difference between the final value of D and the value D_0 computed in the last iteration is less than a preset tolerance. Such an iterative process is illustrated in [Figure 22.58](#).

22.6.3 Dynamic Analysis

The dynamic analysis may be carried out in one of the two forms: response spectrum analysis and time-history analysis. Response spectrum analysis usually involves application of the concepts of response spectrum and modal superposition, and so on. Since these concepts primarily come from the dynamics of linear systems, the response spectrum analysis is only suitable for isolation systems with linear

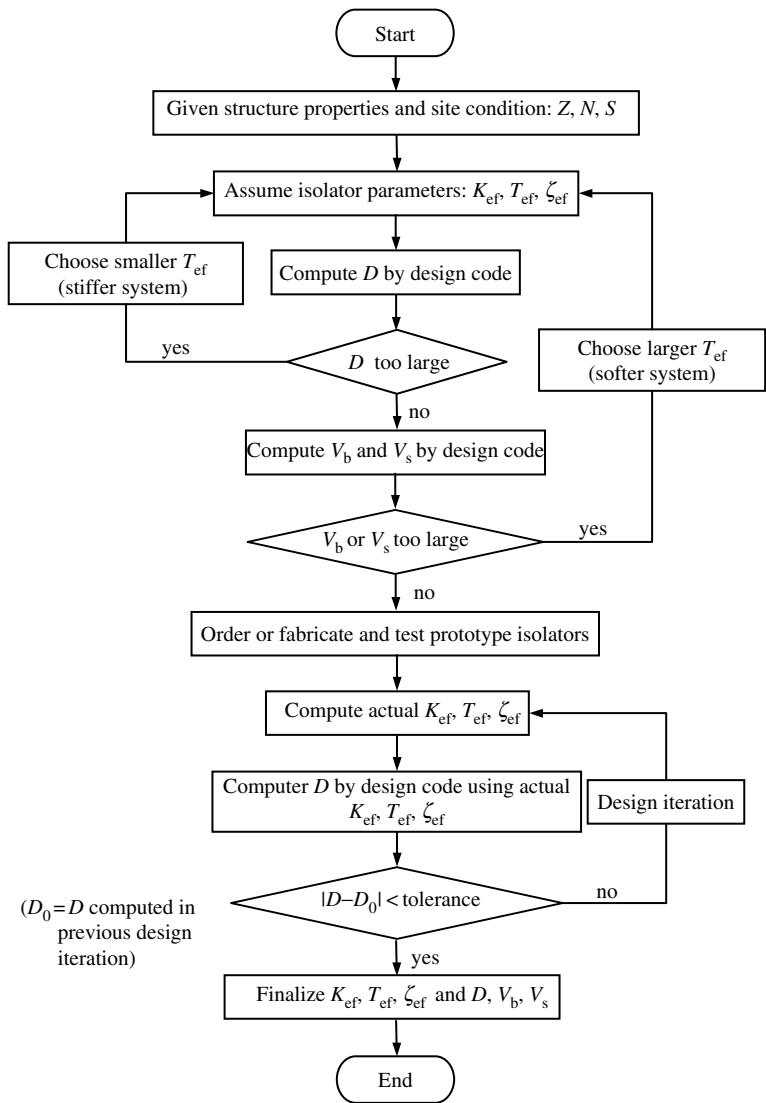

FIGURE 22.58 Flow chart of static analysis.

properties. For the case when the isolation system or the superstructure appears to be highly nonlinear, a time-history analysis is generally required.

Because dynamic analysis depends generally on the usage of computer programs, relatively few formulas have been given in the dynamic analysis sections of design codes. Nevertheless, for a successful time-history analysis, the designer must prepare the following three basic elements: (1) a set of representative input ground motions, (2) accurate mathematic models for isolators and superstructures, and (3) a computer program that is capable of performing the nonlinear time-history analysis. These three elements are explained below.

22.6.3.1 Input Ground Motions

The response of an isolated system depends greatly on the chosen input ground motions, which are usually expressed in the form of ground accelerations. Each ground motion is called one record event.

The chosen events must be representative of the site conditions and soil characteristics. Design codes usually specify the minimum number of events required for analysis. Each ground motion event must be scaled so that all events are compatible with each other and also with the code specified target spectrum. In the UBC (1997), the scaling factor for each event is obtained in response spectra, and then applied to the time domain of the record data. In particular, site specific ground motions are required in the UBC for the following cases: (1) an isolated structure located on a soft soil, (2) an isolated structure located within certain distance (e.g., 10 km) of an active fault, (3) an isolated structure with very long period of vibration (e.g., greater than 3 sec).

22.6.3.2 Mathematic Models

Before any time-history analysis can be carried out, a mathematic model that can accurately reflect the mechanical behavior of the isolation system and the superstructure must be constructed. If the isolation system is nonlinear, the nonlinear parameters must be identified so that the constructed mathematic model can correctly describe the hysteretic behavior of the isolation system. In many cases, the isolation system is assumed to be nonlinear, but the superstructure linear. Establishing an accurate mathematic model is curial for obtaining reliable results in a time-history analysis.

22.6.3.3 Computer Programs

In practice, the task of time-history analysis is executed through the use of a computer program. The mathematic model properties mentioned above will be input to the program for analysis. The computer program selected should be capable of simulating the three-dimensional behavior of structures with selected nonlinear elements. To serve the purpose of isolation design and analysis, several structural analysis programs running on the platform of personal computers have been developed for easy access. Some of the widely used programs include (but are not limited to): ETABS (ETABS, 2004), SAP-2000 Nonlinear (SAP, 2000), and 3D-BASIS (Nagarajaiah et al., 1993). Most of these programs provide a set of imbedded mathematic models for the widely used isolator elements with linear or nonlinear parameters. The designers using these programs can easily build up the mathematic model for the isolated structure considered, specify the parameters of the isolator elements selected, and execute a nonlinear time-history analysis on a personal computer.

22.6.4 Concluding Remarks

In this section, the design concept of seismic isolation for structures was briefly reviewed. The design methods can be based either on static or dynamic analysis. The fundamental issues that should be considered in each design method were highlighted, along with some relevant formulas for computing the relevant parameters. It is believed that, with the concepts and procedures presented in this section, the readers should have a general knowledge of the procedure for base isolation design of structures and equipment.

The authors are indebted to the graduate student, Cheng-Yan Wu, at the Department of Construction Engineering, National Kaohsiung First University of Science and Technology, for preparing some of the graphs presented in this chapter.

Nomenclature

Symbol	Quantity	Symbol	Quantity
c, c_s	damping coefficients of superstructure	V_b	total shear force of isolation system
c_e	damping coefficients of equipment	V_s	total base shear of superstructure
c_{EDF}	damping of the EDF system	w_i	weight of the i th floor
D	maximum isolator displacement	W	total weight of superstructure
f_r	interfacial frictional force	$x, x_s(t)$	relative-to-the-ground displacements of superstructure
F_i	seismic load applied on the i th floor	$x_b(t)$	relative-to-the-ground displacements of base mat
k, k_s	stiffness of superstructure	$x_e(t)$	relative-to-the-ground displacements of equipment
k_b	stiffness of isolation system	$\ddot{x}_g(t)$	ground acceleration
k_e	stiffness of equipment	Z	zone factor
k_{EDF}	stiffness of the EDF system	μ	frictional coefficient of sliding isolation system
k_f	stiffness of the fictitious spring in sliding isolation	ω_b	frequency of isolation system
K_{ef}	effective stiffness of isolation system	ω_e	frequencies of equipment
m, m_s	mass of superstructure	ω_g	frequency of ground excitation
m_b	mass of base mat	ζ_e	damping ratios of equipment
m_e	mass of equipment	ζ_{ef}	effective damping ratios of isolation system
n	number of building stories	ζ, ζ_s	damping ratios of superstructure
N	near fault factor	Ω_d	damped natural frequency
R_l	ductility factor	Ω, ω_s	frequencies of superstructure
S	soil factor		
T	natural period of superstructure		
T_d	damped period of superstructure		
T_{ef}	effective isolation period

Summary

The fundamental principles of vibration-control systems are formulated in this chapter. There are many important areas directly or indirectly related to the main theme of the chapter. These include practical implementation of vibration-control systems, nonlinear control schemes, actual hardware implementation, actuator bandwidth requirements, reliability, and cost. Furthermore, in the process of designing a vibration-control system, in practice, several critical criteria must be considered. These include weight, size, shape, center-of-gravity, types of dynamic disturbances, allowable system response, ambient environment, and service life. Keeping these in mind, general design steps and procedures for vibration-control systems are provided.

23.1 Introduction

The problem of reducing the level of vibration in constructions and structures arises in various branches of engineering, technology, and industry. In most of today's mechatronic systems, a number of possible devices such as reaction or momentum wheels, rotating devices, and electric motors are essential to the system's operation and performance. These devices, however, can also be sources of detrimental vibrations that may significantly influence the mission performance, effectiveness, and accuracy of operation. Therefore, there is a need for vibration control. Several techniques are utilized either to limit or alter the vibration response characteristics of such systems. During recent years, there has been considerable interest in the practical implementation of these vibration-control systems. This chapter presents the basic theoretical concepts for vibration-control systems design and implementation, followed by an overview of recent developments and control techniques in this subject. Some related practical developments in variable structure control (VSC), as well as piezoelectric vibration control of flexible structures, are also provided, followed by a summary of design steps and procedures for vibration-control systems. A further treatment of the subject is found in [Chapter 32](#).

23.1.1 Vibration Isolation vs. Vibration Absorption

In vibration isolation, either the source of vibration is isolated from the system of concern (also called “force transmissibility”; see Figure 23.1a), or the device is protected from vibration of its point of attachment (also called “displacement transmissibility”; see Figure 23.1b). Unlike the isolator, a vibration absorber consists of a secondary system (usually mass–spring–damper trio) added to the primary device to protect it from vibrating (see Figure 23.1c). By properly selecting absorber mass, stiffness, and damping, the vibration of the primary system can be minimized (Inman, 1994).

23.1.2 Vibration Absorption vs. Vibration Control

In vibration-control schemes, the driving forces or torques applied to the system are altered in order to regulate or track a desired trajectory while simultaneously suppressing the vibrational transients in the system. This control problem is rather challenging since it must achieve the motion tracking objectives while stabilizing the transient vibrations in the system. Several control methods have been developed for such applications: optimal control (Sinha, 1998); finite element approach (Bayo, 1987); model reference adaptive control (Ge et al., 1997); adaptive nonlinear boundary control (Yuh, 1987); and several other techniques including VSC methods (Chalhoub and Ulsoy, 1987; de Querioz et al., 1999; de Querioz et al., 2000).

As discussed before, in vibration-absorber systems, a secondary system is added in order to mimic the vibratory energy from the point of interest (attachment) and transfer it into other components or dissipate it into heat. Figure 23.2 demonstrates a comparative schematic of vibration control (both single-input control and multi-input configurations) on translating and rotating flexible beams, which could represent many industrial robot manipulators as well as vibration absorber applications for automotive suspension systems.

23.1.3 Classifications of Vibration-Control Systems

Passive, active, and semiactive (SA) are referred to, in the literature, as the three most commonly used classifications of vibration-control systems, either as isolators or absorbers (see Figure 23.3; Sun et al., 1995). A vibration-control system is said to be active, passive, or SA depending on the amount of

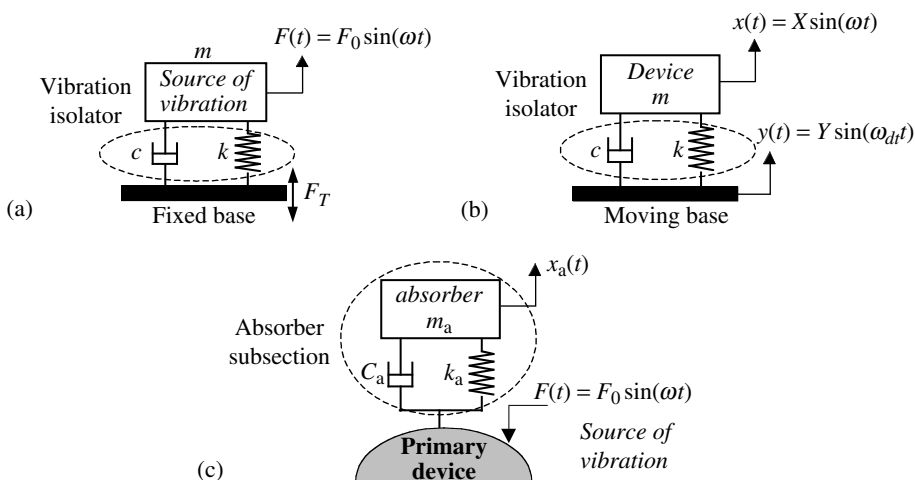

FIGURE 23.1 Schematic of (a) force transmissibility for foundation isolation; (b) displacement transmissibility for protecting device from vibration of the base and (c) application of vibration absorber for suppressing primary system vibration.

FIGURE 23.2 A comparative schematic of vibration-control systems: (a) single-input simultaneous tracking and vibration control; (b) multi-input tracking and vibration control and (c) a two-DoF vehicle model with dynamic vibration absorber.

external power required for the vibration-control system to perform its function. A passive vibration control consists of a resilient member (stiffness) and an energy dissipater (damper) either to absorb vibratory energy or to load the transmission path of the disturbing vibration (Korenev and Reznikov, 1993; Figure 23.3a). This type of vibration-control system performs best within the frequency region of its highest sensitivity. For wideband excitation frequency, its performance can be improved considerably by optimizing the system parameters (Puksand, 1975; Warburton and Ayorinde, 1980; Esmailzadeh and Jalili, 1998a). However, this improvement is achieved at the cost of lowering narrowband suppression characteristics.

The passive vibration control has significant limitations in structural applications where broadband disturbances of highly uncertain nature are encountered. In order to compensate for these limitations, active vibration-control systems are utilized. With an additional active force introduced as a part of absorber subsection, $u(t)$ (Figure 23.3b), the system is controlled using different algorithms to make it more responsive to source of disturbances (Soong and Constantinou, 1994; Olgac and Holm-Hansen, 1995; Sun et al., 1995; Margolis, 1998). The SA vibration-control system, a combination of active and passive treatment, is intended to reduce the amount of external power necessary to achieve the desired performance characteristics (Lee-Glauser et al., 1997; Jalili, 2000; Jalili and Esmailzadeh, 2002), see Figure 23.3c.

FIGURE 23.3 A typical primary structure equipped with three versions of suspension systems: (a) passive; (b) active and (c) SA configurations.

23.1.4 Performance Characteristics of Vibration-Control Systems

In the design of a vibration-control system, it often occurs that the system is required to operate over a wideband load and frequency range that is impossible to meet with a single choice of required stiffness and damping. If the desired response characteristics cannot be obtained, an active vibration-control system may provide an attractive alternative vibration control for such broadband disturbances. However, active vibration-control systems suffer from control-induced instability in addition to the large control effort requirement. This is a serious concern, which prevents them from the common usage in most industrial applications. On the other hand, passive systems are often hampered by a phenomenon known as “detuning.” Detuning implies that the passive system is no longer effective in suppressing the vibration it was designed for. This occurs due to one of the following reasons: (1) the vibration-control system may deteriorate and its structural parameters can be far from the original nominal design, (2) the structural parameters of the primary device itself may alter, or (3) the excitation frequency or the nature of disturbance may change over time.

A semiactive (also known as adaptive-passive) vibration-control system addresses these limitations by effectively integrating a tuning control scheme with tunable passive devices. For this, active force generators are replaced by modulated variable compartments such as variable rate damper and stiffness (see Figure 23.3c; Hrovat et al., 1988; Nemir et al., 1994; Franchek et al., 1995). These variable components are referred to as “tunable parameters” of the suspension system, which are retailored *via* a tuning control, thus resulting in semiactively inducing optimal operation. Much attention is being paid to these systems because of their low energy requirement and cost. Recent advances in smart materials, and adjustable dampers and absorbers have significantly contributed to applicability of these systems (Garcia et al., 1992; Wang et al., 1996; Shaw, 1998).

23.2 Vibration-Control Systems Concept

23.2.1 Introduction

With a history of almost a century (Frahm, 1911), the dynamic vibration absorber has proven to be a useful vibration-suppression device, widely used in hundreds of diverse applications. It is elastically attached to the vibrating body to alleviate detrimental oscillations from its point of attachment (see Figure 23.3). This section overviews the conceptual design and theoretical background of three types of vibration-control systems, namely the passive, active and SA configurations, along with some related practical implementations.

23.2.2 Passive Vibration Control

The underlying proposition in all vibration control or absorber systems is to adjust properly the absorber parameters such that the system becomes absorbent of the vibratory energy within the frequency interval of interest. In order to explain the underlying concept, a single-degree-of-freedom (single-DoF) primary system with a single-DoF absorber attachment is considered (Figure 23.4). The governing dynamics is expressed as

$$\begin{aligned} m_a \ddot{x}_a(t) + c_a \dot{x}_a(t) + k_a x_a(t) \\ = c_a \dot{x}_p(t) + k_a x_p(t) \end{aligned} \quad (23.1)$$

FIGURE 23.4 Application of a passive absorber to single-DoF primary system.

$$m_p \ddot{x}_p(t) + (c_p + c_a) \dot{x}_p(t) + (k_p + k_a)x_p(t) - c_a \dot{x}_a(t) - k_a x_a(t) = f(t) \quad (23.2)$$

where $x_p(t)$ and $x_a(t)$ are the respective primary and absorber displacements, $f(t)$ is the external force, and the rest of the parameters including absorber stiffness, k_a , and damping, c_a , are defined as per Figure 23.4. The transfer function between the excitation force and primary system displacement in the Laplace domain is then written as

$$TF(s) = \frac{X_p(s)}{F(s)} = \left\{ \frac{m_a s^2 + c_a s + k_a}{H(s)} \right\} \quad (23.3)$$

where

$$H(s) = \{m_p s^2 + (c_p + c_a)s + k_p + k_a\}(m_a s^2 + c_a s + k_a) - (c_a s + k_a)^2 \quad (23.4)$$

and $X_a(s)$, $X_p(s)$, and $F(s)$ are the Laplace transformations of $x_a(t)$, $x_p(t)$, and $f(t)$, respectively.

23.2.2.1 Harmonic Excitation

When excitation is tonal, the absorber is generally tuned at the disturbance frequency. For this case, the steady-state displacement of the system due to harmonic excitation can be expressed as

$$\left| \frac{X_p(j\omega)}{F(j\omega)} \right| = \left| \frac{k_a - m_a \omega^2 + j c_a \omega}{H(j\omega)} \right| \quad (23.5)$$

where ω is the disturbance frequency and $j = \sqrt{-1}$. An appropriate parameter tuning scheme can then be selected to minimize the vibration of primary system subject to external disturbance, $f(t)$.

For complete vibration attenuation, the steady state, $|X_p(j\omega)|$, must equal zero. Consequently, from Equation 23.5, the ideal stiffness and damping of absorber are selected as

$$k_a = m_a \omega^2, \quad c_a = 0 \quad (23.6)$$

Notice that this tuned condition is only a function of absorber elements (m_a , k_a , and c_a). That is, the absorber tuning does not need information from the primary system and hence its design is stand alone. For tonal application, theoretically, zero damping in the absorber subsection results in improved performance. In practice, however, the damping is incorporated in order to maintain a reasonable trade-off between the absorber mass and its displacement. Hence, the design effort for this class of application is focused on having precise tuning of the absorber to the disturbance frequency and controlling the damping to an appropriate level. Referring to Snowdon (1968), it can be proven that the absorber, in the presence of damping, can be most favorably tuned and damped if adjustable stiffness and damping are selected as

$$k_{\text{opt}} = \frac{m_a m_p^2 \omega^2}{(m_a + m_p)^2}, \quad c_{\text{opt}} = m_a \sqrt{\frac{3k_{\text{opt}}}{2(m_a + m_p)}} \quad (23.7)$$

23.2.2.2 Broadband Excitation

In broadband vibration control, the absorber subsection is generally designed to add damping to and change the resonant characteristics of the primary structure in order to dissipate vibrational energy maximally over a range of frequencies. The objective of the absorber design is, therefore, to adjust the *absorber parameters* to minimize the peak magnitude of the frequency transfer function ($FTF(\omega) = |TF(s)|_{s=j\omega}$) over the absorber parameters vector $\mathbf{p} = \{c_a, k_a\}^T$. That is, we seek \mathbf{p} to

$$\min_{\mathbf{p}} \left\{ \max_{\omega_{\min} \leq \omega \leq \omega_{\max}} \{|FTF(\omega)|\} \right\} \quad (23.8)$$

Alternatively, one may select the mean square displacement response (MSDR) of the primary system for vibration-suppression performance. That is, the absorber parameters vector, \mathbf{p} , is selected such that

the MSDR

$$E\{\{\tilde{x}_p\}^2\} = \int_0^\infty \{FTF(\omega)\}^2 S(\omega) d\omega \quad (23.9)$$

is minimized over a desired wideband frequency range. $S(\omega)$ is the power spectral density of the excitation force, $f(t)$, and FTF was defined earlier.

This optimization is subjected to some constraints in \mathbf{p} space, where only positive elements are acceptable. Once the optimal absorber suspension properties, c_a and k_a , are determined, they can be implemented using adjustment mechanisms on the spring and the damper elements. This is viewed as a SA adjustment procedure as it adds no energy to the dynamic structure. The conceptual devices for such adjustable suspension elements and SA treatment will be discussed later in Section 23.2.5.

23.2.2.3 Example Case Study

To better recognize the effectiveness of the dynamic vibration absorber over the passive and optimum passive absorber settings, a simple example case is presented. For the simple system shown in Figure 23.4, the following nominal structural parameters (marked by an overscore) are taken:

$$\begin{aligned} \bar{m}_p &= 5.77 \text{ kg}, & \bar{k}_p &= 251.132 \times 10^6 \text{ N/m}, & \bar{c}_p &= 197.92 \text{ kg/sec} \\ \bar{m}_a &= 0.227 \text{ kg}, & \bar{k}_a &= 9.81 \times 10^6 \text{ N/m}, & \bar{c}_a &= 355.6 \text{ kg/sec} \end{aligned} \quad (23.10)$$

These are from an actual test setting, which is optimal by design (Olgac and Jalili, 1999). That is, the peak of the FTF is minimized (see thin lines in Figure 23.5). When the primary stiffness and damping increase 5% (for instance during the operation), the FTF of the primary system deteriorates considerably (the dashed line in Figure 23.5), and the absorber is no longer an optimum one for the present primary. When the absorber is optimized based on optimization problem 8, the retuned setting is reached as

$$k_a = 10.29 \times 10^6 \text{ N/m}, \quad c_a = 364.2 \text{ kg/sec} \quad (23.11)$$

which yields a much better frequency response (see dark line in Figure 23.5).

The vibration absorber effectiveness is better demonstrated at different frequencies by frequency sweep test. For this, the excitation amplitude is kept fixed at unity and its frequency changes every 0.15 sec from

FIGURE 23.5 Frequency transfer functions (FTFs) for nominal absorber (thin-solid line), detuned absorber (thin-dotted line), and retuned absorber (thick-solid line) settings. (Source: From Jalili, N. and Olgac, N., *AIAA J. Guidance Control Dyn.*, 23, 961–970, 2000a. With permission.)

1860 to 1970 Hz. The primary responses with nominally tuned, with detuned, and with retuned absorber settings are given in Figure 23.6a–c, respectively.

23.2.3 Active Vibration Control

As discussed, passive absorption utilizes resistive or reactive devices either to absorb vibrational energy or load the transmission path of the disturbing vibration (Korennev and Reznikov, 1993; see [Figure 23.7](#), top). Even with optimum absorber parameters (Warburton and Ayorinde, 1980;

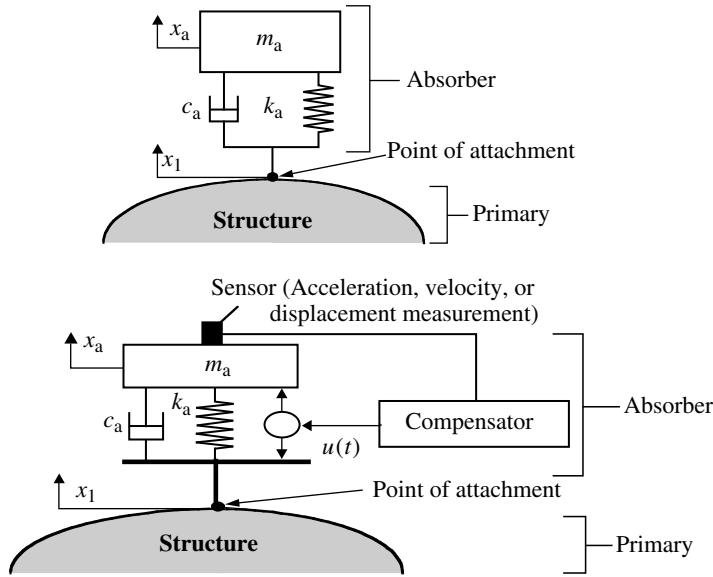

FIGURE 23.7 A general primary structure with passive (top) and active (bottom) absorber settings.

Esmailzadeh and Jalili, 1998a), the passive absorption has significant limitations in structural applications where broadband disturbances of highly uncertain nature are encountered.

In order to compensate for these limitations, active vibration-suppression schemes are utilized. With an additional active force, $u(t)$ (Figure 23.7, bottom), the absorber is controlled using different algorithms to make it more responsive to primary disturbances (Sun et al., 1995; Margolis, 1998; Jalili and Olgac, 1999). One novel implementation of the tuned vibration absorbers is the active resonator absorber (ARA) (Knowles et al., 2001b). The concept of the ARA is closely related to the concept of the delayed resonator (Olgac and Holm-Hansen, 1994; Olgac, 1995). Using a simple position (or velocity or acceleration) feedback control within the absorber subsection, the delayed resonator enforces that the dominant characteristic roots of the absorber subsection be on the imaginary axis, hence leading to resonance. Once the ARA becomes resonant, it creates perfect vibration absorption at this frequency. The conceptual design and implementation issues of such active vibration-control systems, along with their practical applications, are discussed in Section 23.3.

23.2.4 Semiactive Vibration Control

Semiactive (SA) vibration-control systems can achieve the majority of the performance characteristics of fully active systems, thus allowing for a wide class of applications. The idea of SA suspension is very simple: to replace active force generators with continually adjustable elements which can vary and/or shift the rate of the energy dissipation in response to instantaneous condition of motion (Jalili, 2002).

23.2.5 Adjustable Vibration-Control Elements

Adjustable vibration-control elements are typically comprised of variable rate damper and stiffness. Significant efforts have been devoted to the development and implementation of such devices for a variety of applications. Examples of such devices include electro-rheological (ER) (Petek, 1992; Wang et al., 1994; Choi, 1999), magneto-rheological (MR) (Spencer et al., 1998; Kim and Jeon, 2000) fluid dampers, and variable orifice dampers (Sun and Parker, 1993), controllable friction braces (Dowell and Cherry, 1994), and variable stiffness and inertia devices (Walsh and Lamnacula, 1992;

Nemir et al., 1994; Franchek et al., 1995; Abe and Igusa, 1996). The conceptual devices for such adjustable properties are briefly reviewed in this section.

23.2.5.1 Variable Rate Dampers

A common and very effective way to reduce transient and steady-state vibration is to change the amount of damping in the SA vibration-control system. Considerable design work on SA damping was done in the 1960s to the 1980s (Crosby and Karnopp, 1973; Karnopp et al., 1974) for vibration control of civil structures such as buildings and bridges (Hrovat et al., 1983) and for reducing machine tool oscillations (Tanaka and Kikushima, 1992). Since then, SA dampers have been utilized in diverse applications ranging from trains (Stribersky et al., 1998) and other off-road vehicles (Horton and Crolla, 1986) to military tanks (Miller and Nobles, 1988). During recent years, there has been considerable interest in the SA concept in the industry for improvement and refinements of the concept (Karnopp, 1990; Emura et al., 1994). Recent advances in smart materials have led to the development of new SA dampers, which are widely used in different applications.

In view of these SA dampers, ER and MR fluids probably serve as the best potential hardware alternatives for the more conventional variable-orifice hydraulic dampers (Sturk et al., 1995). From a practical standpoint, the MR concept appears more promising for suspension, since it can operate, for instance, on vehicle battery voltage, whereas the ER damper is based on high-voltage electric fields. Owing to their importance in today's SA damper technology, we briefly review the operation and fundamental principles of SA dampers here.

23.2.5.1.1 Electro-Rheological Fluid Dampers

ER fluids are materials that undergo significant instantaneous reversible changes in material characteristics when subjected to electric potentials (Figure 23.8). The most significant change is associated with complex shear moduli of the material, and hence ER fluids can be usefully exploited in SA absorbers where variable-rate dampers are utilized. Originally, the idea of applying an ER damper to vibration control was initiated in automobile suspensions, followed by other applications (Austin, 1993; Petek et al., 1995).

The flow motions of an ER fluid-based damper can be classified by shear mode, flow mode, and squeeze mode. However, the rheological property of ER fluid is evaluated in the shear mode (Choi, 1999). As a result, the ER fluid damper provides an adaptive viscous and frictional damping for use in SA system (Dimarogonas-Andrew and Kollias, 1993; Wang et al., 1994).

FIGURE 23.8 A schematic configuration of an ER damper. (Source: From Choi, S.B., *ASME J. Dyn. Syst. Meas. Control*, 121, 134–138, 1999. With permission.)

23.2.5.1.2 Magneto-Rheological Fluid Dampers

MR fluids are the magnetic analogies of ER fluids and typically consist of micron-sized, magnetically polarizable particles dispersed in a carrier medium such as mineral or silicon oil. When a magnetic field is applied, particle chains form and the fluid becomes a semisolid, exhibiting plastic behavior similar to that of ER fluids (Figure 23.9). Transition to rheological equilibrium can be achieved in a few milliseconds, providing devices with high bandwidth (Spencer et al., 1998; Kim and Jeon, 2000).

FIGURE 23.9 A schematic configuration of an MR damper. (Source: From Spencer, B.F. et al., *Proc. 2nd World Conf. on Structural Control*, 1998. With permission.)

23.2.5.2 Variable-Rate Spring Elements

In contrast to variable dampers, studies of SA springs or time-varying stiffness have also been geared for vibration-isolation applications (Hubard and Marolis, 1976), for structural controls and for vibration attenuation (Sun et al., 1995 and references therein). The variable stiffness is a promising practical complement to SA damping, since, based on the discussion in Section 23.2, both the absorber damping and stiffness should change to adapt optimally to different conditions. Clearly, the absorber stiffness has a significant influence on optimum operation (and even more compared to the damping element; Jalili and Olgac, 2000b).

Unlike the variable rate damper, changing the effective stiffness requires high energy (Walsh and Lamnaca, 1992). Semiactive or low-power implementation of variable stiffness techniques suffers from limited frequency range, complex implementation, high cost, and so on. (Nemir et al., 1994; Franchek et al., 1995). Therefore, in practice, both absorber damping and stiffness are concurrently adjusted to reduce the required energy.

23.2.5.2.1 Variable-Rate Stiffness (Direct Methods)

The primary objective is to directly change the spring stiffness to optimize a vibration-suppression characteristic such as the one given in Equation 23.8 or Equation 23.9. Different techniques can be utilized ranging from traditional variable leaf spring to smart spring utilizing magnetostrictive materials. A tunable stiffness vibration absorber was utilized for a four-DoF building (Figure 23.10), where a spring is threaded through a collar plate and attached to the absorber mass from one side and to the driving gear from the other side (Franchek et al., 1995). Thus, the effective number of coils, N , can be changed resulting in a variable spring stiffness, k_a :

$$k_a = \frac{d^4 G}{8D^3 N} \quad (23.12)$$

where d is the spring wire diameter, D is the spring diameter, and G is modulus of shear rigidity.

23.2.5.2.2 Variable-Rate Effective Stiffness (Indirect Methods)

In most SA applications, directly changing the stiffness might not be always possible or may require large amount of control effort. For such cases, alternatives methods are utilized to change the effective tuning ratio ($\tau = \sqrt{k_a/m_a}/\omega_{\text{primary}}$), thus resulting in a tunable resonant frequency.

In Liu et al. (2000), a SA flutter-suppression scheme was proposed using differential changes of external store stiffness. As shown in Figure 23.11, the motor drives the guide screw to rotate with slide block, G , moving along it, thus changing the restoring moment and resulting in a change of store

FIGURE 23.10 The application of a variable-stiffness vibration absorber to a four-DoF building. (Source: From Franchek, M.A. et al., *J. Sound Vib.*, 189, 565–585, 1995. With permission.)

FIGURE 23.11 A SA flutter control using adjustable pitching stiffness. (Source: From Liu, H.J. et al., *J. Sound Vib.*, 229, 199–205, 2000. With permission.)

pitching stiffness. Using a double-ended cantilever beam carrying intermediate lumped masses, a SA vibration absorber was recently introduced (Jalili and Esmailzadeh, 2002), where positions of moving masses are adjustable (see Figure 23.12). Figure 23.13 shows an SA absorber with an adjustable effective inertia mechanism (Jalili et al., 2001; Jalili and Fallahi, 2002). The SA absorber consists of a rod carrying a moving block and a spring and damper, which are mounted on a casing. The position of the moving block, r_v , on the rod is adjustable which provides a tunable resonant frequency.

23.2.5.3 Other Variable-Rate Elements

Recent advances in smart materials have led to the development of new SA vibration-control systems using indirect influence on the suspension elements. Wang et al. used a SA piezoelectric network (1996) for structural-vibration control. The variable resistance and inductance in an external RL circuit are used as real-time adaptable control parameters.

Another class of adjustable suspensions is the so-called hybrid treatment (Fujita et al., 1991). The hybrid design has two modes, an active mode and a passive mode. With its aim of lowering the

FIGURE 23.12 A typical primary system equipped with the double-ended cantilever absorber with adjustable tuning ration through moving masses, m . (Source: From Jalili, N. and Esmailzadeh, E., *J. Multi-Body Dyn.*, 216, 223–235, 2002. With permission.)

FIGURE 23.13 Schematic of the adjustable effective inertia vibration absorber. (Source: From Jalili, N. et al., *Int. J. Model. Simulat.*, 21, 148–154, 2001. With permission.)

control effort, relatively small vibrations are reduced in active mode, while passive mode is used for large oscillations. Analogous to hybrid treatment, the semiautomated approach combines SA and active suspensions to benefit from the advantages of individual schemes while eliminating their shortfalls (Jalili, 2000). By altering the adjustable structural properties (in the SA unit) and control parameters (in the active unit), a search is conducted to minimize an objective function subject to certain constraints, which may reflect performance characteristics.

23.3 Vibration-Control Systems Design and Implementation

23.3.1 Introduction

This section provides the basic fundamental concepts for vibration-control systems design and implementation. These systems are classified into two categories: vibration absorbers and vibration-control systems. Some related practical developments in ARAs and piezoelectric vibration control of flexible structures are also provided.

23.3.2 Vibration Absorbers

Undesirable vibrations of flexible structures have been effectively reduced using a variety of dynamic vibration absorbers. The active absorption concept offers a wideband of vibration-attenuation

frequencies as well as real-time tunability as two major advantages. It is clear that the active control could be a destabilizing factor for the combined system, and therefore, the stability of the combined system (i.e., the primary and the absorber subsystems) must be assessed.

An actively tuned vibration-absorber scheme utilizing a resonator generation mechanism forms the underlying concept here. For this, a stable primary system (see Figure 23.7, top, for instance) is forced into a marginally stable one through the addition of a controlled force in the active unit (see Figure 23.7, bottom). The conceptual design for generating such resonance condition is demonstrated in Figure 23.14, where the system's dominant characteristic roots (poles) are moved and placed on the imaginary axis. The absorber then becomes a resonator capable of mimicking the vibratory energy from the primary system at the point of attachment. Although there seem to be many ways to generate such resonance, only two widely accepted practical vibration-absorber resonators are discussed next.

FIGURE 23.14 Schematic of the active resonator absorber concept through placing the poles of the characteristic equation on the imaginary axis.

23.3.2.1 Delayed-Resonator Vibration Absorbers

A recent active vibration-absorption strategy, the delayed resonator (DR), is considered to be the first type of active vibration absorber when operated on a flexible beam (Olgac and Jalili, 1998; Olgac and Jalili, 1999). The DR vibration absorber offers some attractive features in eliminating tonal vibrations from the objects to which it is attached (Olgac and Holm-Hansen, 1994; Olgac, 1995; Renzulli et al., 1999), some of which are real-time tunability, the stand-alone nature of the actively controlled absorber, and the simplicity of the implementation. Additionally, this single-DoF absorber can also be tuned to handle multiple frequencies of vibration (Olgac et al., 1996). It is particularly important that the combined system, that is, the primary structure and the absorber together, is asymptotically stable when the DR is implemented on a flexible beam.

23.3.2.1.1 An Overview of the Delayed-Resonator Concept

An overview of the DR is presented here to help the reader. The equation of motion governing the absorber dynamics alone is

$$m_a \ddot{x}_a(t) + c_a \dot{x}_a(t) + k_a x_a(t) - u(t) = 0, \quad u(t) = g \ddot{x}_a(t - \tau) \quad (23.13)$$

where $u(t)$ represents the delayed acceleration feedback. The Laplace domain transformation of this equation yields the characteristics equation

$$m_a s^2 + c_a s + k_a - g s^2 e^{-\tau s} = 0 \quad (23.14)$$

Without feedback ($g = 0$), this structure is dissipative with two characteristic roots (poles) on the left half of the complex plane. For g and $\tau > 0$, however, these two finite stable roots are supplemented by infinitely many additional finite roots. Note that these characteristic roots (poles) of Equation 23.14 are discretely located (say at $s = a + j\omega$), and the following relation holds:

$$g = \frac{|m_a s^2 + c_a s + k_a|}{|s^2|} e^{\tau a} \quad (23.15)$$

where $|\cdot|$ denotes the magnitude of the argument.

Using Equation 23.15, the following observation can be made:

- For $g = 0$: there are two finite stable poles and all the remaining poles are at $a = -\infty$.
- For $g = +\infty$: there are two poles at $s = 0$, and the rest are at $a = +\infty$.

Considering these and taking into account the continuity of the root loci for a given time delay, τ , and as g varies from 0 to ∞ , it is obvious that the roots of Equation 23.14 move from the stable left half to the unstable right half of the complex plane. For a certain critical gain, g_c , one pair of poles reaches the imaginary axis. At this operating point, the DR becomes a perfect resonator and the imaginary characteristic roots are $s = \pm j\omega_c$, where ω_c is the resonant frequency and $j = \sqrt{-1}$. The subscript “c” implies the crossing of the root loci on the imaginary axis. The control parameters of concern, g_c and τ_c , can be found by substituting the desired $s = \pm j\omega_c$ into Equation 23.14 as

$$g_c = \frac{1}{\omega_c^2} \sqrt{(c_a \omega_c)^2 + (m_a \omega_c - k_a)^2}, \quad \tau_c = \frac{1}{\omega_c} \left\{ \tan^{-1} \left[\frac{c_a \omega_c}{m_a \omega_c^2 - k_a} \right] + 2(\ell - 1)\pi \right\}, \quad \ell = 1, 2, \dots \quad (23.16)$$

When these g_c and τ_c are used, the DR structure mimics a resonator at frequency ω_c . In turn, this resonator forms an *ideal absorber* of the tonal vibration at ω_c . The objective of the control, therefore, is to maintain the DR absorber at this marginally stable point. On the DR stability, further discussions can be found in Olgac and Holm-Hansen (1994) and Olgac et al. (1997).

23.3.2.1.2 Vibration-Absorber Application on Flexible Beams

We consider a general beam as the primary system with absorber attached to it and subjected to a harmonic force excitation, as shown in Figure 23.15. The point excitation is located at b , and the absorber is placed at a . A uniform cross section is considered for the beam and Euler–Bernoulli assumptions are made. The beam parameters are all assumed to be constant and uniform. The elastic deformation from the undeformed natural axis of the beam is denoted by $y(x, t)$ and, in the derivations that follow, the dot ($\dot{\cdot}$) and prime ($'$) symbols indicate a partial derivative with respect to the time variable, t , and position variable x , respectively.

Under these assumptions, the kinetic energy of the system can be written as

$$T = \frac{1}{2} \rho \int_0^L \left(\frac{\partial y}{\partial t} \right)^2 dx + \frac{1}{2} m_a \dot{q}_a^2 + \frac{1}{2} m_e \dot{q}_e^2 \quad (23.17)$$

The potential energy of this system using linear strain is given by

$$U = \frac{1}{2} EI \int_0^L \left(\frac{\partial^2 y}{\partial x^2} \right)^2 dx + \frac{1}{2} k_a \{y(a, t) - q_a\}^2 + \frac{1}{2} k_e \{y(b, t) - q_e\}^2 \quad (23.18)$$

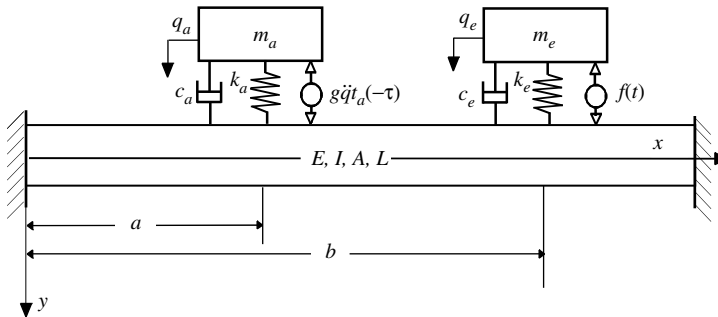

FIGURE 23.15 Beam–absorber–exciter system configuration. (Source: From Olgac, N. and Jalili, N., *J. Sound Vib.*, 218, 307–331, 1998. With permission.)

The equations of motion may now be derived by applying Hamilton's Principle. However, to facilitate the stability analysis, we resort to an assumed-mode expansion and Lagrange's equations. Specifically, y is written as a finite sum "Galerkin approximation":

$$y(x, t) = \sum_{i=1}^n \Phi_i(x) q_{bi}(t) \quad (23.19)$$

The orthogonality conditions between these mode shapes can also be derived as (Meirovitch, 1986)

$$\int_0^L \rho \Phi_i(x) \Phi_j(x) dx = N_i \delta_{ij}, \quad \int_0^L EI \Phi_i''(x) \Phi_j''(x) dx = S_i \delta_{ij} \quad (23.20)$$

where $i, j = 1, 2, \dots, n$, δ_{ij} is the Kronecker delta, and N_i and S_i are defined by setting $i = j$ in Equation 23.20.

The feedback of the absorber, the actuator excitation force, and the damping dissipating forces in both the absorber and the exciter are considered as non-conservative forces in Lagrange's formulation. Consequently, the equations of motion are derived.

Absorber dynamics is governed by

$$m_a \ddot{q}_a(t) + c_a \left\{ \dot{q}_a(t) - \sum_{i=1}^n \Phi_i(a) \dot{q}_{bi}(t) \right\} + k_a \left\{ q_a(t) - \sum_{i=1}^n \Phi_i(a) q_{bi}(t) \right\} - g \ddot{q}_a(t - \tau) = 0 \quad (23.21)$$

The exciter is given by

$$m_e \ddot{q}_e(t) + c_e \left\{ \dot{q}_e(t) - \sum_{i=1}^n \Phi_i(b) \dot{q}_{bi}(t) \right\} + k_e \left\{ q_e(t) - \sum_{i=1}^n \Phi_i(b) q_{bi}(t) \right\} = -f(t) \quad (23.22)$$

Finally, the beam is represented by

$$\begin{aligned} N_i \ddot{q}_{bi}(t) + S_i q_{bi}(t) + c_a \left\{ \sum_{i=1}^n \Phi_i(a) \dot{q}_{bi}(t) - \dot{q}_a(t) \right\} \Phi_i(a) + c_e \left\{ \sum_{i=1}^n \Phi_i(b) \dot{q}_{bi}(t) - \dot{q}_e(t) \right\} \Phi_i(b) \\ + k_a \left\{ \sum_{i=1}^n \Phi_i(a) q_{bi}(t) - q_a(t) \right\} \Phi_i(a) + k_e \left\{ \sum_{i=1}^n \Phi_i(b) q_{bi}(t) - q_e(t) \right\} \Phi_i(b) + g \Phi_i(a) \ddot{q}_a(t - \tau) \\ = f(t) \Phi_i(b), \quad i = 1, 2, \dots, n \end{aligned} \quad (23.23)$$

Equation 23.21 to Equation 23.23 form a system of $n + 2$ second-order coupled differential equations.

By proper selection of the feedback gain, the absorber can be tuned to the desired resonant frequency, ω_c . This condition, in turn, forces the beam to be motionless at a , when the beam is excited by a tonal force at frequency ω_c . This conclusion is reached by taking the Laplace transform of Equation 23.21 and using feedback control law for the absorber. In short,

$$Y(a, s) = \sum_{i=1}^n \Phi_i(a) Q_{bi}(s) = 0 \quad (23.24)$$

where $Y(a, s) = \mathfrak{L}\{y(a, t)\}$, $Q_a(s) = \mathfrak{L}\{q_a(t)\}$ and $Q_{bi}(s) = \mathfrak{L}\{q_{bi}(t)\}$. Equation 23.24 can be rewritten in time domain as

$$y(a, t) = \sum_{i=1}^n \Phi_i(a) q_{bi}(t) = 0 \quad (23.25)$$

which indicates that the steady-state vibration of the point of attachment of the absorber is eliminated. Hence, the absorber mimics a resonator at the frequency of excitation and absorbs all the vibratory energy at the point of attachment.

23.3.2.1.3 Stability of the Combined System

In the preceding section, we have derived the equations of motion for the beam–exciter–absorber system in its most general form. As stated before, inclusion of the feedback control for active absorption is, indeed, an invitation to instability. This topic is treated next.

The Laplace domain representation of the combined system takes the form (Olgac and Jalili, 1998)

$$\mathbf{A}(s)\mathbf{Q}(s) = \mathbf{F}(s) \quad (23.26)$$

where

$$\mathbf{Q}(s) = \begin{Bmatrix} Q_a(s) \\ Q_e(s) \\ Q_{b1}(s) \\ \vdots \\ Q_{bn}(s) \end{Bmatrix}_{(n+2) \times 1}, \quad \mathbf{F}(s) = \begin{Bmatrix} 0 \\ -F(s) \\ 0 \\ \vdots \\ 0 \end{Bmatrix}_{(n+2) \times 1},$$

$$\mathbf{A}(s) = \begin{pmatrix} m_a s^2 + c_a s + k_a - g s^2 e^{-\tau s} & 0 & -\Phi_1(a)(c_a s + k_a) & \cdots & -\Phi_n(a)(c_a s + k_a) \\ 0 & m_e s^2 + c_e s + k_e & -\Phi_1(b)(c_e s + k_e) & \cdots & -\Phi_n(b)(c_e s + k_e) \\ m_a \Phi_1(a) s^2 & m_e \Phi_1(b) s^2 & N_1 s^2 + c s + S_1(1 + j\delta) & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ m_a \Phi_n(a) s^2 & m_e \Phi_n(b) s^2 & 0 & \cdots & N_n s^2 + c s + S_n(1 + j\delta) \end{pmatrix} \quad (23.27)$$

In order to assess the combined system stability, the roots of the characteristic equation, $\det(\mathbf{A}(s)) = 0$ are analyzed. The presence of feedback (transcendental delay term for this absorber) in the characteristic equations complicates this effort. The root locus plot observation can be applied to the entire system. It is typical that increasing feedback gain causes instability as the roots move from left to right in the complex plane. This picture also yields the frequency range for stable operation of the combined system (Olgac and Jalili, 1998).

23.3.2.1.4 Experimental Setting and Results

The experimental setup used to verify the findings is shown in [Figure 23.16](#). The primary structure is a 3/8' in. \times 1' in. \times 12' in. steel beam (2) clamped at both ends to a granite bed (1). A piezoelectric actuator with a reaction mass (3 and 4) is used to generate the periodic disturbance on the beam. A similar actuator-mass setup constitutes the DR absorber (5 and 6). The two setups are located symmetrically at one quarter of the length along the beam from the center. The feedback signal used to implement the DR is obtained from the accelerometer (7) mounted on the reaction mass of the absorber structure. The other accelerometer (8) attached to the beam is present only to monitor the vibrations of the beam and to evaluate the performance of the DR absorber in suppressing them. The control is applied *via* a fast data acquisition card using a sampling of 10 kHz.

The numerical values for this beam–absorber–exciter setup are taken as

- *Beam*: $E = 210$ GPa, $\rho = 1.8895$ kg/m
- *Absorber*: $m_a = 0.183$ kg, $k_a = 10,130$ kN/m, $c_a = 62.25$ N sec/m, $a = L/4$
- *Exciter*: $m_e = 0.173$ kg, $k_e = 6426$ kN/m, $c_e = 3.2$ N sec/m, $b = 3L/4$

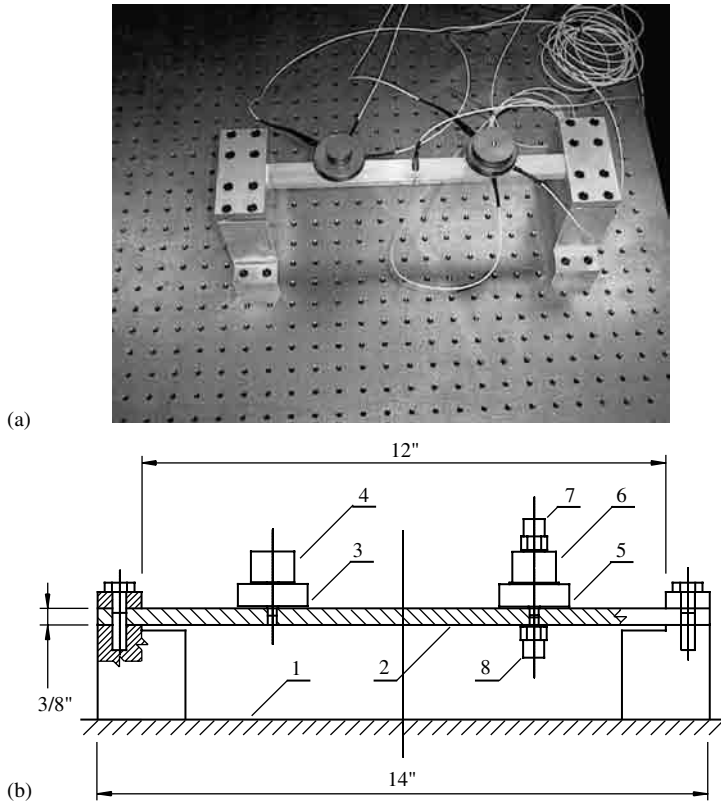

FIGURE 23.16 (a) Experimental structure and (b) schematic depiction of the setup. (Source: From Olgac, N. and Jalili, N., *J. Sound Vib.*, 218, 307–331, 1998. With permission.)

23.3.2.1.5 Dynamic Simulation and Comparison with Experiments

For the experimental set up at hand, the natural frequencies are measured for the first two natural modes, ω_1 and ω_2 . These frequencies are obtained much more precisely than those of higher-order natural modes. Table 23.1 offers a comparison between the experimental (*real*) and analytical (*ideal*) clamped–clamped beam natural frequencies.

The discrepancies arrive from two sources: first, the experimental frequencies are structurally damped natural frequencies, and second, they reflect the effect of partially clamped BCs. The theoretical frequencies, on the other hand, are evaluated for an undamped ideal clamped–clamped beam.

After observing the effect of the number of modes used on the beam deformation, a minimum of three natural modes are taken into account. We then compare the simulated time response vs. the experimental results of vibration suppression. Figure 23.17 shows a test with the excitation frequency $\omega_c = 1270$ Hz. The corresponding theoretical control parameters are $g_{c \text{ theory}} = 0.0252$ kg and $\tau_{c \text{ theory}} = 0.8269$ msec. The experimental control parameters for this frequency are found to be $g_{c \text{ exp.}} = 0.0273$ kg and $\tau_{c \text{ exp.}} = 0.82$ msec. The exciter disturbs the beam for 5 msec, then the DR tuning is triggered. The acceleration of the beam at the point of attachment decays exponentially. For all intents and purposes, the suppression takes effect in approximately 200 ms. These results match very closely with the experimental data, Figure 23.18. The only noticeable difference is in the frequency content of the exponential decay. This property is dictated by the dominant poles of the combined system. The imaginary part, however, is smaller in the analytical study. This difference is a nuance that does not affect the earlier observations.

TABLE 23.1 Comparison between Experimental and Theoretical Beam Natural Frequencies (Hz)

Natural Modes	Peak Frequencies (Experimental)	Natural Frequencies (Clamped–Clamped)
First mode	466.4	545.5
Second mode	1269.2	1506.3

23.3.2.2 Active Resonator Vibration Absorbers

One novel implementation of the tuned vibration absorbers is the ARA (Knowles et al., 2001b). The concept of the ARA is closely related to the concept of the delayed resonator (Olgac and Holm-Hansen, 1994; Olgac and Jalili, 1999). Using a simple position (or velocity or acceleration) feedback control within the absorber section, it enforces the dominant characteristic roots of the absorber subsection to be on the imaginary axis, and hence leading to resonance. Once the ARA becomes resonant, it creates perfect vibration absorption at this frequency.

A very important component of any active vibration absorber is the actuator unit. Recent advances in smart materials have led to the development of advanced actuators using piezoelectric ceramics, shape memory alloys, and magnetostrictive materials (Garcia et al., 1992; Shaw, 1998). Over the past two decades, piezoelectric ceramics have been utilized as potential replacements for conventional transducers.

FIGURE 23.19 A PCB series 712 PZT inertial actuator (left), schematic of operation (middle), and a simple single-DoF mathematical model (right). (Active Vibration Control Instrumentation, A Division of PCB Piezotronics, Inc., www.pcb.com.)

These materials are compounds of lead zirconate–titanate (PZT). The PZT properties can be optimized to suit specific applications by appropriate adjustment of the zirconate–titanate ratio. Specifically, a piezoelectric inertial actuator is an efficient and inexpensive solution for active structural vibration control. As shown in Figure 23.19, it applies a point force to the structure to which it is attached.

23.3.2.2.1 An Overview of PZT Inertial Actuators

PZT inertial actuators are most commonly made out of two parallel piezoelectric plates. If voltage is applied, one of the plates expands as the other one contracts, hence producing displacement that is proportional to the input voltage. The resonance of such an actuator can be adjusted by the size of the inertial mass (see Figure 23.19). Increasing the size of the inertial mass will lower the resonant frequency and decreasing the mass will increase it. The resonant frequency, f_r , can be expressed as

$$f_r = \frac{1}{2\pi} \sqrt{\frac{k_a}{m_a}} \quad (23.28)$$

where k_a is the effective stiffness of the actuator, m_a , is defined as

$$m_a = m_{\text{ePZT}} + m_{\text{inertial}} + m_{\text{acc}} \quad (23.29)$$

The PZT effective mass is m_{ePZT} , m_{inertial} is the inertial mass, and m_{acc} is the accelerometer mass. Using a simple single-DoF system (see Figure 23.19), the parameters of the PZT inertial actuators can be experimentally determined (Knowles et al., 2001a). This “parameter identification” problem is an inverse problem. We refer interested readers to Banks and Ito (1988) and Banks and Kunisch (1989) for a general introduction to parameter estimation or inverse problems governed by differential equations.

23.3.2.2.2 Active Resonator Absorber Concept

The concept of ARA is closely related to that of the DR (Olgac, 1995; Olgac and Holm-Hansen, 1995; Olgac and Jalili, 1998). Instead of a compensator, the DR uses a simple delayed position (or velocity, or acceleration) feedback control within the absorber subsection for the mentioned “sensitization.”

In contrast to that of the DR absorber, the characteristic equation of the proposed control scheme is rational in nature and is hence easier to implement when closed-loop stability of the system is concerned. Similar to the DR absorber, the proposed ARA requires only one signal from the absorber mass, absolute or relative to the point of attachment (see Figure 23.7 bottom). After the signal is processed through a compensator, an additional force is produced, for instance, by a PZT inertial actuator. If the compensator parameters are properly set, the absorber should behave as an ideal resonator at one or even more frequencies. As a result, the resonator will absorb vibratory energy from the primary mass at given frequencies. The frequency to be absorbed can be tuned in real time. Moreover, if the controller or the actuator fails, the ARA will still function as a passive absorber, and thus it is inherently fail-safe. A similar vibration absorption methodology is given by Filipović and Schröder (1999) for linear systems. The ARA, however, is not confined to the linear regime.

For the case of linear assumption for the PZT actuator, the dynamics of the ARA (Figure 23.7, bottom) can be expressed as

$$m_a \ddot{x}_a(t) + c_a \dot{x}_a(t) + k_a x_a(t) - u(t) = c_a \dot{x}_1(t) + k_a x_1(t) \quad (23.30)$$

where $x_1(t)$ and $x_a(t)$ are the respective primary (at the absorber point of attachment) and absorber mass displacements. The mass, m_a , is given by Equation 23.29 and the control, $u(t)$, is designed to produce designated resonance frequencies within the ARA.

The objective of the feedback control, $u(t)$, is to convert the dissipative structure (Figure 23.7, top) into a conservative or marginally stable one (Figure 23.7, bottom) with a designated resonant frequency, ω_c . In other words, the control aims the placement of dominant poles at $\pm j\omega_c$ for the combined system, where $j = \sqrt{-1}$ (see Figure 23.14). As a result, the ARA becomes marginally stable at particular frequencies in the determined frequency range. Using simple position (or velocity or acceleration) feedback within the absorber section (i.e., $U(s) = \bar{U}(s)X_a(s)$), the corresponding dynamics of the ARA, given by Equation 23.30, in the Laplace domain become

$$(m_a s^2 + c_a s + k_a)X_a(s) - \bar{U}(s)X_a(s) = C(s)X_a(s) = (c_a s + k_a)X_1(s) \quad (23.31)$$

The compensator transfer function, $\bar{U}(s)$, is then selected such that the primary system displacement at the absorber point of attachment is forced to be zero; that is

$$C(s) = (m_a s^2 + c_a s + k_a) - \bar{U}(s) = 0 \quad (23.32)$$

The parameters of the compensator are determined through introducing resonance conditions to the absorber characteristic equation, $C(s)$; that is, the equations $\text{Re}\{C(j\omega_i)\} = 0$ and $\text{Im}\{C(j\omega_i)\} = 0$ are simultaneously solved, where $i = 1, 2, \dots, l$ and l is the number of frequencies to be absorbed. Using additional compensator parameters, the stable frequency range or other properties can be adjusted in real time.

Consider the case where $U(s)$ is taken as a proportional compensator with a single time constant based on the acceleration of the ARA, given by

$$U(s) = \bar{U}(s)X_a(s), \quad \text{where } \bar{U}(s) = \frac{g s^2}{1 + T s} \quad (23.33)$$

Then, in the time domain, the control force, $u(t)$, can be obtained from

$$u(t) = \frac{g}{T} \int_0^t e^{-(t-\tau)/T} \ddot{x}_a(\tau) d\tau \quad (23.34)$$

To achieve ideal resonator behavior, two dominant roots of Equation 23.32 are placed on the imaginary axis at the desired crossing frequency, ω_c . Substituting $s = \pm j\omega_c$ into Equation 23.32 and solving for the control parameters, g_c and T_c , one can obtain

$$g_c = m_a \left(\frac{c_a^2}{m_a^2 \left(\omega^2 - \frac{k_a}{m_a} \right)} - \frac{k_a}{m_a \omega^2} + 1 \right), \quad T_c = \frac{c_a \sqrt{k_a/m_a}}{\sqrt{m_a k_a} \left(\omega^2 - \frac{k_a}{m_a} \right)}, \quad \text{for } \omega = \omega_c \quad (23.35)$$

The control parameters, g_c and T_c , are based on the physical properties of the ARA (i.e., c_a , k_a , and m_a) as well as the frequency of the disturbance, ω , illustrating that the ARA does not require any information from the primary system to which it is attached. However, when the physical properties of the ARA are not known within a high degree of certainty, a method to autotune the control parameters must be considered. The stability assurance of such autotuning proposition will bring primary system parameters into the derivations, and hence the primary system cannot be totally decoupled. This issue will be discussed later in the chapter.

23.3.2.2.3 Application of ARA to Structural-Vibration Control

In order to demonstrate the effectiveness of the proposed ARA, a simple single-DoF primary system subjected to tonal force excitations is considered. As shown in Figure 23.20, two PZT inertial actuators are used for both the primary (model 712-A01) and the absorber (model 712-A02) subsections. Each system consists of passive elements (spring stiffness and damping properties of the PZT materials) and active compartment with the physical parameters listed in Table 23.2. The top actuator acts as the ARA with the controlled force, $u(t)$, while the bottom one represents the primary system subjected to the force excitation, $f(t)$.

The governing dynamics for the combined system can be expressed as

$$m_a \ddot{x}_a(t) + c_a \dot{x}_a(t) + k_a x_a(t) - u(t) = c_a \dot{x}_1(t) + k_a x_1(t) \quad (23.36)$$

$$m_1 \ddot{x}_1(t) + (c_1 + c_a) \dot{x}_1(t) + (k_1 + k_a) x_1(t) - \{c_a \dot{x}_a(t) + k_a x_a(t) - u(t)\} = f(t) \quad (23.37)$$

where $x_1(t)$ and $x_a(t)$ are the respective primary and absorber displacements.

23.3.2.2.4 Stability Analysis and Parameter Sensitivity

The sufficient and necessary condition for asymptotic stability is that all roots of the characteristic equation have negative real parts. For the linear system, Equation 23.36 and Equation 23.37, when utilizing controller (Equation 23.34), the characteristic equation of the combined system (Figure 23.20, right) can be determined and the stability region for compensator parameters, g and T , can be obtained using the Routh–Hurwitz method.

23.3.2.2.5 Autotuning Proposition

When using the proposed ARA configuration in real applications where the physical properties are not known or vary over time, the compensator parameters, g and T , only provide partial vibration suppression. In order to remedy this, a need exists for an autotuning method to adjust the compensator

FIGURE 23.20 Implementation of the ARA concept using two PZT actuators (left) and its mathematical model (right).

TABLE 23.2 Experimentally Determined Parameters of PCB Series 712 PZT Inertial Actuators

PZT System Parameters	PCB Model 712-A01	PCB Model 712-A02
Effective mass, m_{ePZT} (gr)	7.20	12.14
Inertial mass, m_{inertial} (gr)	100.00	200.00
Stiffness, k_a (kN/m)	3814.9	401.5
Damping, c_a (Ns/m)	79.49	11.48

parameters, g and T , by some quantities, Δg and ΔT , respectively (Jalili and Olgac, 1998b; Jalili and Olgac, 2000a). For the case of the linear compensator with a single time constant, given by Equation 23.33, the transfer function between primary displacement, $X_1(s)$, and absorber displacement, $X_a(s)$, can be obtained as

$$G(s) = \frac{X_1(s)}{X_a(s)} = \frac{m_a s^2 + c_a s + k_a - \frac{g s^2}{1 + Ts}}{c_a s + k_a} \quad (23.38)$$

The transfer function can be rewritten in the frequency domain for $s = j\omega$ as

$$G(j\omega) = \frac{X_1(j\omega)}{X_a(j\omega)} = \frac{-m_a \omega^2 + c_a j\omega + k_a + \frac{g \omega^2}{1 + Tj\omega}}{c_a j\omega + k_a} \quad (23.39)$$

where $G(j\omega)$ can be obtained in real time by convolution of accelerometer readings (Renzulli et al., 1999) or other methods (Jalili and Olgac, 2000a). Following a similar procedure as is utilized in Renzulli et al. (1999), the numerator of the transfer function (Equation 23.39) must approach zero in order to suppress primary system vibration. This is accomplished by setting

$$G(j\omega) + \Delta G(j\omega) = 0 \quad (23.40)$$

where $G(j\omega)$ is the real-time transfer function and $\Delta G(j\omega)$ can be written as a variational form of Equation 23.39 as

$$\Delta G(j\omega) = \frac{\partial G}{\partial g} \Delta g + \frac{\partial G}{\partial T} \Delta T + \text{higher order terms} \quad (23.41)$$

Since the estimated physical parameters of the absorber (i.e., c_a , k_a , and m_a) are within the vicinity of the actual parameters, Δg and ΔT should be small quantities and the higher-order terms of Equation 23.41 can be neglected. Using Equation 23.40 and Equation 23.41 and neglecting higher-order terms, we have

$$\begin{aligned} \Delta g &= \text{Re}[G(j\omega)] \left[\frac{2Tc_a \omega^2 - k_a + k_a T^2 \omega^2}{\omega^2} \right] + \text{Im}[G(j\omega)] \left[\frac{c_a - T^2 \omega^2 c_a + 2k_a T}{\omega^2} \right], \\ \Delta T &= \text{Re}[G(j\omega)] \left[\frac{c_a - T^2 \omega^2 c_a + 2k_a T}{g \omega^2} \right] + \text{Im}[G(j\omega)] \left[\frac{k_a - 2Tc_a \omega^2 - k_a T^2 \omega^2}{g \omega^3} \right] + \frac{T}{g} \Delta g \end{aligned} \quad (23.42)$$

In the above expressions, g and T are the current compensator parameters given by Equation 23.35, c_a , k_a , and m_a are the estimated absorber parameters, ω is the absorber base excitation frequency, and $G(j\omega)$ is the transfer function obtained in real time. That is, the retuned control parameters, g and T , are determined as follows

$$g_{\text{new}} = g_{\text{current}} + \Delta g \quad \text{and} \quad T_{\text{new}} = T_{\text{current}} + \Delta T \quad (23.43)$$

where Δg and ΔT are those given by Equation 23.42. After compensator parameters, g and T , are adjusted by Equation 23.43, the process can be repeated until $|G(j\omega)|$ falls within the desired level of tolerance. $G(j\omega)$ can be determined in real time as shown in Liu et al. (1997) by

$$G(j\omega) = |G(j\omega)| e^{(j\phi(j\omega))} \quad (23.44)$$

where the magnitude and phase are determined assuming that the absorber and primary displacements are harmonic functions of time given by

$$x_a(t) = X_a \sin(\omega t + \phi_a), \quad x_1(t) = X_1 \sin(\omega t + \phi_1) \quad (23.45)$$

With the magnitudes and phase angles of Equation 23.44, the transfer function can be determined from Equation 23.44 and the following:

$$|G(j\omega)| = \frac{X_1}{X_a}, \quad \phi(j\omega) = \phi_1 - \phi_a$$

23.3.2.2.6 Numerical Simulations and Discussions

To illustrate the feasibility of the proposed absorption methodology, an example case study is presented. The ARA control law is the proportional compensator with a single time constant as given in Equation 23.34. The primary system is subjected to a harmonic excitation with unit amplitude and a frequency of 800 Hz. The ARA and primary system parameters are taken as those given in Table 23.2. The simulation was done using Matlab/Simulink® and the results for the primary system and the absorber displacements are given in Figure 23.21.

As seen, vibrations are completely suppressed in the primary subsection after approximately 0.05 sec, at which the absorber acts as a marginally stable resonator. For this case, all physical parameters are assumed to be known exactly. However, in practice these parameters are not known exactly and may vary with time, so the case with estimated system parameters must be considered.

To demonstrate the feasibility of the proposed autotuning method, the nominal system parameters (m_a , m_1 , k_a , k_1 , c_a , c_1) were fictitiously perturbed by 10% (i.e., representing the actual values) in the simulation. However, the nominal values of m_a , m_1 , k_a , k_1 , c_a , and c_1 were used for calculation of the compensator parameters, g and T . The results of the simulation using nominal parameters are given in Figure 23.22. From Figure 23.22, top, the effect of parameter variation is shown as steady-state oscillations of the primary structure. This undesirable response will undoubtedly be encountered when the experiment is implemented. Thus, an autotuning procedure is needed.

The result of the first autotuning iteration is given in Figure 23.22, middle, where the control parameters, g and T , are adjusted based on Equation 23.43. One can see tremendous improvement in the primary system response with only one iteration (see Figure 23.22, middle). A second iteration is

FIGURE 23.21 Primary system and absorber displacements subjected to 800 Hz harmonic disturbance.

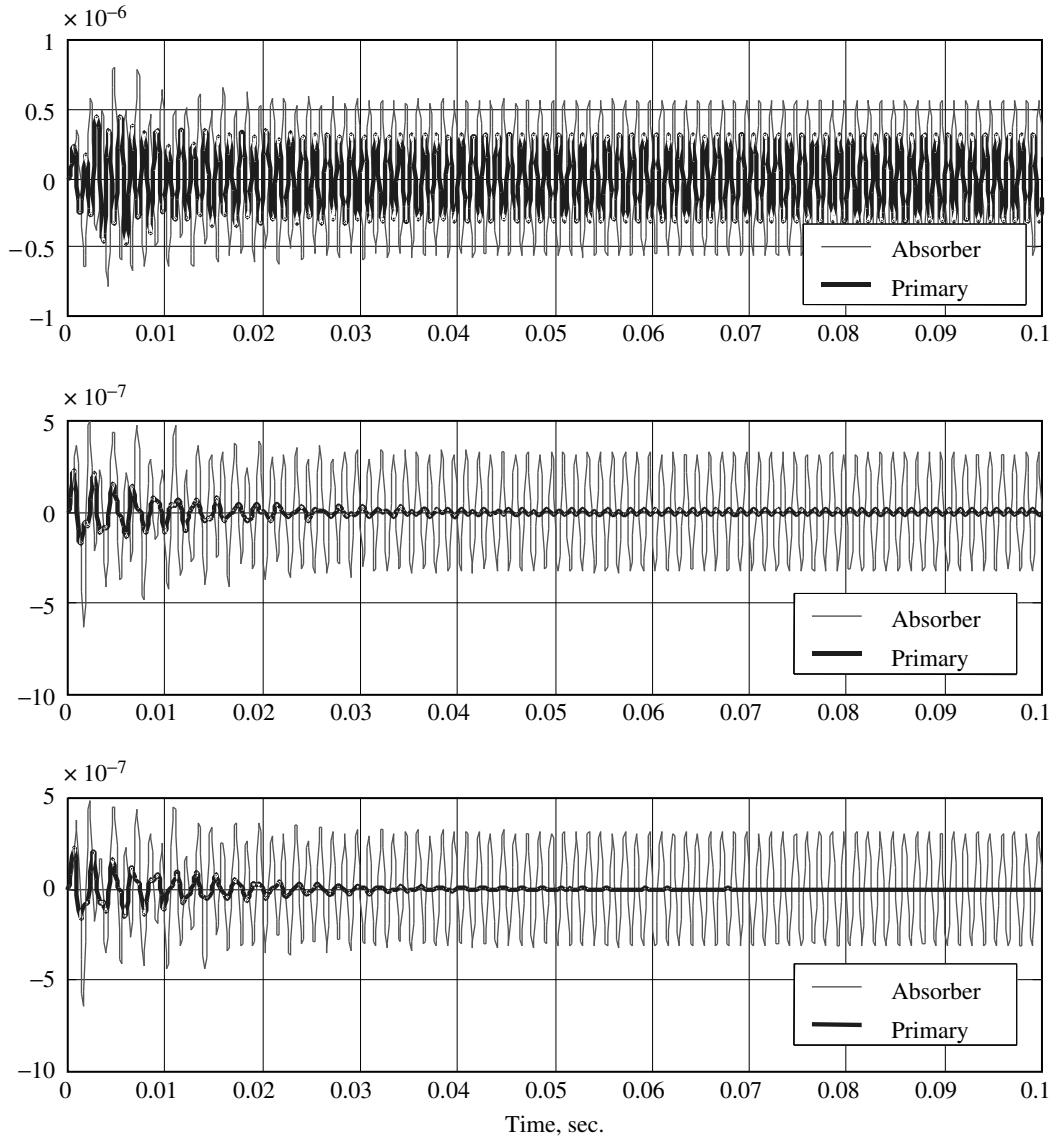

FIGURE 23.22 System responses (displacement, m) for (a) nominal absorber parameters; (b) after first autotuning procedure and (c) after second autotuning procedure.

performed, as shown in Figure 23.22, bottom. The response closely resembles that from Figure 23.21, where all system parameters are assumed to be known exactly.

23.3.3 Vibration-Control Systems

As discussed, in vibration-control schemes, the control inputs to the systems are altered in order to regulate or track a desired trajectory while simultaneously suppressing the vibrational transients in the system. This control problem is rather challenging since it must achieve the motion-tracking objectives while stabilizing the transient vibrations in the system. This section provides two recent control methods developed for the regulation and tracking of flexible beams. The experimental implementations are also discussed. The first control method is a single-input vibration-control system discussed in

Section 23.3.3.1, while the second application utilizes a secondary input control in addition to the primary control input to improve the vibrational characteristics of the system (see Section 23.3.3.2).

23.3.3.1 Variable Structure Control of Rotating Flexible Beams

The vibration-control problem of a flexible manipulator consists in achieving the motion-tracking objectives while stabilizing the transient vibrations in the arm. Several control methods have been developed for flexible arms (Skaar and Tucker, 1986; Bayo, 1987; Yuh, 1987; Sinha, 1988; Lou, 1993; Ge et al., 1997; de Querioz et al., 1999). Most of these methods concentrate on a model-based controller design, and some of these may not be easy to implement due to the uncertainties in the design model, large variations of the loads, ignored high frequency dynamics, and high order of the designed controllers. In view of these methods, VSC is particularly attractive due to its simplicity of implementation and its robustness to parameter uncertainties (Yeung and Chen, 1989; Singh et al., 1994; Jalili et al., 1997).

23.3.3.1.1 Mathematical Modeling

As shown in Figure 23.23, one end of the arm is free and the other end is rigidly attached to a vertical gear shaft, driven by a DC motor. A uniform cross section is considered for the arm, and we make the Euler–Bernoulli assumptions. The control torque, τ , acting on the output shaft, is normal to the plane of motion. Viscous frictions and the ever-present unmodeled dynamics of the motor compartment are to be compensated *via* a perturbation estimation process, as explained later in the text. Since the dynamic system considered here has been utilized in literature quite often, we present only the resulting partial differential equation (PDE) of the system and refer interested readers to Junkins and Kim (1993) and Luo et al. (1999) for detailed derivations.

The system is governed by

$$I_h \ddot{\theta}(t) + \rho \int_0^L x \ddot{z}(x, t) dx = \tau \quad (23.46)$$

$$\rho \ddot{z}(x, t) + EI z''''(x, t) = 0 \quad (23.47)$$

with the corresponding boundary conditions

$$z(0, t) = 0, \quad z'(0, t) = \theta(t), \quad z''(L, t) = 0, \quad z'''(L, t) = 0 \quad (23.48)$$

where ρ is the arm's linear mass density, L is the arm length, E is Young's modulus of elasticity, I is the cross-sectional moment of inertia, I_h is the equivalent mass moment of inertia at the root end of the arm, $I_t = I_h + \rho L^3/3$ is the total inertia, and the global variable z is defined as

$$z(x, t) = x\theta(t) + y(x, t) \quad (23.49)$$

Clearly, the arm vibration equation (Equation 23.47) is a homogeneous PDE but the boundary conditions (Equation 23.48) are nonhomogeneous. Therefore, the closed form solution is very tedious to obtain, if not impossible. Using the application of VSC, these equations and their associated boundary conditions can be converted to a homogeneous boundary value problem, as discussed next.

23.3.3.1.2 Variable Structure Controller

The controller objective is to track the arm angular displacement from an initial angle, $\theta_d = \theta(0)$, to zero position, $\theta(t \rightarrow \infty) = 0$, while minimizing the flexible arm oscillations. To achieve the control

FIGURE 23.23 Flexible arm in the horizontal plane and kinematics of deformation. (Source: From Jalili, N., *ASME J. Dyn. Syst. Meas. Control*, 123, 712–719, 2001. With permission.)

insensitivity against modeling uncertainties, the nonlinear control routine of sliding mode control with an additional perturbation estimation (SMCPE) compartment is adopted here (Elmali and Olgac, 1992; Jalili and Olgac, 1998a). The SMCPE method, presented in Elmali and Olgac (1992), has many attractive features, but it suffers from the disadvantages associated with the truncated-model-base controllers. On the other hand, the infinite-dimensional distributed (IDD)-base controller design, proposed in Zhu et al. (1997), has practical limitations due to its measurement requirements in addition to the complex control law.

Initiating from the idea of the IDD-base controller, we present a new controller design approach in which an online perturbation estimation mechanism is introduced and integrated with the controller to relax the measurement requirements and simplify the control implementation. As utilized in Zhu et al. (1997), for the tip-vibration suppression, it is further required that the sliding surface enable the transformation of nonhomogeneous boundary conditions (Equation 23.48) to homogeneous ones. To satisfy vibration suppression and robustness requirements simultaneously, the sliding hyperplane is selected as a combination of tracking (regulation) error and arm flexible vibration as

$$s = \dot{w} + \sigma w \quad (23.50)$$

where $\sigma > 0$ is a control parameter and

$$w = \theta(t) + \frac{\mu}{L} z(L, t) \quad (23.51)$$

with the scalar, μ , being selected later. When $\mu = 0$, controller (Equation 23.50) reduces to a sliding variable for rigid-link manipulators (Jalili and Olgac, 1998a; Yeung and Chen, 1988). The motivation for such sliding a variable is to provide a suitable boundary condition for solving the beam Equation 23.47, as will be discussed next and is detailed in Jalili (2001).

For the system described by Equation 23.46 to Equation 23.48, if the variable structure controller is given by

$$\tau = \psi_{\text{est}} + \frac{I_t}{1 + \mu} \left(-k \operatorname{sgn}(s) - Ps - \frac{\mu}{L} \ddot{y}(L, t) - \sigma(1 + \mu) \dot{\theta} - \frac{\sigma\mu}{L} \dot{y}(L, t) \right) \quad (23.52)$$

where ψ_{est} is an estimate of the beam flexibility effect

$$\psi = \rho \int_0^L x \ddot{y}(x, t) dx \quad (23.53)$$

k and P are positive scalars $k \geq 1 + \mu/I_t |\psi - \psi_{\text{est}}|$, $-1.2 < \mu < -0.45$, $\mu \neq -1$ and $\operatorname{sgn}(\cdot)$ represents the standard signum function, then, the system's motion will first reach the sliding mode $s = 0$ in a finite time, and consequently converge to the equilibrium position $w(x, t) = 0$ exponentially with a time-constant $1/\sigma$ (Jalili, 2001).

23.3.3.1.3 Controller Implementation

In the preceding section, it was shown that by properly selecting control variable, μ , the motion exponentially converges to $w = 0$ with a time-constant $1/\sigma$, while the arm stops in a finite time. Although the discontinuous nature of the controller introduces a robustifying mechanism, we have made the scheme more insensitive to parametric variations and unmodeled dynamics by reducing the required measurements and hence easier control implementation. The remaining measurements and ever-present modeling imperfection effects have all been estimated through an online estimation process. As stated before, in order to simplify the control implementation and reduce the measurement effort, the effect of all uncertainties, including flexibility effect ($\int_0^L x \ddot{y}(x, t) dx$) and the ever-present unmodeled dynamics, is gathered into a single quantity named perturbation, ψ , as given by Equation 23.53. Noting Equation 23.46, the perturbation term can be expressed as

$$\psi = \tau - I_t \ddot{\theta}(t) \quad (23.54)$$

which requires the yet-unknown control feedback τ . In order to resolve this dilemma of causality, the current value of control torque, τ , is replaced by the most recent control, $\tau(t - \delta)$, where δ is the small time-step used for the loop closure. This replacement is justifiable in practice since such an algorithm is implemented on a digital computer and the sampling speed is high enough to claim this. Also, in the absence of measurement noise, $\ddot{\theta}(t) \cong \ddot{\theta}_{\text{cal}}(t) = [\dot{\theta}(t) - \dot{\theta}(t - \delta)]/\delta$.

In practice and in the presence of measurement noise, appropriate filtering may be considered and combined with these approximate derivatives. This technique is referred to as “switched derivatives”. This backward differences are shown to be effective when δ is selected to be small enough and the controller is run on a fast DSP (Cannon and Schmitz, 1984). Also, $\ddot{y}(L, t)$ can be obtained by attaching an accelerometer at arm-tip position. All the required signals are, therefore, measurable by currently available sensor facilities and the controller is thus realizable in practice. Although these signals may be quite inaccurate, it should be pointed out that the signals, either measurements or estimations, need not be known very accurately, since robust sliding control can be achieved if k is chosen to be large enough to cover the error existing in the measurement/signal estimation (Yeung and Chen, 1989).

23.3.3.1.4 Numerical Simulations

In order to show the effectiveness of the proposed controller, a lightweight flexible arm is considered ($h \gg b$ in Figure 23.23). For numerical results, we consider $\theta_a = \theta(0) = \pi/2$ for the initial arm base angle, with zero initial conditions for the rest of the state variables. The system parameters are listed in Table 23.3. Utilizing assumed mode model (AMM), the arm vibration, Equation 23.47, is truncated to three modes and used in the simulations. It should be noted that the controller law, Equation 23.52, is based on the original infinite dimensional equation, and this truncation is utilized only for simulation purposes.

We take the controller parameter $\mu = -0.66$, $P = 7.0$, $k = 5$, $\varepsilon = 0.01$ and $\sigma = 0.8$. In practice, σ is selected for maximum tracking accuracy taking into account unmodeled dynamics and actuator hardware limitations (Moura et al., 1997). Although such restrictions do not exist in simulations (i.e., with ideal actuators, high sampling frequencies and perfect measurements), this selection of σ was decided based on actual experiment conditions.

The sampling rate for the simulations is $\delta = 0.0005$ sec, while data are recorded at the rate of only 0.002 sec for plotting purposes. The system responses to the proposed control scheme are shown in Figure 23.24. The arm-base angular position reaches the desired position, $\theta = 0$, in approximately 4 to 5 sec, which is in agreement with the approximate settling time of $t_s = 4/\sigma$ (Figure 23.24a). As soon as the system reaches the sliding mode layer, $|\dot{s}| < \varepsilon$ (Figure 23.24d), the tip vibrations stop (Figure 23.24b), which demonstrates the feasibility of the proposed control technique. The control torque exhibits some residual vibration, as shown in Figure 23.24c. This residual oscillation is expected since the system

motion is not forced to stay on $s = 0$ surface (instead it is forced to stay on $|s| < \varepsilon$) when saturation function is used. The sliding variable s is also depicted in Figure 23.24d. To demonstrate better the feature of the controller, the system responses are displayed when $\mu = 0$ (Figure 23.25). As discussed, $\mu = 0$ corresponds to the sliding variable for the rigid link. The undesirable oscillations at the arm tip are evident (see Figure 23.25b and c).

23.3.3.1.5 Control Experiments

In order to demonstrate better the effectiveness of the controller, an experimental setup is constructed and used to verify the numerical results and concepts discussed in the preceding sections. The experimental setup is shown in Figure 23.26. The arm is a slender beam made of stainless steel, with the same dimensions as used in the simulations. The experimental setup parameters are listed in Table 23.3. One end of the arm is clamped to a solid clamping fixture, which is driven by a high-quality DC servomotor. The motor drives a built-in gearbox ($N = 14:1$) whose output drives an antibacklash gear. The antibacklash gear, which is equipped with a precision encoder, is utilized to measure the arm base angle as well as to eliminate the backlash. For tip deflection, a light source is attached to the tip of the arm, which is detected by a camera mounted on the rotating base.

The DC motor can be modeled as a standard armature circuit; that is, the applied voltage, v , to the DC motor is

$$v = R_a i_a + L_a \frac{di_a}{dt} + K_b \dot{\theta}_m \quad (23.55)$$

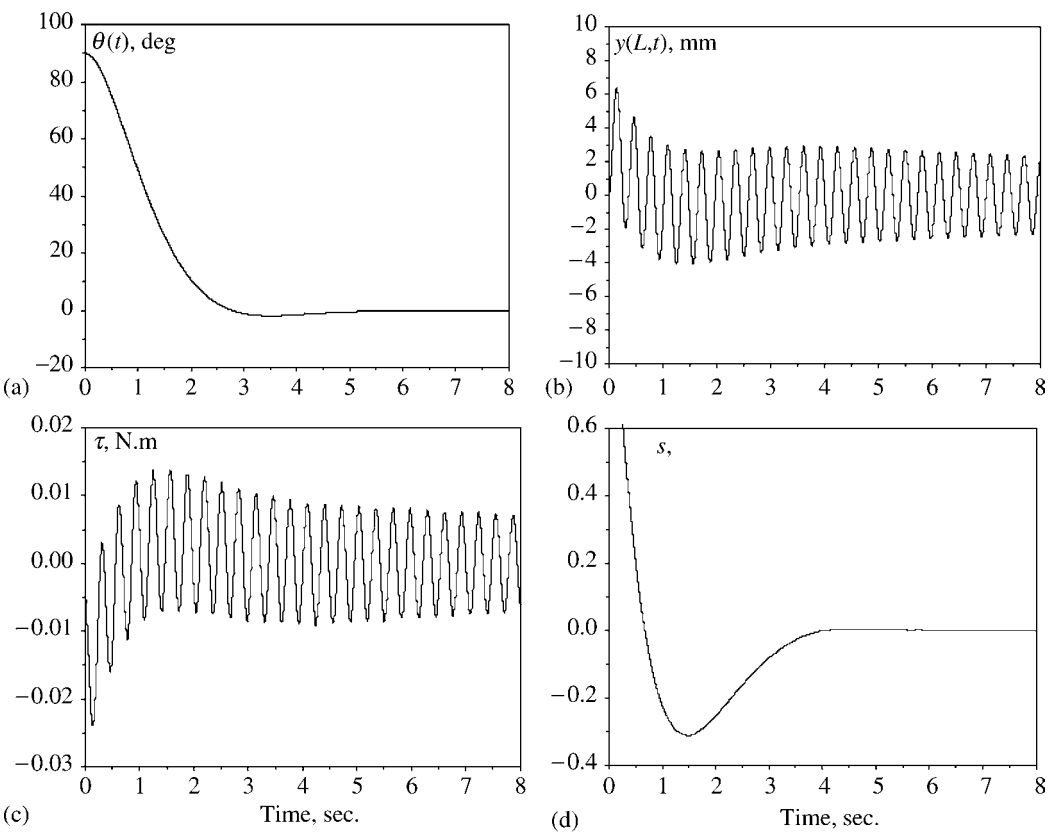

FIGURE 23.25 Analytical system responses to controller without inclusion of arm flexibility, that is, $\mu = 0$: (a) arm angular position; (b) arm-tip deflection; (c) control torque and (d) sliding variable sec. (Source: From Jalili, N., *ASME J. Dyn. Syst. Meas. Control*, 123, 712–719, 2001. With permission.)

FIGURE 23.26 The experimental device and setup configuration. (Source: From Jalili, N., *ASME J. Dyn. Syst. Meas. Control*, 123, 712–719, 2001. With permission.)

where R_a is the armature resistance, L_a is the armature inductance, i_a is the armature current, K_b is the back-EMF (electro-motive-force) constant, and θ_m is the motor shaft position. The motor torque, τ_m from the motor shaft with the torque constant, K_t , can be written as

$$\tau_m = K_t i_a \quad (23.56)$$

The motor dynamics thus become

$$I_e \ddot{\theta}_m + C_v \dot{\theta}_m + \tau_a = \tau_m = K_t i_a \quad (23.57)$$

where C_v is the equivalent damping constant of the motor, and $I_e = I_m + I_L/N^2$ is the equivalent inertia load including motor inertia, I_m , and gearbox, clamping frame and camera inertia, I_L . The available torque from the motor shaft for the arm is τ_a .

Utilizing the gearbox from the motor shaft to the output shaft and ignoring the motor electric time constant, (L_a/R_a) , one can relate the servomotor input voltage to the applied torque (acting on the arm) as

$$\tau = \frac{NK_t}{R_a} v - \left(C_v + \frac{K_t K_b}{R_a} \right) N^2 \dot{\theta} - I_h \ddot{\theta} \quad (23.58)$$

where $I_h = N^2 I_e$ is the equivalent inertia of the arm base used in the derivation of governing equations. By substituting this torque into the control law, the reference input voltage, V , is obtained for experiment.

The control torque is applied *via* a digital signal processor (DSP) with sampling rate of 10 kHz, while data are recorded at the rate 500 Hz (for plotting purposes only). The DSP runs the control routine in a single-input–single-output mode as a free standing CPU. Most of the computations and hardware commands are done on the DSP card. For this setup, a dedicated 500 MHz Pentium III serves as the host PC, and a state-of-the-art dSPACE® DS1103 PPC controller board equipped with a Motorola Power PC 604e at 333 MHz, 16 channels ADC, 12 channels DAC, as microprocessor.

The experimental system responses are shown in Figure 23.27 and Figure 23.28 for similar cases discussed in the numerical simulation section. Figure 23.27 represents the system responses when controller (Equation 23.52) utilizes the flexible arm (i.e., $\mu = -0.66$). As seen, the arm base reaches the desired position (Figure 23.27a), while tip deflection is simultaneously stopped (Figure 23.27b). The good correspondence between analytical results (Figure 23.24) and experimental findings (Figure 23.27) is noticeable from a vibration suppression characteristics point of view. It should be noted that the controller is based on the original governing equations, with arm-base angular position and tip deflection measurements only. The unmodeled dynamics, such as payload effect (owing to the light source at the tip, see Table 23.3) and viscous friction (at the root end of the arm), are being compensated through the proposed online perturbation estimation routine. This, in turn, demonstrates the capability of the proposed control scheme when considerable deviations between model and plant are encountered. The only noticeable difference is the fast decaying response as shown in Figure 27b and c. This clearly indicates the high friction at the motor, which was not considered in the simulations (Figure 24b and c). Similar responses are obtained when the controller is designed based on the rigid link only, that is, $\mu = 0$. The system responses are displayed in Figure 23.28. Similarly, the undesirable arm-tip oscillations are obvious. The overall agreement between simulations (Figure 24 and Figure 25) and the experiment (Figure 27 and Figure 28) is one of the critical contributions of this work.

23.3.3.2 Observer-Based Piezoelectric Vibration Control of Translating Flexible Beams

Many industrial robots, especially those widely used in automatic manufacturing assembly lines, are Cartesian types (Ge et al., 1998). A flexible Cartesian robot can be modeled as a flexible cantilever beam with a translational base support. Traditionally, a PD control strategy is used to regulate the movement of the robot arm. In lightweight robots, the base movement will cause undesirable vibrations at the arm tip because of the flexibility distributed along the arm. In order to eliminate

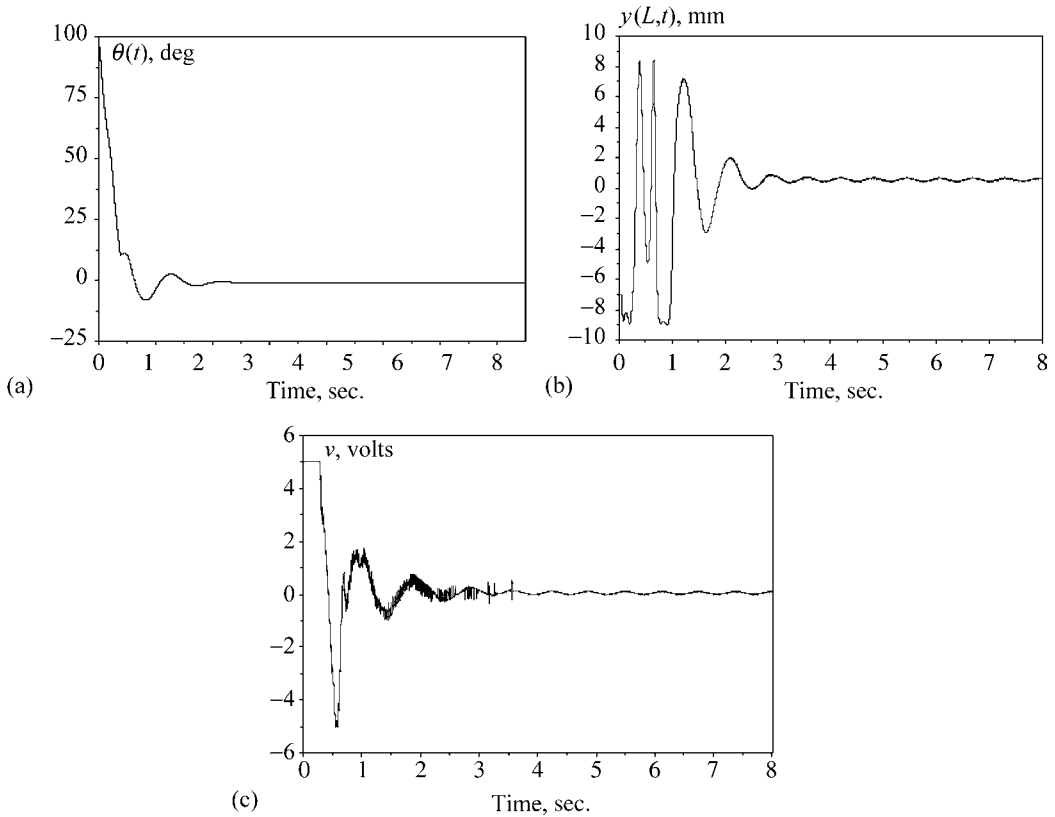

FIGURE 23.27 Experimental system responses to controller with inclusion of arm flexibility, that is, $\mu = -0.66$: (a) arm angular position; (b) arm-tip deflection; (c) control voltage applied to DC servomotor. (Source: From Jalili, N., *ASME J. Dyn. Syst. Meas. Control*, 123, 712–719, 2001. With permission.)

such vibrations, the PD controller must be upgraded with additional compensating terms. In order to improve further the vibration suppression performance, which is a requirement for the high-precision manufacturing market, a second controller, such as a piezoelectric (PZT) patch actuator attached on the surface of the arm, can be utilized (Oueini et al., 1998; Ge et al., 1999; Jalili et al., 2002).

In this section, an observer-based control strategy is presented for regulating the arm motion (Liu et al., 2002). The base motion is controlled utilizing an electrodynamic shaker, while a piezoelectric (PZT) patch actuator is bonded on the surface of the flexible beam for suppressing residual arm vibrations. The control objective here is to regulate the arm base movement, while simultaneously suppressing the vibration transients in the arm. To achieve this, a simple PD control strategy is selected for the regulation of the movement of the base, and a Lyapunov-based controller is selected for the PZT voltage signal. The selection of the proposed energy-based Lyapunov function naturally results in velocity-related signals, which are not physically measurable (Dadfarnia et al., 2003). To remedy this, a reduced-order observer is designed to estimate the velocity related signals. For this, the control structure is designed based on the truncated two-mode beam model.

23.3.3.2.1 Mathematical Modeling

For the purpose of model development, we consider a uniform flexible cantilever beam with a PZT actuator bonded on its top surface. As shown in Figure 23.29, one end of the beam is clamped into

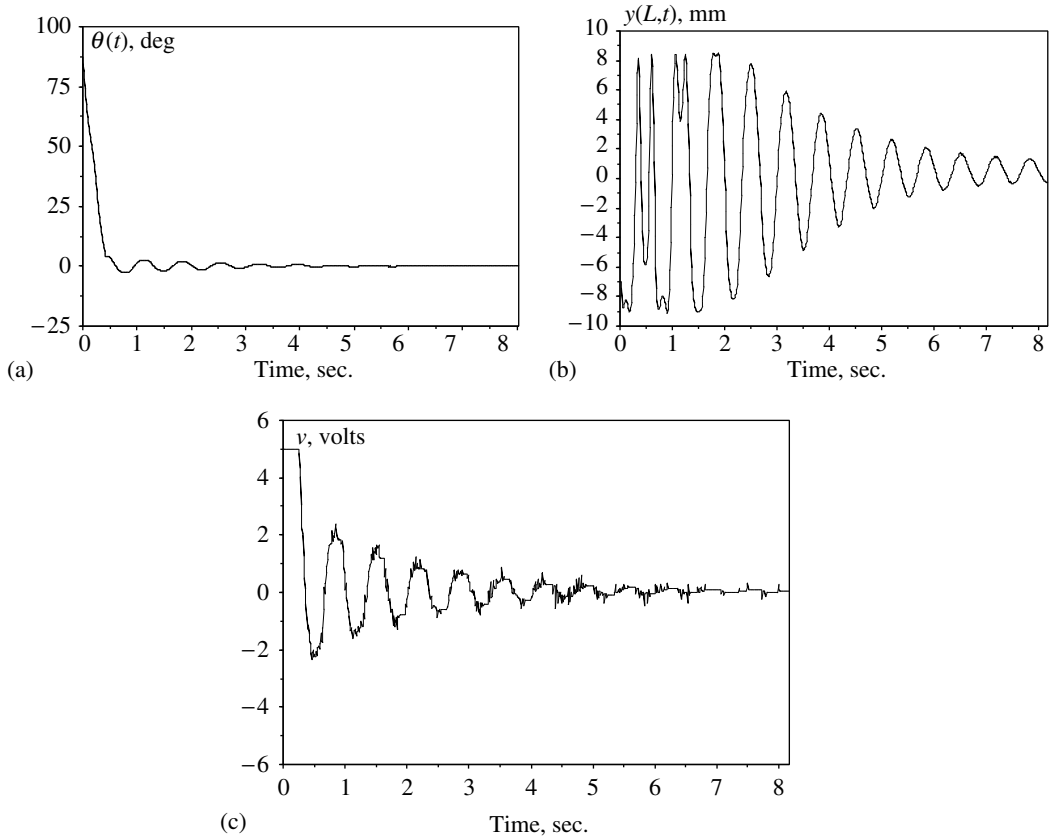

FIGURE 23.28 Experimental system responses to controller without inclusion of arm flexibility, that is, $\mu = 0$: (a) arm angular position; (b) arm-tip deflection; (c) control voltage applied to DC servomotor. (Source: From Jalili, N., *ASME J. Dyn. Syst. Meas. Control*, 123, 712–719, 2001. With permission.)

a moving base with the mass of m_b , and a tip mass, m_t , is attached to the free end of the beam. The beam has total thickness t_b , and length L , while the piezoelectric film possesses thickness and length t_p and $(l_2 - l_1)$, respectively. We assume that the PZT and the beam have the same width, b . The PZT actuator is perfectly bonded on the beam at distance l_1 measured from the beam support. The force, $f(t)$, acting on the base and the input voltage, $v(t)$, applied to the PZT actuator are the only external effects.

To establish a coordinate system for the beam, the x -axis is taken in the longitudinal direction and the z -axis is specified in the transverse direction of the beam with midplane of the beam to be $z = 0$, as shown in Figure 23.30. This coordinate is fixed to the base.

The fundamental relations for the piezoelectric materials are given as (Ikeda, 1990)

$$\mathbf{F} = \mathbf{c}\mathbf{S} - \mathbf{h}\mathbf{D} \quad (23.59)$$

$$\mathbf{E} = -\mathbf{h}^T\mathbf{S} + \boldsymbol{\beta}\mathbf{D} \quad (23.60)$$

where $\mathbf{F} \in \mathcal{R}^6$ is the stress vector, $\mathbf{S} \in \mathcal{R}^6$ is the strain vector, $\mathbf{c} \in \mathcal{R}^{6 \times 6}$ is the symmetric matrix of elastic stiffness coefficients, $\mathbf{h} \in \mathcal{R}^{6 \times 3}$ is the coupling coefficients matrix, $\mathbf{D} \in \mathcal{R}^3$ is the electrical displacement vector, $\mathbf{E} \in \mathcal{R}^3$ is the electrical field vector, and $\boldsymbol{\beta} \in \mathcal{R}^{3 \times 3}$ is the symmetric matrix of impermeability coefficients.

An energy method is used to derive the equations of motion. Neglecting the electrical kinetic energy, the total kinetic energy of the system is expressed as (Liu et al., 2002; Dadfarnia et al., 2004)

$$\begin{aligned}
 E_k &= \frac{1}{2} m_b \dot{s}(t)^2 + \frac{1}{2} b \int_0^{l_1} \rho_b t_b (\dot{s}(t) + \dot{w}(x, t))^2 dx \\
 &+ \frac{1}{2} b \int_{l_1}^{l_2} (\rho_b t_b + \rho_p t_p) (\dot{s}(t) + \dot{w}(x, t))^2 dx \\
 &+ \frac{1}{2} b \int_{l_2}^L \rho_b t_b (\dot{s}(t) + \dot{w}(x, t))^2 dx \\
 &+ \frac{1}{2} m_t (\dot{s}(t) + \dot{w}(L, t))^2 \\
 &= \frac{1}{2} m_b \dot{s}(t)^2 + \frac{1}{2} \int_0^L \rho(x) (\dot{s}(t) + \dot{w}(x, t))^2 dx \\
 &+ \frac{1}{2} m_t (\dot{s}(t) + \dot{w}(L, t))^2 \quad (23.61)
 \end{aligned}$$

where

$$\begin{aligned}
 \rho(x) &= [\rho_b t_b + G(x) \rho_p t_p] b \\
 G(x) &= H(x - l_1) - H(x - l_2) \quad (23.62)
 \end{aligned}$$

and $H(x)$ is the Heaviside function, ρ_b and ρ_p are the respective beam and PZT volumetric densities. Neglecting the effect of gravity due to planar motion and the higher-order terms of quadratic in w' (Esmailzadeh and Jalili, 1998b), the total potential energy of the system can be expressed as

$$\begin{aligned}
 E_p &= \frac{1}{2} b \int_0^{l_1} \int_{-t_b/2}^{t_b/2} \mathbf{F}^T \mathbf{S} dy dx + \frac{1}{2} b \int_{l_1}^{l_2} \int_{-t_b/2}^{t_b/2} \mathbf{F}^T \mathbf{S} dy dx + \frac{1}{2} b \int_{l_1}^{l_2} \int_{t_b/2}^{(t_b/2)+t_p} [\mathbf{F}^T \mathbf{S} + \mathbf{E}^T \mathbf{D}] dy dx \\
 &+ \frac{1}{2} b \int_{l_2}^L \int_{-t_b/2}^{t_b/2} \mathbf{F}^T \mathbf{S} dy dx \\
 &= \frac{1}{2} \int_0^L c(x) \left[\frac{\partial^2 w(x, t)}{\partial x^2} \right]^2 dx + h_l D_y(t) \int_{l_1}^{l_2} \frac{\partial^2 w(x, t)}{\partial x^2} dx + \frac{1}{2} \beta_l (l_2 - l_1) D_y(t)^2 \quad (23.63)
 \end{aligned}$$

FIGURE 23.30 Coordinate system.

FIGURE 23.29 Schematic of the SCARA/Cartesian robot (last link).

where

$$c(x) = \frac{b}{3} \left\{ \left(\frac{c_{11}^b t_b^3}{4} \right) + G(x) \left\{ 3c_{11}^b t_b z_n^2 + c_{11}^p \left(t_p^3 + 3t_p \left(\frac{t_b}{2} - z_n \right)^2 + 3t_p^2 \left(\frac{t_b}{2} - z_n \right) \right) \right\} \right\} \quad (23.64)$$

$$h_l = h_{12} t_p b (t_p + t_b - 2z_n)/2, \quad \beta_l = \beta_{22} b t_p$$

and

$$z_n = \frac{c_{11}^p t_p (t_p + t_b)}{c_{11}^b t_b + c_{11}^p t_p}$$

The beam and PZT stiffnesses are c_{11}^b and c_{11}^p , respectively.

Using the AMM for the beam vibration analysis, the beam deflection can be written as

$$w(x, t) = \sum_{i=1}^{\infty} \phi_i(x) q_i(t), \quad P(x, t) = s(t) + w(x, t) \quad (23.65)$$

The equations of motion can now be obtained using the Lagrangian approach

$$\left[m_b + m_t + \int_0^L \rho(x) dx \right] \ddot{s}(t) + \sum_{j=1}^{\infty} m_j \ddot{q}_j(t) = f(t) \quad (23.66a)$$

$$m_i \ddot{s}(t) + m_{di} \ddot{q}_i(t) + \omega_i^2 m_{di} q_i(t) + h_l (\phi_i'(l_2) - \phi_i'(l_1)) D_y(t) = 0 \quad (23.66b)$$

$$h_l \sum_{j=1}^{\infty} \{ (\phi_j'(l_2) - \phi_j'(l_1)) q_j(t) \} + \beta_l (l_2 - l_1) D_y(t) = b(l_2 - l_1) v(t) \quad (23.66c)$$

where

$$m_{dj} = \int_0^L \rho(x) \phi_j^2(x) dx + m_t \phi_j^2(L), \quad m_j = \int_0^L \rho(x) \phi_j(x) dx + m_t \phi_j(L) \quad (23.67)$$

Calculating $D_y(t)$ from Equation 23.66b and substituting into Equation 23.66c results in

$$\begin{aligned} m_i \ddot{s}(t) + m_{di} \ddot{q}_i(t) + \omega_i^2 m_{di} q_i(t) - \frac{h_l^2 (\phi_i'(l_2) - \phi_i'(l_1))}{\beta_l (l_2 - l_1)} \sum_{j=1}^{\infty} \{ (\phi_j'(l_2) - \phi_j'(l_1)) q_j(t) \} \\ = - \frac{h_l b (\phi_i'(l_2) - \phi_i'(l_1))}{\beta_l} v(t), \quad i = 1, 2, \dots \end{aligned} \quad (23.68)$$

which will be used to derive the controller, as discussed next.

23.3.3.2.2 Derivation of the Controller

Utilizing Equation 23.66a and Equation 23.68, the truncated two-mode beam with PZT model reduces to

$$\left[m_b + m_t + \int_0^L \rho(x) dx \right] \ddot{s}(t) + m_1 \ddot{q}_1(t) + m_2 \ddot{q}_2(t) = f(t) \quad (23.69a)$$

$$\begin{aligned} m_1 \ddot{s}(t) + m_{d1} \ddot{q}_1(t) + \omega_1^2 m_{d1} q_1(t) - \frac{h_l^2 (\phi_1'(l_2) - \phi_1'(l_1))}{\beta_l (l_2 - l_1)} \\ \times \{ (\phi_1'(l_2) - \phi_1'(l_1)) q_1(t) + (\phi_2'(l_2) - \phi_2'(l_1)) q_2(t) \} \\ = - \frac{h_l b (\phi_1'(l_2) - \phi_1'(l_1))}{\beta_l} v(t) \end{aligned} \quad (23.69b)$$

$$\begin{aligned}
& m_2 \ddot{s}(t) + m_{d2} \ddot{q}_2(t) + \omega_2^2 m_{d2} q_2(t) - \frac{h_l^2 (\phi_2'(l_2) - \phi_2'(l_1))}{\beta_l (l_2 - l_1)} \\
& \quad \times \{(\phi_1'(l_2) - \phi_1'(l_1)) q_1(t) + (\phi_2'(l_2) - \phi_2'(l_1)) q_2(t)\} \\
& = - \frac{h_l b (\phi_2'(l_2) - \phi_2'(l_1))}{\beta_l} v(t)
\end{aligned} \tag{23.69c}$$

The equations in Equation 23.69 can be written in the following more compact form

$$\mathbf{M} \ddot{\Delta} + \mathbf{K} \Delta = \mathbf{F}_e \tag{23.70}$$

where

$$\mathbf{M} = \begin{bmatrix} \psi & m_1 & m_2 \\ m_1 & m_{d1} & 0 \\ m_2 & 0 & m_{d2} \end{bmatrix}, \quad \mathbf{K} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & k_{11} & k_{12} \\ 0 & k_{12} & k_{22} \end{bmatrix}, \quad \mathbf{F}_e = \begin{Bmatrix} f(t) \\ \epsilon_1 v(t) \\ \epsilon_2 v(t) \end{Bmatrix}, \quad \Delta = \begin{Bmatrix} s(t) \\ q_1(t) \\ q_2(t) \end{Bmatrix} \tag{23.71}$$

and

$$\begin{aligned}
\psi &= m_b + m_t + \int_0^L \rho(x) dx, \quad \epsilon_1 = -\frac{h_l b}{\beta_l} (\phi_1'(l_2) - \phi_1'(l_1)), \quad \epsilon_2 = -\frac{h_l b}{\beta_l} (\phi_2'(l_2) - \phi_2'(l_1)), \\
k_{11} &= \omega_1^2 m_{d1} - \frac{h_l^2}{\beta_l (l_2 - l_1)} (\phi_1'(l_2) - \phi_1'(l_1))^2, \\
k_{12} &= -\frac{h_l^2}{\beta_l (l_2 - l_1)} (\phi_1'(l_2) - \phi_1'(l_1)) (\phi_2'(l_2) - \phi_2'(l_1)), \\
k_{22} &= \omega_2^2 m_{d2} - \frac{h_l^2}{\beta_l (l_2 - l_1)} (\phi_2'(l_2) - \phi_2'(l_1))^2
\end{aligned} \tag{23.72}$$

For the system described by Equation 23.70, if the control laws for the arm base force and PZT voltage generated moment are selected as

$$f(t) = -k_p \Delta s - k_d \dot{s}(t) \tag{23.73}$$

$$v(t) = -k_v (\epsilon_1 \dot{q}_1(t) + \epsilon_2 \dot{q}_2(t)) \tag{23.74}$$

where k_p and k_d are positive control gains, $\Delta s = s(t) - s_d$, s_d is the desired set-point position, and $k_v > 0$ is the voltage control gain, then the closed-loop system will be stable, and in addition

$$\lim_{t \rightarrow \infty} \{q_1(t), q_2(t), \Delta s\} = 0$$

See Dadfarnia et al. (2004) for a detailed proof.

23.3.3.2.3 Controller Implementation

The control input, $v(t)$, requires the information from the velocity-related signals, $\dot{q}_1(t)$ and $\dot{q}_2(t)$, which are usually not measurable. Sun and Mills (1999) solved the problem by integrating the acceleration signals measured by the accelerometers. However, such controller structure may result in unstable closed-loop system in some cases. In this paper, a reduced-order observer is designed to estimate the velocity signals, \dot{q}_1 and \dot{q}_2 . For this, we utilize three available signals: base displacement, $s(t)$, arm-tip deflection, $P(L, t)$, and beam root strain, $\epsilon(0, t)$; that is

$$y_1 = s(t) = x_1 \tag{23.75a}$$

$$y_2 = P(L, t) = x_1 + \phi_1(L) x_2 + \phi_2(L) x_3 \tag{23.75b}$$

$$y_3 = \epsilon(0, t) = \frac{t_b}{2} (\phi_1''(0) x_2 + \phi_2''(0) x_3) \tag{23.75c}$$

It can be seen that the first three states can be obtained by

$$\begin{Bmatrix} x_1 \\ x_2 \\ x_3 \end{Bmatrix} = \mathbf{C}_1^{-1} \mathbf{y} \quad (23.76)$$

Since this system is observable, we can design a reduced-order observer to estimate the velocity-related state signals. Defining $\mathbf{X}_1 = [x_1 \ x_2 \ x_3]^T$ and $\mathbf{X}_2 = [x_4 \ x_5 \ x_6]^T$, the estimated value for \mathbf{X}_2 can be designed as

$$\hat{\mathbf{X}}_2 = \mathbf{L}_r \mathbf{y} + \hat{\mathbf{z}} \quad (23.77)$$

$$\dot{\hat{\mathbf{z}}} = \mathbf{F}\hat{\mathbf{z}} + \mathbf{G}\mathbf{y} + \mathbf{H}\mathbf{u} \quad (23.78)$$

where $\mathbf{L}_r \in R^{3 \times 3}$, $\mathbf{F} \in R^{3 \times 3}$, $\mathbf{G} \in R^{3 \times 3}$, and $\mathbf{H} \in R^{3 \times 2}$ will be determined by the observer pole placement. Defining the estimation error as

$$\mathbf{e}_2 = \mathbf{X}_2 - \hat{\mathbf{X}}_2 \quad (23.79)$$

the derivative of the estimation error becomes

$$\dot{\mathbf{e}}_2 = \dot{\mathbf{X}}_2 - \dot{\hat{\mathbf{X}}}_2 \quad (23.80)$$

Substituting the state-space equations of the system (Equation 23.77 and Equation 23.78) into Equation 23.80 and simplifying, we obtain

$$\dot{\mathbf{e}}_2 = \mathbf{F}\mathbf{e}_2 + (\mathbf{A}_{21} - \mathbf{L}_r \mathbf{C}_1 \mathbf{A}_{11} - \mathbf{G}\mathbf{C}_1 + \mathbf{F}\mathbf{L}_r \mathbf{C}_1) \mathbf{X}_1 + (\mathbf{A}_{22} - \mathbf{L}_r \mathbf{C}_1 \mathbf{A}_{12} - \mathbf{F}) \mathbf{X}_2 + (\mathbf{B}_2 - \mathbf{L}_r \mathbf{C}_1 \mathbf{B}_1 - \mathbf{H}) \mathbf{u} \quad (23.81)$$

In order to force the estimation error, \mathbf{e}_2 , to go to zero, matrix \mathbf{F} should be selected to be Hurwitz and the following relations must be satisfied (Liu et al., 2002):

$$\mathbf{F} = \mathbf{A}_{22} - \mathbf{L}_r \mathbf{C}_1 \mathbf{A}_{12} \quad (23.82)$$

$$\mathbf{H} = \mathbf{B}_2 - \mathbf{L}_r \mathbf{C}_1 \mathbf{B}_1 \quad (23.83)$$

$$\mathbf{G} = (\mathbf{A}_{21} - \mathbf{L}_r \mathbf{C}_1 \mathbf{A}_{11} + \mathbf{F}\mathbf{L}_r \mathbf{C}_1) \mathbf{C}_1^{-1} \quad (23.84)$$

The matrix \mathbf{F} can be chosen by the desired observer pole placement requirement. Once \mathbf{F} is known, \mathbf{L}_r , \mathbf{H} , and \mathbf{G} can be determined utilizing Equation 23.82, to Equation 23.84, respectively. The velocity variables, $\hat{\mathbf{X}}_2$, can now be estimated by Equation 23.77 and Equation 23.78.

23.3.3.2.4 Numerical Simulations

In order to show the effectiveness of the controller, the flexible beam structure in Figure 23.29 is considered with the PZT actuator attached on the beam surface. The system parameters are listed in Table 23.4.

First, we consider the beam without PZT control. We take the PD control gains to be $k_p = 120$ and $k_d = 20$. Figure 23.31 shows the results for the beam without PZT control (i.e., with only PD force control for the base movement). To investigate the effect of PZT controller on the beam vibration, we consider the voltage control gain to be $k_v = 2 \times 10^7$. The system responses to the proposed controller with a piezoelectric actuator based on the two-mode model are shown in Figure 23.32. The comparison between the tip displacement, from Figure 31 and Figure 32, shows that the beam vibration can be suppressed significantly utilizing the PZT actuator.

23.3.3.2.5 Control Experiments

In order to demonstrate better the effectiveness of the controller, an experimental setup is constructed and used to verify the numerical results. The experimental apparatus consists of a flexible beam with a PZT actuator and strain sensor attachments, as well as data acquisition,

TABLE 23.4 System Parameters Used in Numerical Simulations and Experimental Setup for Translational Beam

Properties	Symbol	Value	Unit
Beam Young's modulus	c_{11}^b	69×10^9	N/m ²
Beam thickness	t_b	0.8125	mm
Beam and PZT width	b	20	mm
Beam length	L	300	mm
Beam volumetric density	ρ_b	3960.0	kg/m ³

Tip mass	m_t	0	kg

FIGURE 23.31 Numerical simulations for the case without PZT control: (a) base motion; (b) tip displacement; (c) control force and (d) PZT voltage.

amplifier, signal conditioner and the control software. As shown in [Figure 23.33](#), the plant consists of a flexible aluminum beam with a strain sensor and a PZT patch actuator bound on each side of the beam surface. One end of the beam is clamped to the base with a solid clamping fixture, which is driven by a shaker. The shaker is connected to the arm base by a connecting rod. The experimental setup parameters are listed in [Table 23.4](#).

[Figure 23.34](#) shows the high-level control block diagram of the experiment, where the shaker provides the input control force to the base and the PZT applies a controlled moment on the beam. Two laser sensors measure the position of the base and the beam-tip displacement. A strain-gauge sensor, which is attached near the base of the beam, is utilized for the dynamic strain measurement. These three signals

FIGURE 23.32 Numerical simulations for the case with PZT control: (a) base motion; (b) tip displacement; (c) control force and (d) PZT voltage.

are fed back to the computer through the ISA MultiQ data acquisition card. The remaining required signals for the controller (Equation 23.66) are determined as explained in the preceding section. The data acquisition and control algorithms are implemented on an AMD Athlon 1100 MHz PC running under the RT-Linux operating system. The Matlab/Simulink environment and Real Time Linux Target are used to implement the controller.

The experimental results for both cases (i.e., without PZT and with PZT control) are depicted in Figure 35 and Figure 36, respectively. The results demonstrate that with PZT control, the arm vibration is eliminated in less than 1 sec, while the arm vibration lasts for more than 6 sec when PZT control is not used. The experimental results are in agreement with the simulation results except for some differences at the beginning of the motion. The slight overshoot and discrepancies at the beginning of the motion are due to the limitations of the experiment (e.g., the shaker saturation limitation) and unmodeled dynamics in the modeling (e.g., the friction modeling). However, it is still apparent that the PZT voltage control can substantially suppress the arm vibration despite such limitations and modeling imperfections.

23.4 Practical Considerations and Related Topics

23.4.1 Summary of Vibration-Control Design Steps and Procedures

In order to select a suitable vibration-control system, especially a vibration isolator, a number of factors must be considered.

23.4.1.1 Static Deflection

The static deflection of the vibration-control system under the deadweight of the load determines to a considerable extent the type of the material to be used in the isolator. Organic materials, such as rubber

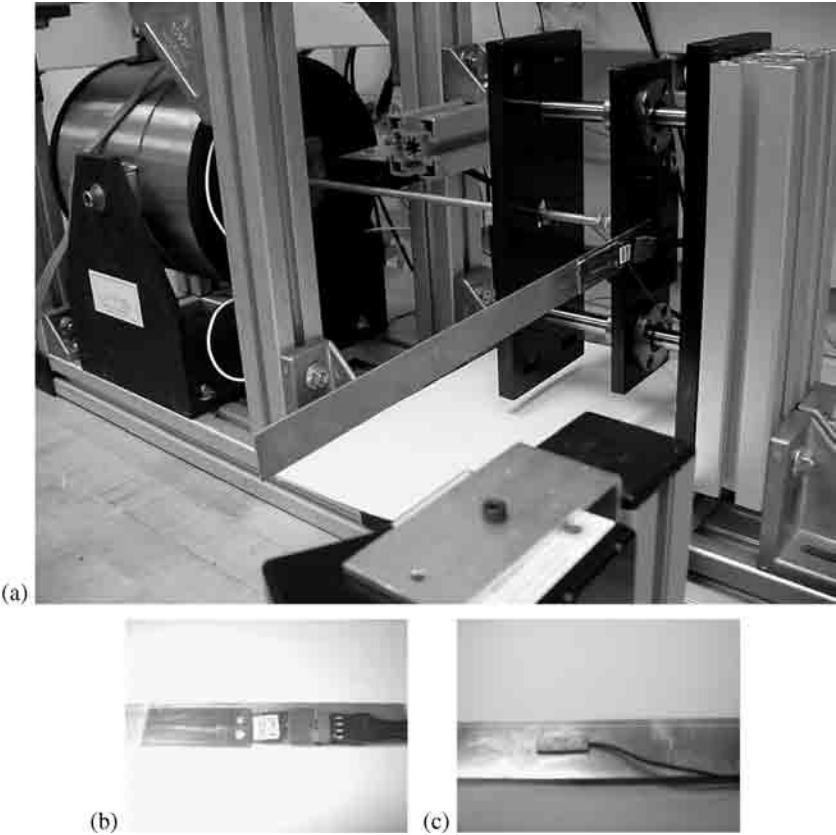

FIGURE 23.33 The experimental setup: (a) the whole system; (b) PZT actuator, ACX model No. QP21B; (c) dynamic strain sensor (attached on the other side of the beam), model No. PCB 740B02.

and cork, are capable of sustaining very large strains provided they are applied momentarily. However, if large strains remain for an appreciable period of time, they tend to drift or creep. On the other hand, metal springs undergo permanent deformation if the stress exceeds the yield stress of the material, but show minimal drift or creep when the stress is maintained below the yield stress.

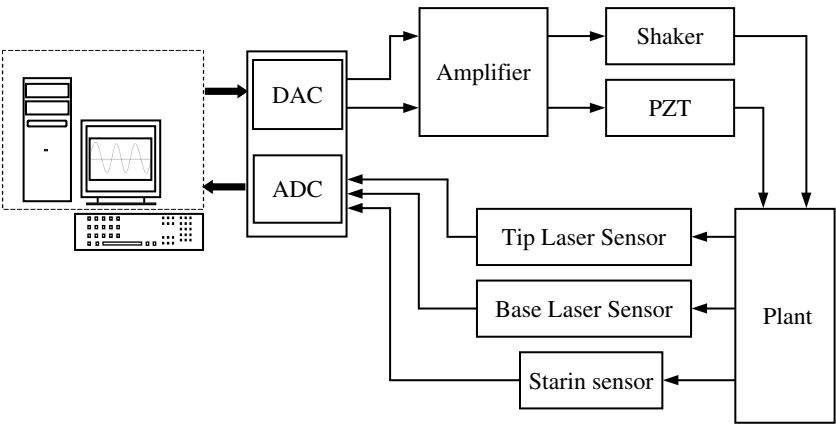

FIGURE 23.34 High-level control-block diagram.

FIGURE 23.35 Experimental results for the case without PZT control: (a) base motion; (b) tip displacement; (c) control force and (d) PZT voltage.

FIGURE 23.36 Experimental results for the case with PZT control: (a) base motion; (b) tip displacement; (c) control force and (d) PZT voltage.

23.4.1.2 Stiffness in Lateral Directions

Resilient materials strained in compression are most useful when the load is relatively large and the static deflection is small. Such applications are difficult to design for a small load, unless the required

static deflection is small. Otherwise, the small area and great thickness tend to cause a condition of instability. To a considerable extent, this limitation can be overcome by using sponge rubber, a material of lower modulus. In general, when the load is small, it is preferable to use rubber springs that carry the load in shear.

23.4.1.3 Environmental Conditions

It is highly common for vibration-control systems to be subjected to harsh environmental conditions. Especially in military applications, extreme ambient temperatures are encountered in addition to exposure to substances like ozone, rocket fuels, and so on. Organic materials are usually more susceptible to these environmental conditions than metal materials. However, owing to the superior mechanical properties of organic materials, such as lighter weight, smaller size, greater damping, and the ability to store large amounts of energy under shock, organic materials that are capable of withstanding the harsh conditions are being developed.

23.4.1.4 Damping Characteristics

In most of the vibration-control applications, the excitations cover a wide range of frequencies and may have random properties requiring the vibration-control systems to possess adequate damping. Elastomers possess very good damping properties when compared with metal springs, and they also eliminate the trouble of standing waves that occurs at high frequencies. If a metal spring is used in vibration-control applications requiring isolation of vibration at high frequencies, it is common to employ rubber pads in series with the metal spring, which also results in the damping of vibrations due to the addition of damping material.

23.4.1.5 Weight and Space Limitations

The amount of load-carrying resilient material is determined by the quantity of energy to be stored. In most of the cases, the vibration amplitude tends to be small relative to the static deflection, and the amount of material may be calculated by equating the energy stored in the material to the work done on the vibration control system.

23.4.1.6 Dynamic Stiffness

In the case of organic materials like rubber, the natural frequency calculated using the stiffness determined from a static-force deflection test of the spring is almost invariably lower than that experienced during vibration; that is, the dynamic modulus is greater than static modulus. The ratio between the dynamic and static modulus is generally between one and two. In many vibration-control applications, it is not feasible to mount the equipment directly upon the vibration-control system (isolator). Instead, a heavy, rigid block, usually made of concrete or heavy steel, supported by the isolator is employed.

23.4.2 Future Trends and Developments

During recent years, there has been considerable interest in the design and implementation of a variety of vibration-control systems. Recent developments in multivariable control design methodology and microprocessor implementation of modern control algorithms have opened a new era for the design of externally controlled passive systems for use in such systems: fuzzy reasoning (Yoshimura, 1998); adaptive algorithms (Venhovens, 1994); observer design (Hedrick et al., 1994); and many others.

Observing these developments combined with the substantial ongoing theoretical advances in the areas of adaptive and nonlinear controls (Astrom and Wittenmark, 1989; Alleyne and Hedrick, 1995), it is expected that the future will bring applications of these techniques in advanced vibration-control system design. For practical implementation, however, it is preferable to simplify these strategies, thus leading to simpler software implementations. Suboptimal policy neglecting some performance requirements can serve as an example of such simplifications.

Summary

Before a helicopter leaves the plant, its rotors need to be tuned so that the helicopter vibration meets the required specifications during different flight regimes. For this, three different adjustments can be made to each rotor blade in response to the magnitude and phase of vibration. In this chapter, the basic concepts for determining the blade adjustments are discussed, and three methods with fundamentally different approaches are described. A neural network-based method is described, which trains a feedforward network as the inverse model of the effect of the blade adjustments on helicopter vibrations, and uses the inverse model to determine the blade adjustments. Another is a probability-based method that maximizes the likelihood of success of the selected blade adjustments based on a stochastic model of the probability densities of the vibration components. The third method is an adaptive method that uses an interval model to represent the range of effect of blade adjustments on helicopter vibration, so as to cope with the nonlinear and stochastic nature of aircraft vibration. This method includes the a priori knowledge of the process by defining the initial coefficients of the interval model according to sensitivity coefficients between the blade adjustments and helicopter vibration, but then transforms these coefficients into intervals and updates them after each tuning iteration, to improve the model estimation accuracy. The details of rotor tuning are described through a case study, which demonstrates the application of the adaptive method.

24.1 Introduction

Helicopter rotor tuning (track and balance) is the process of adjusting the rotor blades so as to reduce the aircraft vibration and the spread of rotors. Rotor tuning as applied to Sikorsky's Black Hawk (H-60) helicopters is performed as follows. For initial measurements, the aircraft is flown through six different regimes, during which measurements of rotor track and vibration (balance) are recorded. Rotor track is measured by optical sensors, which detect the vertical position of the blades (see Chapter 15). Vibration is measured at the frequency of once per blade revolution (per rev) by two accelerometers, A and B, attached to the sides of the cockpit (see Figure 24.1, detail B). The vibration data are vectorially combined into two components: $A + B$, representing the vertical vibration of the aircraft, and $A - B$, representing its roll vibration. A sample of peak vibration levels for the six flight regimes, as well as the peak angular positions relative to a reference blade, are given in Table 24.1, along with a sample of track data.

FIGURE 24.1 Illustration of the position of accelerometers A and B on the aircraft, and the rotor blade adjustments (push rod, trim tab, and hub weights).

TABLE 24.1 Typical Track and Balance Data Recorded during a Flight

Flight Regime	Vibration			
	A + B		A - B	
	Magnitude (ips)	Phase (°)	Magnitude (ips)	Phase (°)
fp	0.19	332	0.38	272

145	5	18	-3	-20
vh	2	13	-1	-14

The six flight regimes in Table 24.1 are: ground (fpm), hover (hov), 80 knots (80), 120 knots (120), 145 knots (145), and maximum horizontal speed (vh). The track data indicate the vertical position of each blade relative to a mean position.

In order to bring track and one per rev vibration within specification, three types of adjustments can be made to the rotor system: pitch control rod adjustments, trim tab adjustments, and balance weight adjustments (see Figure 24.1). Pitch control rods can be extended or contracted by a certain number of notches to alter the pitch of the rotor blades. Positive push rod adjustments indicate extension. Trim tabs, which are adjustable surfaces on the trailing edge of the rotor blades, affect the aerodynamic pitch moment of the air foils and consequently their vibration characteristics. Tab adjustments are measured in thousandths of an inch, with positive and negative changes representing upward and downward tabbing, respectively. Finally, balance weights can be either added to or removed from the rotor hub to tune vibrations through changes in the blade mass. Balance weights are measured in ounces, with positive adjustments representing the addition of weight. In the case of the Sikorsky H-60 helicopter, which has four main rotor blades, a total of 12 adjustments can be made to tune the rotors (i.e., three adjustments per blade). Among them, balance weights primarily affect the ground vibration, so they are not commonly used for in-flight tuning. Furthermore, since the symmetry of rotor blades in four-bladed aircraft produces identical effects for adjustments to opposite blades, the combined form of blade adjustments to opposite blade pairs can be used as inputs. Accordingly, the input vector can be defined as

$$\Delta \mathbf{x} = [\Delta x_1, \Delta x_2, \Delta x_3, \Delta x_4]^T \quad (24.1)$$

where Δx_1 and Δx_3 denote the combined (condensed) trim tab adjustments (ΔT) to blade combinations one/three and two/four, respectively, and Δx_2 and Δx_4 represent the combined pitch control rod adjustments (ΔP) to blade combinations one/three and two/four, respectively. The relationships between the combined and individual adjustments are in the form:

$$\Delta x_1 = \Delta T_3 - \Delta T_1 \quad (24.2)$$

$$\Delta x_2 = \Delta P_3 - \Delta P_1 \quad (24.3)$$

$$\Delta x_3 = \Delta T_4 - \Delta T_2 \quad (24.4)$$

$$\Delta x_4 = \Delta P_4 - \Delta P_2 \quad (24.5)$$

Ideally, identical adjustments made to any two aircraft with different tail numbers should result in identical changes in vibration. In reality, however, significant inconsistencies in vibration changes may be present for identical adjustments to different tail numbers. This is perhaps due more to nonuniformity of flight conditions from weather or error in implementing the blade adjustments than factors such as dissimilarities between aircraft and rotor blades.

Virtually all of the current systems of rotor track and balance rely on the strategy shown in Figure 24.2, whereby the measurements of the flight just completed are used as the basis of search for the new blade adjustments. The search for blade adjustments is guided by the “process model” (see Figure 24.2), which represents the relationship between vibration changes and blade adjustments. A difficulty of rotor tuning is the excess of equations compared to degrees of freedom (four inputs to control 24 outputs), which translates into one-to-many mapping. Another difficulty is caused by the high level of noise present in the vibration measurements.

The traditional approach to rotor tuning uses linear relationships to define the process model

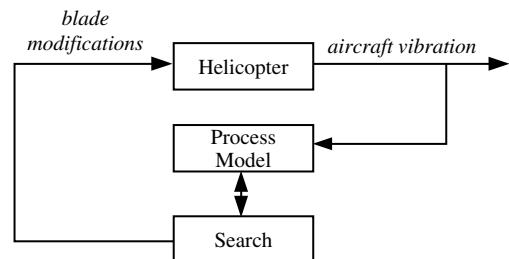

FIGURE 24.2 Tuning strategy of the current methods.

and uses model inversion to streamline the search. The drawback of the traditional approach, therefore, is its neglect of the potential nonlinearity of track and balance, and the vibration noise, as well as its limited capacity to produce comprehensive solutions to facilitate model inversion due to its consideration of the most extreme vibration components. In an attempt to include the potential nonlinearity of the process, Taitel et al. (1995) trained a set of neural networks with actual track and balance data to map vibration measurements to blade adjustments as well as to evaluate the goodness of the solution. In effect, they developed an inverse model based on the solutions available in the historical track and balance data, and provided a forward model to evaluate the solution. The potential advantage of this method is that it can interpolate among the historical solutions to address potential nonlinearity and vibration noise. Its disadvantages are that it is only applicable to helicopters with extensive track and balance history, and that its solutions are constrained by those contained in the historical data.

Another deviation from the traditional approach is introduced by Ventres and Hayden (2000), who define the relationships between blade adjustments and vibration in frequency domain, and provide an extension of these relationships to higher order vibrations. They use an optimization method to search for the adjustments to reduce per rev vibration as well as higher-order vibrations. Accordingly, this approach has the capacity to provide a comprehensive solution, but it too neglects the potential nonlinearity between the blade adjustments and aircraft vibration as well as the noise in the measurements.

The most recent solutions to rotor tuning are those by Wang et al. (2005a, 2005b), which are designed to address both the stochastics of vibration and the potential nonlinearity of the tuning process. In the first solution, which is a probability-based method, the underlying model comprises two components: a deterministic component and a probability component. The method relies on the probability model to estimate the likelihood of the measured vibration satisfying the specifications and to search for blade adjustments that will maximize this likelihood. The likelihood measures in the probability model are computed according to the probability distribution of vibration derived from historical track and balance data. The second solution is an adaptive method that uses an interval model to cope with the potential nonlinearity of the process and to account for vibration noise. This method, which also incorporates learning to provide adaptation to the rotor tuning process, initializes the coefficients of the interval model according to the sensitivity coefficients between the blade adjustments and helicopter vibration. However, it modifies these coefficients after the first iteration to better represent the vibration measurements acquired. This method takes into account vibration data from all of the flight regimes during the search for the appropriate blade adjustments; therefore, it has the capacity to provide comprehensive solutions. The remainder of this chapter describes three of the methods discussed above to provide a representation of various solutions proposed for rotor tuning, followed by a case study to demonstrate the application of the adaptive method.

24.2 Neural Network-Based Tuning

As mentioned earlier, rotor tuning in four-bladed aircraft is performed by first specifying a condensed set of adjustments to reduce vibrations, and then expanding these adjustments into a detailed set to satisfy the track requirements. This same strategy is implemented in the system of neural networks shown in [Figure 24.3](#) (Taitel et al., 1995). The first network in this system, called the selection net, determines the condensed blade adjustments (output) that will bring about a given change in vibration (input). To eliminate vibration, the negatives of the vibration measurements from the flight are utilized as inputs to this network. The validity of the condensed adjustments is then checked by predicting their effect on vibration via the condensed simulation net. Theoretically, these simulated vibration changes should be the negative of the vibration measurements from the aircraft so that their summation will be zero. However, owing to the inexactness of the neural network models and noise, the resultant vibration will most likely not equal zero. In cases where the resultant vibration is not within specifications (usually less than 0.20 inches per second [ips]), the condensed adjustments may be refined by feeding the resultant

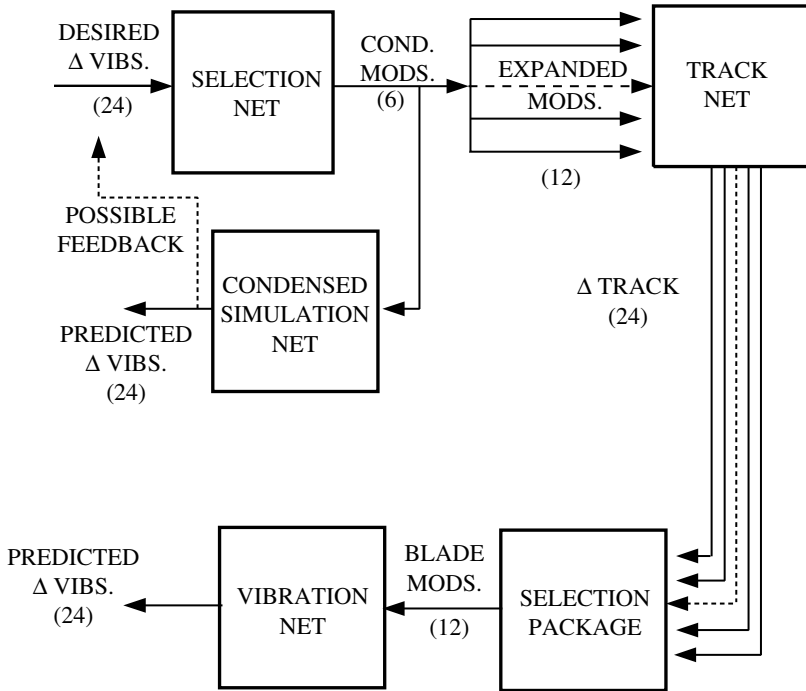

FIGURE 24.3 Schematic of the rotor tuning system. The numbers inside parentheses represent the number of inputs or outputs of individual nets.

vibration back into the selection net. This feedback is depicted by the dashed feedback line in Figure 24.3. It should be noted that the condensed simulation net may also serve as a diagnostic tool by indicating behavior out of the norm. For example, an aircraft with vibrations significantly different from those predicted by this network may suffer from defective components.

Just as with the traditional approach, once the condensed solution has been specified, it needs to be expanded into a detailed form to satisfy the rotor track requirements. As previously mentioned, the condensed set of adjustments may be viewed as the constraint on detailed adjustments so as to ensure that the vibration solution is not compromised for track. Each one of these detailed sets of adjustments is a candidate for the final rotor tuning solution, and it is left to the track net and the selection package to determine which set of detailed adjustments provides the best tracking performance. For selection purposes, the track net simulates the changes in track due to a candidate set of detailed adjustments, and then adds these changes to the initial track measurements from the flight to estimate the resultant track. The set of detailed adjustments that yields the smallest estimated track (i.e., smallest maximum blade spread) is selected as the solution to the rotor tuning problem. The selected set of detailed adjustments is then checked via the vibration net, which, similar to the condensed simulation net, serves as an independent evaluator of the selected adjustments.

24.3 Probability-Based Tuning

The noted contribution of this method is its introduction of the likelihood of success as a criterion in the search for the blade adjustments (Wang et al., 2005). This method speculates the effectiveness of various adjustment sets in reducing the vibration and selects the set with the maximum probability of producing acceptable vibration (see Chapter 5 for useful concepts of random or stochastic vibration). The concept of this method is explained in the context of a simple example. If the measured vibration from the current

flight is denoted by $V_j(k-1)$ and the estimated vibration change according to the model is represented by $\Delta\hat{V}_j(k) = f(\Delta x)$ as a function of the blade adjustments, Δx , then the predicted vibration of the next flight, $\hat{V}_j(k)$, can be defined as

$$\hat{V}_j(k) = V_j(k-1) + \Delta\hat{V}_j(k) \quad (24.6)$$

$$V_j(k) = \hat{V}_j(k) + \hat{e}_j(k) \quad (24.7)$$

where $V_j(k)$ denotes the measured vibration for the next flight. In rotor tuning, the adjustments are selected according to the predicted vibration, $\hat{V}_j(k)$, whereas the objective is defined in terms of the measured vibration. The inclusion of the probability model here is to account for the inevitable uncertainty in the actual position of the measured vibration. According to Equation 24.7, the mean value of the measured vibration is equal to the value of the predicted vibration plus the mean value of the prediction error. However, since the predicted vibration is a deterministic entity, the probability distribution of the measured vibration is the same as that of the prediction error. Accordingly, whereas the nominal value of the measured vibration can be controlled by the blade adjustment, its optimal position within the specification region should be determined according to its probability distribution. For a case where the prediction error, $\hat{e}_j(k)$, is zero-mean and normally distributed, as illustrated in Figure 24.4, placing the predicted vibration at the center of the specification range will be synonymous with maximizing the probability that the measured vibration will be within the range. The likelihood of success of blade adjustments can therefore be measured by the area under the probability density function of prediction error located within the specification region. The blade adjustment set that produces the highest likelihood will be the preferred adjustment.

The main difficulty with rotor tuning, however, is the limited number of DoFs, which precludes perfect positioning of the predicted vibration. This point is illustrated in Figure 24.5 for a case where two vibration components are to be positioned at the center of the specification region with only one adjustment. If one assumes that the effect of adjustment, Δx , on the change in the two vibration components, $\Delta\hat{V}_j(k)$, can be represented by a linear model, as

$$\Delta\hat{V}_j(k) = a_{ij}\Delta x$$

then the position of the predicted vibration components will be constrained to the line L in Figure 24.5. As illustrated in this figure, since it will be impossible to place the predicted vibration components at the center, a compromised position needs to be selected. In this method, the best compromised position for the predicted vibration is that which renders the largest probability of satisfying the specifications for the measured vibration. This position, for the two-component vibration example, is one that maximizes $P_r[(V_1, V_2) \in S] = \int_{(V_1, V_2) \in S} P(V_1, V_2) dV_1 dV_2$. The above formulation indicates that the placement of the predicted vibration requires knowledge of

FIGURE 24.4 Illustration of improved placement of the predicted vibration within the specification range.

FIGURE 24.5 Restricted placement of vibration components within the specification region for a two-dimensional case.

the joint probability density function, $p(V_1, V_2)$, of the vibration components. In the ideal case of independent vibration components with equal probability distributions, the loci of the points with equal probabilities $P_r[(V_1, \dots, V_n) \in S]$ are surfaces of hyperspheres. Such ideal loci for the two-component vibration example of Figure 24.5 are circles centered at the origin (see Figure 24.5), which lead to point P as the best compromised position closest on line L to the center of the specification circle. Point P, however, does not represent the best position if the two vibration components are dependent or have unequal distributions. The loci of equal probabilities for this more general case are elliptical, as also shown in Figure 24.5, indicating point Q as the best position on line L for placing the predicted vibration. The inadequacy of the DoFs illustrated here is exacerbated in rotor tuning, where 24 correlated vibration components need to be positioned within the specification region using only four condensed blade adjustments. For the 24-component vector of measured vibration $\mathbf{V}(k) = [V_{c1}(k), V_{s1}(k), \dots, V_{c12}(k), V_{s12}(k)]^T$, where V_c and V_s represent the cosine and sine components of each vibration measurement, respectively, the joint probability density function of measured vibration for the k th flight, $\mathbf{V}(k)$, can be characterized as an N -dimensional Gaussian function:

$$p(\mathbf{V}(k)) = \frac{1}{(2\pi)^{N/2} |\Phi|^{1/2}} \exp \left[-\frac{1}{2} \hat{\mathbf{e}}(k)^T \Phi^{-1} \hat{\mathbf{e}}(k) \right] \quad (24.8)$$

$$\hat{\mathbf{e}}(k) = \mathbf{V}(k) - \mathbf{V}(k-1) - C\Delta\mathbf{x}(k) \quad (24.9)$$

where Φ represents the covariance matrix of the prediction error. Now, if $\Gamma = \{|\mathbf{V}_j| = \sqrt{V_{cj}^2 + V_{sj}^2} \leq \alpha, j = 1, \dots, 12\}$ denotes the specification region in 24-dimensional Euclidean space, the blade adjustments, $\Delta\mathbf{x}^*$, can be selected such that the probability that the measured vibration is within the acceptable range is maximized (see also Table 24.2). Formally,

$$\Delta\mathbf{x}^* = \arg_{\Delta\mathbf{x}} \max \left[\Pr(\mathbf{V}(k) \in \Gamma) = \int_{\Gamma} p(\mathbf{V}(k)) d\mathbf{V}(k) \right] \quad (24.10)$$

TABLE 24.2 Summary of Probability-Based Tuning

For the input vector:

$$\Delta\mathbf{x} = [\Delta x_1, \Delta x_2, \Delta x_3, \Delta x_4]^T$$

where Δx_1 and Δx_3 denote the combined trim tab adjustments to blade combinations one to three and two to four, respectively, and Δx_2 and Δx_4 represent the combined pitch control rod adjustments to blade combinations one to three and two to four, respectively, the blade adjustments, $\Delta\mathbf{x}$, can be selected such that the probability that the measured vibration is within the acceptable range is maximized. Formally,

$$\Delta\mathbf{x}^* = \arg_{\Delta\mathbf{x}} \max [\Pr(\mathbf{V}(k) \in \Gamma) = \int_{\Gamma} p(\mathbf{V}(k)) d\mathbf{V}(k)]$$

where $\Pr(\mathbf{V}(k))$ denotes the probability of the measured vibration, Γ denotes the specification region in 24-dimensional Euclidean space, and $p(\mathbf{V}(k))$ represents the joint probability density of the measured vibration for the k th flight characterized as an N -dimensional Gaussian function:

$$p(\mathbf{V}(k)) = \frac{1}{(2\pi)^{N/2} |\Phi|^{1/2}} \exp \left[-\frac{1}{2} \hat{\mathbf{e}}(k)^T \Phi^{-1} \hat{\mathbf{e}}(k) \right]$$

with

$$\hat{\mathbf{e}}(k) = \mathbf{V}(k) - \mathbf{V}(k-1) - C\Delta\mathbf{x}(k)$$

representing the predicted error in vibration.

24.4 Adaptive Tuning

The schematic of this method is shown in Figure 24.6 (Wang et al., 2005). As in the other methods, it uses a process model as the basis of search for the appropriate blade adjustments, but instead of using a linear model, it uses an interval model to accommodate process nonlinearity and measurement noise. According to this model, the feasible region of the process is estimated first, to include the adjustments that will result in acceptable vibration estimates. This feasible region is then used to search for the blade adjustments that will minimize the modeled vibration. If the application of these adjustments does not result in satisfactory vibration, the interval model will be updated to better estimate the feasible region and improve the choice of blade adjustments for the next flight. Important parameters of adaptive tuning are summarized in Table 24.3.

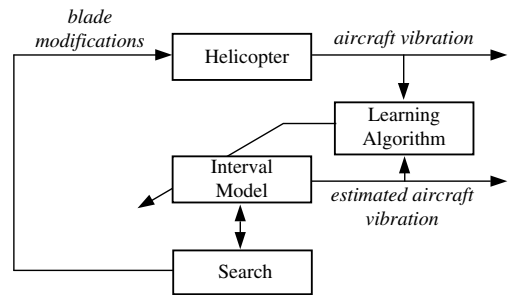

FIGURE 24.6 The strategy of the proposed tuning method.

24.4.1 The Interval Model

In order to account for the stochastics and nonlinearity of vibration, an interval model (Moore, 1979) is defined to represent the range of aircraft vibration caused by blade adjustments. The interval model used here has the form:

$$\Delta \vec{y}_j = \sum_{i=1}^n \vec{C}_{ji} \Delta x_i, \quad j = 1, \dots, m \quad (24.11)$$

where each coefficient is defined as an interval:

$$\vec{C}_{ji} = [C_{Lji}, C_{Uji}]$$

In the above model, the variables with the two-sided arrow, \leftrightarrow , denote intervalled variables, C_{Lji} and C_{Uji} represent, respectively, the current values of the lower and upper bounds of the sensitivity coefficients between each input, Δx_i , and output, $\Delta \vec{y}_j$. The interval $\Delta \vec{y}_j$ denotes the estimated range of change of the j th output caused by the change to the current inputs, $\Delta x_1, \dots, \Delta x_n$.

TABLE 24.3 Summary of Adaptive Tuning

In adaptive tuning, each vibration component is defined as

$$\Delta \vec{y}_j = \sum_{i=1}^n \vec{C}_{ji} \Delta x_i, \quad j = 1, \dots, m$$

where each coefficient is defined as an interval:

$$\vec{C}_{ji} = [C_{Lji}, C_{Uji}]$$

with C_{Lji} and C_{Uji} representing, respectively, the current values of the lower and upper bounds of the sensitivity coefficients between each input, Δx_i , and output, $\Delta \vec{y}_j$. The blade adjustments are then sought by minimizing the objective function:

$$S = \frac{\sum_{e=1}^{N_e} \text{Distance}(x_c, x_e)}{(\prod_{s=1}^{N_s} \text{Distance}(x_c, x_s))^{1/N_s}}$$

where x_c represents a candidate set of blade adjustments within the feasible region, x_e represents any set of blade adjustments within the selection region, x_s denotes each of the previously selected blade adjustments, and N_e and N_s represent the number of the estimated feasible blade adjustments and the previously selected blade adjustments, respectively.

FIGURE 24.7 Estimated range of output by the interval model using one reference input.

The fit provided by the interval model for a mildly nonlinear input/output relationship is illustrated in Figure 24.7, where the output range is estimated relative to one explored input.¹ According to Equation 24.11, the estimated range of the output becomes larger, and therefore less accurate, as the potential input is selected farther from the current input (producing a large Δx_i). This potential drawback of the interval model is considerably reduced when multiple inputs have been explored so that the interval model can take advantage of several inputs for estimating the output range. The estimated output, \tilde{y}_j , at a potential input, x_i , may be computed relative to any set of previously explored inputs, yielding different estimates of \tilde{y}_j (due to different values of Δx_i). In order to cope with the multiplicity of estimates, \tilde{y}_j is defined as the common range among all of the \tilde{y}_j estimates (Yang, 2000). The estimation of \tilde{y}_j using this commonality rule is illustrated in Figure 24.8, which indicates that using this estimation approach enables representation of the system nonlinearities in a piecewise fashion. It can be shown that the lack of commonality between the estimated ranges of output will cause a part of the input–output relationship to not be represented by the interval model. In such cases, however, the lack of compliance between the interval model and the *input–output* relationship can be corrected by adaptation of the coefficient intervals through learning.

24.4.2 Estimation of Feasible Region

The feasible region comprises all sets of blade adjustments that will reduce the aircraft vibration within specifications. The feasible region is estimated here by comparing the individually estimated \tilde{y}_j values with their corresponding constraints, so as to decide whether the corresponding blade adjustments belong to the feasible region. In this method, even when the interval \tilde{y}_j partly overlaps the vibration constraint, the corresponding blade adjustments are included in the estimated feasible region. The above procedure of estimating the feasible region based on individual outputs is then extended to multiple outputs by forming the conjunction of the estimated feasible regions from each output.

24.4.3 Selection of Blade Adjustments

The blade adjustments provide the coordinates of the feasible region, therefore, they need to provide a balanced coverage of the input space. As such, blade adjustment selection becomes synonymous with maximizing the distance of the selected blade adjustments from the previous blade adjustments, as well as

¹An explored input represents an input for which the exact value of the output is available. In rotor tuning, an explored input would denote a blade adjustment that has been applied to the helicopter, and for which the corresponding vibration changes have been measured.

FIGURE 24.8 Estimated range of output by the interval model using seven reference inputs.

bringing them closer to the center of the feasible region. This objective can be pursued by minimizing the following objective function:

$$S = \frac{\sum_{e=1}^{N_e} \text{Distance}(x_c, x_e)}{\left(\prod_{s=1}^{N_s} \text{Distance}(x_c, x_s)\right)^{1/N_s}} \quad (24.12)$$

where x_c represents a candidate set of blade adjustments within the feasible region, x_e represents any set of blade adjustments within the selection region, x_s denotes each of the previously selected blade adjustments, and N_e and N_s represent, respectively, the numbers of the estimated feasible blade adjustments and the previously selected blade adjustments. Note that when the candidate set, x_c , is close to the previously selected blade adjustments, $\left(\prod_{s=1}^{N_s} \text{Distance}(x_c, x_s)\right)^{1/N_s}$ becomes small, and when the candidate set of blade adjustments, x_c , is far from the center of the feasible region, the value of $\sum_{e=1}^{N_e} \text{Distance}(x_c, x_e)$ becomes large. By minimizing S , the candidate blade adjustments are selected such that the above extremes are avoided.

24.4.4 Learning

Although an interval model defined according to the sensitivity coefficients may provide a suitable initial basis for tuning, it may not be the most representative of the rotor tuning process. As such, it may not be able to carry the search process to the end. A noted feature of the proposed method is its learning capability, which enables it to refine its knowledge base. To this end, the coefficients of the model are updated by considering new values for each of the upper and lower limits of individual coefficients. The objective is to make the range of the coefficients as small as possible while making sure that the interval model envelopes the acquired *input-output* data. The learning problem can be defined as

$$\text{Minimize } E = \sum_{m=1}^{K-1} \sum_{k>m}^K \{[y_L(m, k) - y(k)]^2 + [y_U(m, k) - y(k)]^2\} \quad (24.13)$$

subject to

$$y_U(m, k) \geq y(k) \quad (24.14)$$

$$y_L(m, k) \leq y(k) \quad (24.15)$$

$$C_{Ui} - \gamma \geq C_{Li} \quad (24.16)$$

where K represents the total number of sample points collected so far, $y_L(m, k)$ and $y_U(m, k)$ represent, respectively, the lower and upper limits of the estimated output range at the k th sample point relative to

the m th sample point, $y(k)$ denotes the actual output value at the k th sample point, and C_{Ui} and C_{Li} represent the upper and lower limits of the i th coefficient interval, respectively. The parameter γ is a small positive number to control the range of the coefficients.

Most of the approaches that can be potentially used for adapting the coefficient intervals, such as gradient descent (Ishibuchi et al., 1993) or nonlinear programming, cannot be applied to rotor tuning due to their demand for rich training data and their impartiality to the initial value of the coefficients representing the *a priori* knowledge of the process. As an alternative, a learning algorithm is devised here to cope with the scarcity of track and balance data while staying true to the initial values of the coefficients. In this algorithm, the coefficients of the interval model, initially set pointwise at the sensitivity coefficients, are adapted after each flight in two steps: enlargement and shrinkage. First, the vibration measurements from all of the flights completed for the present tail number are matched against the estimated output ranges from the current interval model. If any of the measurements do not fit the upper or lower limits of the estimates, the coefficient intervals are enlarged in small steps, iteratively, and the output ranges are re-estimated at each iteration using the updated interval model. The enlargement of the coefficient intervals stops when the estimated output ranges include all of the measurements. At this point, even though the updated interval model provides a fit for the *input-output* data, it may be overcompensated. In order to rectify this situation, the coefficient intervals are shrunk individually by selecting new candidates for their upper and lower limits.

The shrinkage-enlargement learning algorithm has the form:

$$\Delta C_{Li} = -\eta \delta_L \Delta x_i(m, k) \quad (24.17)$$

$$\Delta C_{Ui} = -\eta \delta_U \Delta x_i(m, k) \quad (24.18)$$

where, during the enlargement phase, δ_L and δ_U are defined as

$$\delta_L = \begin{cases} \Delta y_L & \text{If } \Delta x_i(m, k) > 0 \text{ and } \Delta y_L > 0 \\ \Delta y_U & \text{If } \Delta x_i(m, k) < 0 \text{ and } \Delta y_U < 0 \\ 0 & \text{otherwise} \end{cases} \quad (24.19)$$

$$\delta_U = \begin{cases} \Delta y_U & \text{If } \Delta x_i(m, k) > 0 \text{ and } \Delta y_U < 0 \\ \Delta y_L & \text{If } \Delta x_i(m, k) < 0 \text{ and } \Delta y_L > 0 \\ 0 & \text{otherwise} \end{cases} \quad (24.20)$$

and during the shrinkage phase, they are defined as

$$\delta_L = \begin{cases} \Delta y_L & \text{If } \Delta x_i(m, k) > 0 \text{ and } \Delta y_L < 0 \\ \Delta y_U & \text{If } \Delta x_i(m, k) < 0 \text{ and } \Delta y_U > 0 \\ 0 & \text{otherwise} \end{cases} \quad (24.21)$$

$$\delta_U = \begin{cases} \Delta y_U & \text{If } \Delta x_i(m, k) > 0 \text{ and } \Delta y_U > 0 \\ \Delta y_L & \text{If } \Delta x_i(m, k) < 0 \text{ and } \Delta y_L < 0 \\ 0 & \text{otherwise} \end{cases} \quad (24.22)$$

with

$$\Delta x_i(m, k) = x_i(k) - x_i(m) \quad (24.23)$$

$$\Delta y_L = y_L(m, k) - y(k) \quad (24.24)$$

$$\Delta y_U = y_U(m, k) - y(k) \quad (24.25)$$

This procedure is repeated for each coefficient interval in an iterative fashion until the objective function E (Equation 24.13) is minimized. The minimization of E ensures limited adaptation of the coefficient intervals within the smallest possible range.

At the beginning of tuning, the limited number of *input–output* data available for learning will not provide a comprehensive representation of the process. Therefore, the coefficient intervals should not be shrunk drastically until enough *input–output* data have become available. For this, the length of each coefficient interval $[C_{Li}, C_{Ui}]$ is constrained by the minimal interval length for each tuning iteration as

$$\min L = \{C_{Ui}(0) - C_{Li}(0)\}(1 - \beta)^n \quad (24.26)$$

where $\beta \in [0, 1]$ controls the shrinkage rate of the coefficient interval, and n denotes the number of tuning iterations. The coefficient interval cannot be shrunk when $\beta = 0$ and can be shrunk without limit when $\beta = 1$. Usually, β is selected closer to 0.

24.5 Case Study

The utility of the Interval Model (IM) method is demonstrated in application to Black Hawks. Ideally, the performance of the proposed method should be evaluated side by side against that of the traditional method. However, such an evaluation would require tuning the aircraft with one method, undoing changes, and tuning the aircraft with another. Since such testing is prohibitively costly and infeasible, a compromised approach of evaluating the method in simulation is utilized. A process simulation model is therefore used to represent the block “helicopter” in Figure 24.6, with the block “forward model” represented by an interval model.

24.5.1 Simulation Model

Considering the potential nonlinearity of the effect of blade adjustments on the helicopter vibration and the high level of noise present in vibration measurements, multilayer neural networks offer the most suitable framework for modeling. A series of neural networks were trained with historical balance data to represent the relationships between vibration changes and blade adjustments, and the stochastic aspects of vibration (see Chapter 5) were represented by the addition of random numbers to the outputs of the networks.

A total of 102 sets of vibration data were used to train and test the neural networks. The inputs to these networks were the combined blade adjustments of push rods and trim tabs to opposite blade pairs, and their outputs were the resulting vibration changes between two consecutive flights. Since the vibration data are vector quantities that are represented by both magnitude and phase components (see Table 24.1), the vibration data were transformed into Cartesian coordinates, so that each vector element would denote the change in the cosine or sine component of the $A + B$ or $A - B$ vibration of each of the six flight regimes (see Table 24.1). In this study, each neural network model consisted of four inputs and one output, so a total of 24 networks were trained to represent all of the vibration components. Alternatively, all of the vibration measurements may be represented by one neural network, but such a network is more difficult to train. Formally, the outputs of the neural networks, which represent the cosine and sine components of the vibration at different regimes, $v_{sj}(k)$ and $v_{cj}(k)$, respectively, are defined as

$$\hat{V}_{sj}(k) = V_{sj}(k-1) + \Delta V_{sj}(k) + R_{sj}(k) \quad (24.27)$$

$$\hat{V}_{cj}(k) = V_{cj}(k-1) + \Delta V_{cj}(k) + R_{cj}(k) \quad (24.28)$$

$$\Delta V_{sj}(k) = F_{sj}(\Delta x) \quad (24.29)$$

$$\Delta V_{cj}(k) = F_{cj}(\Delta x) \quad (24.30)$$

$$\hat{V}_j(k) = \sqrt{\hat{V}_{sj}(k)^2 + \hat{V}_{cj}(k)^2} \quad (24.31)$$

where the input vector $\Delta \mathbf{x} = \{\Delta x_1, \Delta x_2, \Delta x_3, \Delta x_4\}$ denotes the set of combined blade adjustments, each of the functionals, F_{sj} and F_{cj} , represent the change in vibration between two consecutive flights as represented by a neural network, and $R_{sj}(k)$ and $R_{cj}(k)$ denote random numbers added to the outputs of the networks to account for measurement noise. Each of the networks consisted of two hidden layers, with four and eight processing elements in the first and second layers, respectively. To avoid overtraining, the 102 sets of data were divided into two equal subsets, one set to train the network and the other to test its performance. The random numbers, R_{cj} and R_{sj} , were generated according to the Gaussian distribution $N(\mu, \sigma^2)$, with the mean μ and variance σ^2 defined as

$$\hat{\mu} = \frac{1}{M} \sum_{i=1}^M e_i \quad (24.32)$$

$$\hat{\sigma}^2 = \frac{1}{M-1} \sum_{i=1}^M (e_i - \hat{\mu})^2 \quad (24.33)$$

In the above formulation, M represents the total number of data sets and e_i denotes the difference between the measured and expected value of vibration, defined as

$$e_j(k) = V_j(k) - V_j(k-1) - \Delta V_j(k) \quad (24.34)$$

A sample of estimated vibration changes generated by the neural network model is compared side by side with the actual vibration changes in Figure 24.9. The results indicate close agreement between the predicted and actual vibration changes.

24.5.2 Interval Modeling

In application to the Black Hawks, a total of 24 interval models need to be constructed to approximate the changes in the cosine and sine components of the A + B and A - B vibrations at each of the six flight regimes. The interval models have the form

$$\tilde{V}_{cj}(k) = V_{cj}(k-1) + \sum_{i=1}^4 \tilde{C}_{cji}(k-1) \Delta x_i(k) \quad (24.35)$$

$$\tilde{V}_{sj}(k) = V_{sj}(k-1) + \sum_{i=1}^4 \tilde{C}_{sji}(k-1) \Delta x_i(k) \quad (24.36)$$

FIGURE 24.9 A sample set of simulated vibration changes shown side by side with the actual vibration changes.

$$\vec{V}_j(k) = \sqrt{\vec{V}_{sj}^2(k) + \vec{V}_{cj}^2(k)}, \quad i = 1, \dots, 4 \text{ and } j = 1, \dots, 12 \quad (24.37)$$

where the $\vec{V}_{cj}(k)$ and $\vec{V}_{sj}(k)$ represent, respectively, the estimated cosine and sine components of $A + B$ or $A - B$ vibration at each of the six flight regimes, $\vec{V}_j(k)$ denotes the magnitude of the vibration, and Δx_i are the same as those in Equation 24.2 to Equation 24.5. For this study, the feasible region was defined to include all of the blade adjustments associated with vibration estimates that satisfied the specification: $\max\{\min(\vec{V}_1), \dots, \min(\vec{V}_{12})\} \leq 0.2$. The above specification ensures that the lower limit of the estimated vibration range of the largest vibration component will be less than 0.2 ips (an industry standard). The selection of the lower limit here is to ensure that the feasible region is as large as possible, so as not to eliminate any potentially good candidate blade adjustments. The computation of the feasible region was based on the range $[-0.015, 0.015]$ for push rods and $[-0.035, 0.035]$ for trim tabs, within which 20,000 random sets of blade adjustments were evaluated for their feasibility. The blade adjustments associated with vibration ranges satisfying the specification were included in the feasible region.

As noted earlier, the proposed method uses the feasible region as the basis of search for the blade adjustments. For this study, the blade adjustments set that produced the smallest value for the objective function S (Equation 24.12) was selected to be applied to the helicopter. It should be noted that, given the stringent constraints on the vibration components, there were cases where the search algorithm could not find any feasible blade adjustments that would satisfy all of the constraints. In such cases, the set of blade adjustments that produced the smallest lower limit of the maximum estimated vibration was used as a compromised solution.

The interval model was updated after each tuning iteration. For shrinkage–enlargement learning, the parameter β in Equation 24.26 was set to 1 and γ to 0, so that the coefficient intervals could be shrunk without limits. Learning was performed separately for each tail number to customize the interval model to individual tail numbers; that is, the interval model was set to the sensitivity coefficients for each tail number and was adapted after the first tuning iteration. Accordingly, the interval model was actually a pointwise model for the first iteration and took the form of an interval model thereafter.

24.5.3 Performance Evaluation

The interval model (IM) method was tested on 39 tail numbers, for which actual track and balance data were available from the field. For each tail number, the IM method was applied iteratively until either the simulated vibrations were within their specifications, or an upper limit of five process iterations had been reached.

Since the stochastic aspects of vibration measurements impose randomness on the rotor tuning process, rotor tuning solutions cannot be evaluated by deterministic measures. This calls for the creation of performance measures that account for uncertainty. One such measure that assesses tuning efficiency is the *average tuning iteration number* (ATIN) which represents the average number of iterations taken for tuning each tail number. The number of flights used by the IM method for the 39 tail numbers is included in Table 24.4 along with those actually performed in the field. The results indicate that the IM method requires a smaller ATIN relative to that actually performed.

Another potentially significant aspect of the IM method is its adaptation capability, which enables it to transform a pointwise model into an IM, and to subsequently update it after the first iteration. Adaptation capability, however, may not be as significant in rotor tuning, which offers limited possibility for training. In order to evaluate the significance of learning in the performance of the IM method, the results in Table 24.4 were reproduced in Table 24.5 with the learning feature turned off. The ATINs indicate that with learning, the IM method requires fewer iterations for tuning each tail number, despite the small number of iterations taken to tune each tail number. This, in turn, indicates that the interval model enhances the performance of the IM method, since without learning, the model remains pointwise at the sensitivity coefficients. However, perhaps an equally interesting set of results in Table 24.5 are those indicating that even without learning, the IM method requires fewer iterations than actually

822	3	2	3
⋮	⋮	⋮	⋮
Total	71	48	62
ATIN	1.82	1.23	1.59

performed in the field. Given that the adjustments associated with both sets of results were selected from the same model (i.e., sensitivity coefficients), the better performance of the IM method can only be attributed to its more effective search strategy that leads to more comprehensive solutions.

A preferred aspect of a system of rotor tuning is its ability to tune the aircraft within one iteration. This aspect of the method was evaluated by checking the number of tail numbers tuned within one iteration. For these results, in order to eliminate the difference between the simulation model and the helicopter, only the vibration estimates from simulation were used to evaluate the suitability of the adjustments. The results of this study are shown in Table 24.6, where the tail numbers tuned within one iteration are shown by a \surd and those requiring more than one iteration are denoted by \times . The results indicate that the IM method satisfies this more stringent criterion better than the actual adjustments, further validating the claim that the IM method benefits from a more effective search engine.

Owing to the randomness of the vibration measurements, repeated applications of an adjustment set may lead to slightly different vibration measurements. This, in turn, may cause a variance in the number of iterations produced by adjustments when the resulting vibration is close to the specified threshold. It would be beneficial, therefore, to devise a measure for the probability of success of adjustments.

TABLE 24.6 Tally of the Tail Numbers Tuned within One Iteration According to Simulated Vibration

⋮	⋮	⋮
822	×	✓
858	×	✓
859	✓	✓
861	✓	✓
Total	19	30

The empirical measure, the acceptability index (AI), is defined here as

$$AI = \frac{1}{N} \sum_{l=1}^N s_l \tag{24.38}$$

to denote the percentage of times an adjustment set will result in the vibration satisfying the specification. In the above equation, N represents the total number of flights simulated to represent the repeated applications of the same adjustment set, and

$$s_l = \begin{cases} 1 & \text{if vibration of the } l\text{th simulation flight is acceptable} \\ 0 & \text{if vibration of the } l\text{th simulation flight is unacceptable} \end{cases}$$

The AIs computed for both the actual and selected adjustments at the first iteration are included in Table 24.7. The results indicate that the IM method provides adjustments with a higher probability of success as judged by the acceptability of vibration estimates from the simulation model. These results, which indicate that the selected adjustments from the IM method can more consistently tune the rotors within one iteration, imply the better positioning of the adjustments within the feasible region.

TABLE 24.7 The Values of Acceptability Index (Trial Mode) Computed for Both the Actual and Selected Adjustments at the First Flight

Tail # (39)	Acceptability Index

822	0.00	0.64
857	0.62	0.55
858	0.64	0.93
859	0.94	0.67
861	0.96	0.74
Average	0.581	0.724

TABLE 24.8 Comparison of the First Iteration Solutions of IM Method and Actual Solutions from Sikorsky’s Production Line with the Cumulative Acceptable Adjustments

Tail #	Modifications		
	Actual Iteration 1 Modifications	CAM	IM Iteration 1 Modifications
801	6, -4, -10, 11	2, -4, -4, 14	3, -5, -6, 12
802	5, 2, 0, 0	9, 0, -10, 10	8, -2, -5, 10
822	6, 0, -20, 0	10, -4, -23, 13	8, -4, -22, 6
858	7, 0, -14, 0	9, -2, -10, 3	9, -2, -15, 4

Another evaluation basis for the adjustments can be established by comparing them to the actual cumulative adjustments performed in the field. The cumulative adjustment set, $\sum x$, can be defined as

$$\sum x = \sum_{k=1}^N \Delta x_k \tag{24.39}$$

where N represents the total number of tuning iterations performed in the field for the tail number and Δx_k denotes the adjustments applied at the k th iteration. A sample of actual first iteration adjustments, actual cumulative adjustments, and first iteration adjustments from the IM method is shown in Table 24.8. The results indicate that the adjustments from the IM method are closer to the actual cumulative adjustments than are the actual first iteration adjustments. Although the cumulative adjustments may not be the most desirable ones for the aircraft, they represent an acceptable set that has been proven in the field. The closeness of the IM method’s solutions to the actual cumulative adjustments further validates its effectiveness.

24.6 Conclusion

A logical feature for future rotor tuning systems will be the capability to adjust the blades during the flight. For this, these systems will need to have the capability to learn from their mistakes. They will also need to be able to monitor the condition of the rotor system in-flight, so they will stop modifying the blade parameters when more drastic actions are necessary for saving the aircraft. As such, these systems will need to be used with strong operator interaction to prevent implementation of inappropriate adjustments, and must have the ability to explain the recommended adjustments to the operator.

Summary

The focus of this chapter is on the definition and description of machine condition monitoring and fault diagnosis. Included are the reasons and justification behind the adoption of any of the techniques presented. The motivation behind the decision making in regard to various applications is both financial and technical. Both of these aspects are discussed, with the emphasis being on the technical side. The chapter defines machinery failure (causes, types, and frequency), and describes basic maintenance strategies and the factors that should be considered when deciding

which to apply in a given situation. Topics considered in detail include transducer selection and mounting location, recording and analysis instrumentation, and display formats and analysis tools (specifically, time domain, frequency domain, modal domain, and quefrency domain-based strategies). The discussion of fault detection is based primarily on standards and acceptance limits in the time and frequency domains. The discussion of fault diagnostics is divided into sections that focus on different forcing functions, specific machine components, specific machine types, and advanced diagnostic techniques. Further considerations on this topic are found in [Chapter 26](#) and [Chapter 27](#).

25.1 Introduction

Approximately half of all operating costs in most processing and manufacturing operations can be attributed to maintenance. This is ample motivation for studying any activity that can potentially lower these costs. Machine condition monitoring and fault diagnostics is one of these activities. Machine condition monitoring and fault diagnostics can be defined as the field of technical activity in which selected physical parameters, associated with machinery operation, are observed for the purpose of determining machinery integrity. Once the integrity of a machine has been estimated, this information can be used for many different purposes. Loading and maintenance activities are the two main tasks that link directly to the information provided. The ultimate goal in regard to maintenance activities is to schedule only what is needed at a time, which results in optimum use of resources. Having said this, it should also be noted that condition monitoring and fault diagnostic practices are also applied to improve end product quality control and as such can also be considered as process monitoring tools.

This definition implies that, while machine condition monitoring and fault diagnostics is being treated as the focus of this chapter, it must also be considered in the broader context of plant operations. With this in mind, this chapter will begin with a description of what is meant by machinery failure and a brief overview of different maintenance strategies and the various tasks associated with each. A short description of different vibration sensors, their modes of operation, selection criteria, and placement for the purposes of measuring accurate vibration signals will then follow. Data collection and display formats will be discussed with the specific focus being on standards common in condition monitoring and fault diagnostics. Machine fault detection and diagnostic practices will make up the remainder of the chapter. The progression of information provided will be from general to specific. The hope is that this will allow a broad range of individuals to make effective use of the information provided.

25.2 Machinery Failure

Most machinery is required to operate within a relatively close set of limits. These limits, or operating conditions, are designed to allow for safe operation of the equipment and to ensure equipment or system design specifications are not exceeded. They are usually set to optimize product quality and throughput (load) without overstressing the equipment. Generally speaking, this means that the equipment will operate within a particular range of operating speeds. This definition includes both steady-state operation (constant speed) and variable speed machines, which may move within a broader range of operation but still have fixed limits based on design constraints. Occasionally, machinery is required to operate outside these limits for short times (during start-up, shutdown, and planned overloads).

The main reason for employing machine condition monitoring and fault diagnostics is to generate accurate, quantitative information on the present condition of the machinery. This enables more confident and realistic expectations regarding machine performance. Having at hand this type of reliable information allows for the following questions to be answered with confidence:

- Will a machine stand a required overload?
- Should equipment be removed from service for maintenance now or later?

- What maintenance activities (if any) are required?
- What is the expected time to failure?
- What is the expected failure mode?

Machinery failure can be defined as the inability of a machine to perform its required function. Failure is always machinery specific. For example, the bearings in a conveyor belt support pulley may be severely damaged or worn, but as long as the bearings are not seized, it has not failed. Other machinery may not tolerate these operating conditions. A computer disk drive may have only a very slight amount of wear or misalignment resulting in noisy operation, which constitutes a failure.

There are also other considerations that may dictate that a machine no longer performs adequately. Economic considerations may result in a machine being classified as obsolete and it may then be scheduled for replacement before it has “worn out.” Safety considerations may also require the replacement of parts in order to ensure the risk of failure is minimized.

25.2.1 Causes of Failure

When we disregard the gradual wear on machinery as a cause of failure, there are still many specific causes of failure. These are perhaps as numerous as the different types of machines. There are, however, some generic categories that can be listed. Deficiencies in the original design, material or processing, improper assembly, inappropriate maintenance, and excessive operational demands may all cause premature failure.

25.2.2 Types of Failure

As with the causes of failure, there are many different types of failure. Here, these types will be subdivided into only two categories. Catastrophic failures are sudden and complete. Incipient failures are partial and usually gradual. In all but a few instances, there is some advanced warning as to the onset of failure; that is, the vast majority of failures pass through a distinct incipient phase. The goal of machine condition monitoring and fault diagnostics is to detect this onset, diagnose the condition, and trend its progression over time. The time until ultimate failure can then hopefully be better estimated, and this will allow plans to be made to avoid undue catastrophic repercussions. This, of course, excludes failures caused by unforeseen and uncontrollable outside forces.

25.2.3 Frequency of Failure

Anecdotal and statistical data describing the frequency of failures can be summarized in what is called a “bathtub curve.” Figure 25.1 shows a typical bathtub curve, which is applicable to an individual machine or population of machines of the same type.

The beginning of a machine’s useful life is usually characterized by a relatively high rate of failure. These failures are referred to as “wear-in” failures. They are typically due to such things as design errors, manufacturing defects, assembly mistakes, installation problems and commissioning errors. As the causes of these failures are found and corrected, the frequency of failure decreases.

The machine then passes into a relatively long period of operation, during which the frequency of failures occurring is relatively low. The failures that do occur mainly happen on a random basis. This period of a machine’s life is called the “normal wear” period and usually makes up most of the life of a machine. There should be a relatively low failure rate during the normal wear period when operating within design specifications.

FIGURE 25.1 Typical bathtub curve.

As a machine gradually reaches the end of its designed life, the frequency of failures again increases. These failures are called “wearout” failures. This gradually increasing failure rate at the expected end of a machine’s useful life is primarily due to metal fatigue, wear mechanisms between moving parts, corrosion, and obsolescence. The slope of the wearout part of the bathtub curve is machine-dependent. The rate at which the frequency of failures increases is largely dependent on the design of the machine and its operational history. If the machine design is such that the operational life ends abruptly, the machine is underdesigned to meet the load expected, or the machine has endured a severe operational life (experienced numerous overloads), the slope of the curve in the wearout section will increase sharply with time. If the machinery is overdesigned or experiences a relatively light loading history, the slope of this part of the bathtub curve will increase only gradually with time.

- Generally (outside of start-up and shutdown) machinery is required to operate at constant speed and load.
- Machinery failure is defined based on performance, operating condition, and system specifications.
- Machinery failure can be defined as the inability of a machine to perform its required function.
- Causes of machinery failure can be generally defined as being due to deficiencies in the original design, material or processing, improper assembly, inappropriate maintenance, or excessive operation demands.
- The frequency of failure for an individual machine or a population of similar machines can be summarized using a “bathtub curve.”

25.3 Basic Maintenance Strategies

Maintenance strategies can be divided into three main types: (1) run-to-failure, (2) scheduled, and (3) condition-based maintenance. Each of these different strategies has distinct advantages and disadvantages, which will be described below. Specific situations within any large facility may require the application of a different strategy. Therefore, no one strategy should be considered as always superior or inferior to another.

25.3.1 Run-to-Failure (Breakdown) Maintenance

Run-to-failure, or breakdown maintenance, is a strategy where maintenance, in the form of repair work or replacement, is only performed when machinery has failed. In general, run-to-failure maintenance is appropriate when the following situations exist:

- The equipment is redundant.
- Low cost spares are available.
- The process is interruptible or there is stockpiled product.
- All known failure modes are safe.
- There is a known long mean time to failure (MTTF) or a long mean time between failure (MTBF).
- There is a low cost associated with secondary damage.
- Quick repair or replacement is possible.

An example of the application of run-to-failure maintenance can be found when one considers the standard household light bulb. This device satisfies all the requirements above and therefore the most cost-effective maintenance strategy is to replace burnt out light bulbs as needed.

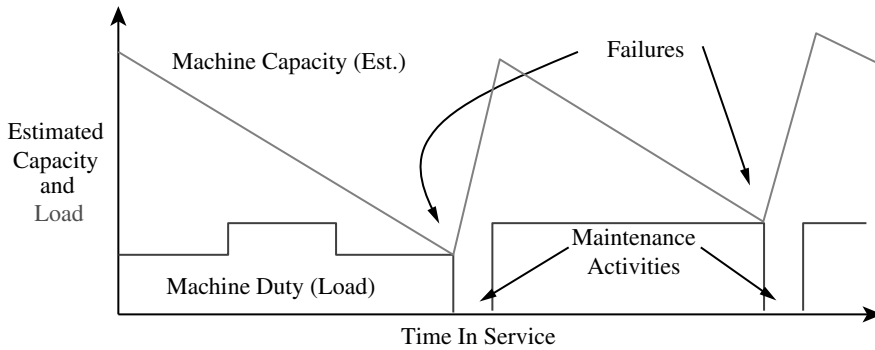

FIGURE 25.2 Time vs. estimated capacity and actual load (run-to-failure maintenance).

Figure 25.2 shows a schematic demonstrating the relationship between a machine's time in service, the load (or duty) placed on the machine, and the estimated remaining capacity of the machine. Whenever the estimated capacity curve intersects with (or drops below) the load curve, a failure will occur. At these times, repair work must be carried out. If the situation that exists fits within the "rules" outlined above, all related costs (repair work and downtime) will be minimized when using run-to-failure maintenance.

25.3.2 Scheduled (Preventative) Maintenance

When specific maintenance tasks are performed at set time intervals (or duty cycles) in order to maintain a significant margin between machine capacity and actual duty, the type of maintenance is called scheduled or preventative maintenance. Scheduled maintenance is most effective under the following circumstances:

- Data describing the statistical failure rate for the machinery is available.
- The failure distribution is narrow, meaning that the MTBF is accurately predictable.
- Maintenance restores close to full integrity of the machine.
- A single, known failure mode dominates.
- There is low cost associated with regular overhaul/replacement of the equipment.
- Unexpected interruptions to production are expensive and scheduled interruptions are not so bad.
- Low cost spares are available.
- Costly secondary damage from failure is likely to occur.

An example of scheduled maintenance practices can be found under the hood of your car. Oil and oil filter changes on a regular basis are part of the scheduled maintenance program that most car owners practice. A relatively small investment in time and money on a regular basis acts to reduce (but not eliminate) the likelihood of a major failure taking place. Again, this example shows how when all, or most, of the criteria listed above are satisfied, overall maintenance costs are minimized.

Figure 25.3 shows a schematic demonstrating the relationship between a machine's time in-service, the load (or duty) placed on the machine and the estimated remaining capacity of the machine when scheduled maintenance is being practiced. In this case, maintenance activities are scheduled at regular intervals in order to restore machine capacity before a failure occurs. In this way, there is always a margin between the estimated capacity and the actual load on the machine. If this margin is always present, there should theoretically never be an unexpected failure, which is the ultimate goal of scheduled maintenance.

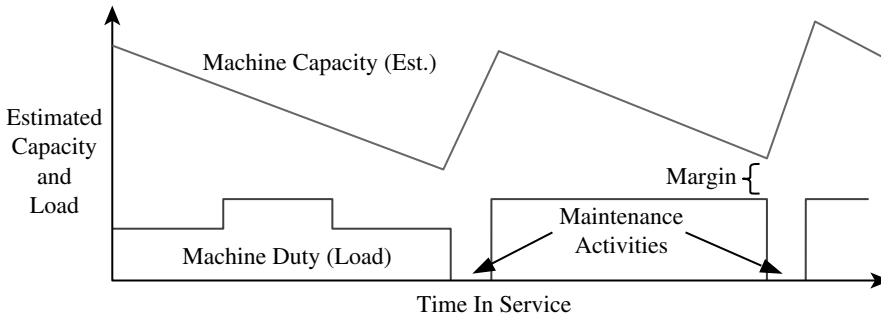

FIGURE 25.3 Time vs. estimated capacity and actual load (scheduled maintenance).

25.3.3 Condition-Based (Predictive, Proactive, Reliability Centered, On-Condition) Maintenance

Condition-based maintenance (which is also known by many other names) requires that some means of assessing the actual condition of the machinery is used in order to optimally schedule maintenance, in order to achieve maximum production, and still avoid unexpected catastrophic failures. Condition-based maintenance should be employed when the following conditions apply:

- Expensive or critical machinery is under consideration.
- There is a long lead-time for replacement parts (no spares are readily available).
- The process is uninterruptible (both scheduled and unexpected interruptions are excessively costly).
- Equipment overhaul is expensive and requires highly trained people.
- Reduced numbers of highly skilled maintenance people are available.
- The costs of the monitoring program are acceptable.
- Failures may be dangerous.
- The equipment is remote or mobile.
- Failures are not indicated by degeneration of normal operating response.
- Secondary damage may be costly.

An example of condition-based maintenance practices can again be found when considering your car, but this time we consider the tires. Regular inspections of the tires (air pressure checks, looking for cracks and scratches, measuring the remaining tread, listening for slippage during cornering) can all be used to make an assessment of the remaining life of the tires and also the risk of catastrophic failure. In order to minimize costs and risk, the tires are replaced before they are worn out completely, but not before they have given up the majority of their useful life. A measure of the actual condition of equipment is used to utilize maintenance resources optimally.

Figure 25.4 shows a schematic drawing that demonstrates the relationship between a machine's time in service, the load (or duty) placed on the machine, and the estimated remaining capacity of the machine when condition-based maintenance is being practiced. Note that the margin between duty and capacity is allowed to become quite small (smaller than in scheduled maintenance), but the two lines never touch (as in run-to-failure maintenance). This results in a longer time between maintenance activities than for scheduled maintenance. Maintenance tasks are scheduled just before a failure is expected to occur, thereby optimizing the use of resources. This requires that there exists a set of accurate measures that can be used to assess the machine integrity.

Each of these maintenance strategies has its advantages and disadvantages and situations exist where one or the other is appropriate. It is the maintenance engineer's role to decide on and justify the use of any one of these procedures for a given machine. There are also instances where a given machine will require more than one maintenance strategy during its operational life, or perhaps even at one

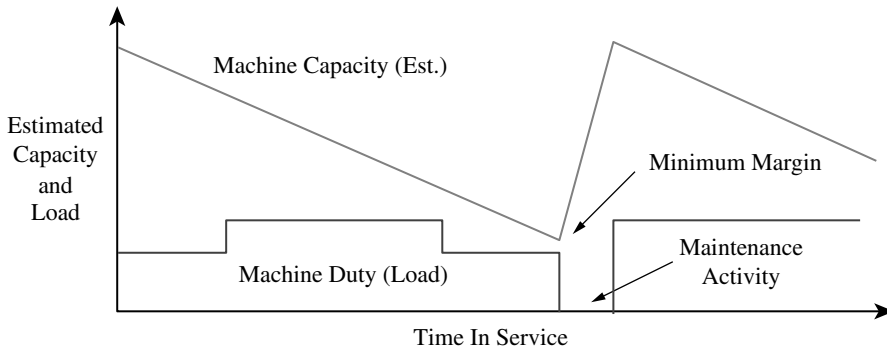

FIGURE 25.4 Time versus estimated capacity and actual load (condition-based maintenance).

time, and situations where more than one strategy is appropriate within a particular plant. Examples of these situations include the need for an increased frequency of monitoring as the age of a machine increases and the likelihood of failure increases, and the scheduling of maximum time between overhauls during the early stages of a machine's useful life, with monitoring in between looking for unexpected failures.

- Maintenance strategies can be divided into three main types: (1) run-to-failure, (2) scheduled, and (3) condition-based maintenance.
- No one strategy should be considered as always superior or inferior to another.
- Run-to-failure, or breakdown maintenance, is a strategy where maintenance, in the form of repair work or replacement, is only performed when machinery has failed.
- When specific maintenance tasks are performed at set time intervals (or duty cycles) in order to maintain a significant margin between machine capacity and actual duty, the type of maintenance is called scheduled or preventative maintenance.
- Condition-based maintenance requires that some means of assessing the actual condition of the machinery is used in order to optimally schedule maintenance, in order to achieve maximum production and still avoid unexpected catastrophic failures.

25.4 Factors which Influence Maintenance Strategy

While there are some general guidelines for choosing the most appropriate maintenance strategy, each case must be evaluated individually. Principal considerations will always be defined in economic terms. Sometimes, a specific company policy (such as safety) will outweigh all other considerations. Below is a list of factors (in no particular order) that should be taken into account when deciding which maintenance strategy is most appropriate for a given situation or machine:

- Classification (size, type) of the machine
- Critical nature of the machine relative to production
- Cost of replacement of the entire machine
- Lead-time for replacement of the entire machine
- Manufacturers' recommendations
- Failure data (history), MTTF, MTBF, failure modes
- Redundancy
- Safety (plant personnel, community, environment)

- Cost and availability of spare parts
- Personnel costs, administrative costs, monitoring equipment costs
- Running costs for a monitoring program (if used)

25.5 Machine Condition Monitoring

With the understanding that condition-based maintenance may not be appropriate in all situations, let us say that some preliminary analysis has been carried out and a decision made to apply machine condition monitoring and fault diagnostics in a selected part of a plant or on a specific machine. The following is a list of potential advantages that should be realized:

- Increased machine availability and reliability
- Improved operating efficiency
- Improved risk management (less downtime)
- Reduced maintenance costs (better planning)
- Reduced spare parts inventories
- Improved safety
- Improved knowledge of the machine condition (safe short-term overloading of machine possible)
- Extended operational life of the machine
- Improved customer relations (less planned/unplanned downtime)
- Elimination of chronic failures (root cause analysis and redesign)
- Reduction of postoverhaul failures due to improperly performed maintenance or reassembly

There are, of course, also some disadvantages that must be weighed in the decision to use machine condition monitoring and fault diagnostics. These disadvantages are listed below:

- Monitoring equipment costs (usually significant).
- Operational costs (running the program).
- Skilled personnel needed.
- Strong management commitment needed.
- A significant run-in time to collect machine histories and trends is usually needed.
- Reduced costs are usually harder to sell to management as benefits when compared with increased profits.

The ultimate goal of machine condition monitoring and fault diagnostics is to get useful information on the condition of equipment to the people who need it in a timely manner. The people who need this information include operators, maintenance engineers and technicians, managers, vendors, and suppliers. These groups will need different information at different times. The task of the person or group in charge of condition monitoring and diagnostics must ensure that useful data is collected, that data is changed into information in a form required by and useful to others, and that the information is provided to the people who need it when they need it. Further general reading can be found in these references: Mitchell (1981), Lyon (1987), Mobley (1990), Rao (1996), and Moubray (1997).

The focus of this chapter will be on vibration-based data, but there are several different types of data that can be useful for assessing machine condition and these should not be ignored. These include physical parameters related to lubrication analysis (oil/grease quality, contamination), wear particle monitoring and analysis, force, sound, temperature, output (machine performance), product quality, odor, and visual inspections. All of these factors may contribute to a complete picture of machine integrity. The types of information that can be gleaned from the data include existing condition, trends, expected time to failure at a given load, type of fault existing or developing, and the type of fault that caused failure.

The specific tasks which must be carried out to complete a successful machine condition monitoring and fault diagnostics program include detection, diagnosis, prognosis, postmortem, and

prescription. Detection requires data gathering, comparison to standards, comparison to limits set in-plant for specific equipment, and trending over time. Diagnosis involves recognizing the types of fault developing (different fault types may be more or less serious and require different action) and determining the severity of given faults once detected and diagnosed. Prognosis, which is a very challenging task, involves estimating (forecasting) the expected time to failure, trending the condition of the equipment being monitored, and planning the appropriate maintenance timing. Postmortem is the investigation of root-cause failure analysis, and usually involves some research-type investigation in the laboratory and/or in the field, as well as modeling of the system. Prescription is an activity that is dictated by the information collected and may be applied at any stage of the condition monitoring and diagnostic work. It may involve recommendations for altering the operating conditions, altering the monitoring strategy (frequency, type), or redesigning the process or equipment.

The tasks listed above have relatively crisp definitions, but there is still considerable room for adjustment within any condition monitoring and diagnostic program. There are always questions, concerning such things as how much data to collect and how much time to spend on data analysis, that need to be considered before the final program is put in place. As mentioned above, things such as equipment class, size, importance within the process, replacement cost, availability, and safety need to be carefully considered. Different pieces of equipment or processes may require different monitoring strategies.

25.5.1 Periodic Monitoring

Periodic monitoring involves intermittent data gathering and analysis with portable, removable monitoring equipment. On occasion, permanent monitoring hardware may be used for this type of monitoring strategy, but data is only collected at specific times. This type of monitoring is usually applied to noncritical equipment where failure modes are well known (historically dependable equipment). Trending of condition and severity level checks are the main focus, with problems triggering more rigorous investigations.

25.5.2 Continuous Monitoring

Constant or very frequent data collection and analysis is referred to as continuous monitoring. Permanently installed monitoring systems are typically used, with samples and analysis of data done automatically. This type of monitoring is carried out on critical equipment (expensive to replace, with downtime and lost production also being expensive). Changes in condition trigger more detailed investigation or possibly an automatic shutdown of the equipment.

- Potential advantages of machine condition monitoring include increased machine availability and reliability, improved efficiency, reduced costs, extended operational life, and improved safety.
- Some of the disadvantages of condition monitoring include monitoring equipment costs, operational costs, and training costs.
- The ultimate goal of machine condition monitoring and fault diagnostics is to get useful information on the condition of equipment to the people who need it, in a timely manner.
- The specific tasks which must be carried out to complete a successful machine condition monitoring and fault diagnostics program include detection, diagnosis, prognosis, postmortem, and prescription.

25.6 Transducer Selection

A transducer is a device that senses a physical quantity (vibration in this case, but it can also be temperature, pressure, etc.) and converts it into an electrical output signal, which is proportional to the measured variable (see Chapter 15). As such, the transducer is a vital link in the measurement chain. Accurate analysis results depend on an accurate electrical reproduction of the measured parameters. If information is missed or distorted during measurement, it cannot be recovered later. Hence, the selection, placement, and proper use of the correct transducer are important steps in the implementation of a condition monitoring and fault diagnostics program.

Considerable research and development work has gone into the design, testing, and calibration of sensors (transducers) for a wide range of applications. The transducer must be:

- Correct for the task
- Properly mounted
- In good working order (properly calibrated)
- Fully understood in terms of operational characteristics

Transducers usually require amplification and conversion electronics to produce a useful output signal. These circuits may be located within the sealed sensor unit or in a separate box. There are advantages and disadvantages to both of these configurations but they will not be detailed here. Traditional vibration sensors fall into three main classes:

- Noncontact displacement transducers (also known as proximity probes or eddy current probes)
- Velocity transducers (electro-mechanical, piezoelectric)
- Accelerometers (piezoelectric)

Force and frequency considerations dictate the type of measurements and applications that are best suited for each transducer. Recently, laser-based noncontact velocity/displacement transducers have become more commonplace. These are still relatively expensive because of their extreme sensitivity, and hence are still predominantly used in the laboratory setting.

Figure 25.5 shows the relationship between the different transducer types in terms of response amplitude and frequency. For constant velocity vibration amplitude across all frequencies, a displacement transducer is more sensitive in the lower frequency range, while an accelerometer is more sensitive at higher frequencies. While it may appear as if the velocity transducer is the best compromise, transducers are selected to optimize sensitivity over the frequency range that is expected to be recorded.

The type of motion sensed by displacement transducers is the relative motion between the point of attachment and the observed surface. Velocity transducers and accelerometers measure the absolute motion of the structure to which they are attached.

25.6.1 Noncontact Displacement Transducers

These types of sensors find application primarily in fluid film (journal) radial or thrust bearings. With the rotor resting on a fluid film there is no way to easily attach a sensor. A noncontact approach is then the best alternative. Noncontact measurements indicate shaft motion and position relative to the bearing. Radial shaft displacements and seal clearances can be conveniently measured. Another advantage of using

FIGURE 25.5 Frequency versus response amplitude for various sensor types.

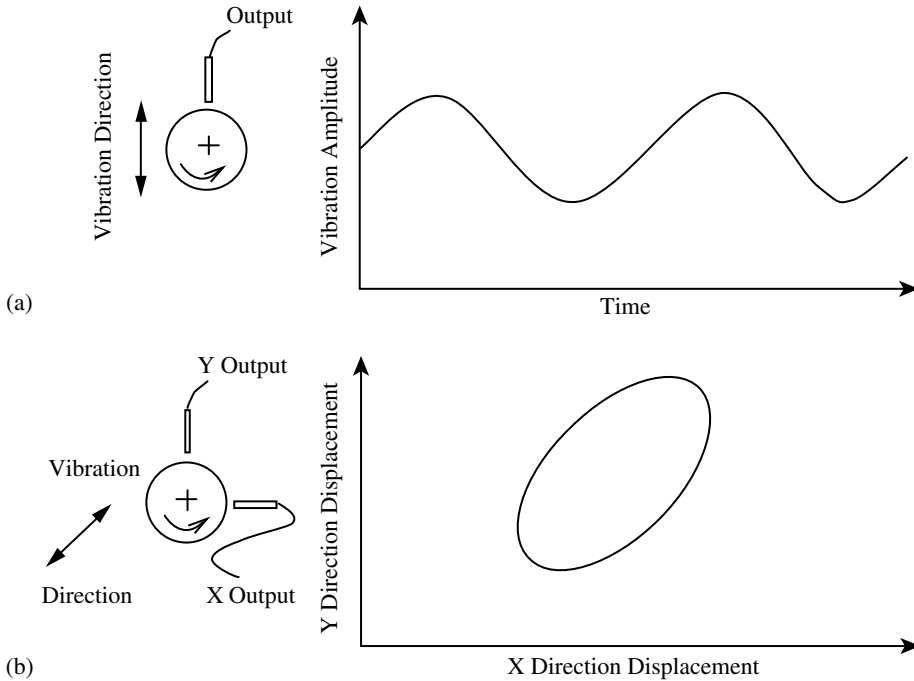

FIGURE 25.6 (a) Shaft displacement with one sensor; (b) shaft orbit with two sensors (x direction versus y direction displacement — assumes shaft is circular).

noncontact displacement probes is that when they are used in pairs, set 90° apart, the signals can be used to show shaft dynamic motion (orbit) within the bearing. Figure 25.6 shows a single channel and dual channel measurement result. When the two channels are plotted against one another, they clearly show what are known as shaft orbits. These orbits define the dynamic motion of the shaft in the bearing, and are valuable fault detection and diagnostic tools.

The linearity and sensitivity of the proximity probe depends on the target conductivity and porosity. Calibration of the probe on the specific material in use is recommended. This type of sensor is capable of both static and dynamic measurements, but temperature and pressure extremes will affect the transducer output. The probe will detect small defects in the shaft (cracks or pits), and these may seem like vibrations in the output signal.

Installation of these sensors requires a rigid mounting. Adaptors for quick removal and replacement without machine disassembly can be useful. The minimum tip clearance from all adjacent surfaces should be two times the tip diameter. Probe extensions must be checked to ensure that the resonant frequency of the extension is not excited during data gathering. As with all sensors, care must be taken when handling the cables and the connections must be kept clean.

25.6.2 Velocity Transducers

There are two general types of velocity transducers. They can be distinguished by considering the mode of operation. The two types are electro-mechanical and piezoelectric crystal based. Piezoelectric crystal-based transducers will be discussed in the next section, so the focus here will be on electro-mechanical (see Chapter 15).

Electro-mechanical velocity transducers function with a permanent magnet (supported by springs) moving within a coil of wire. As the sensor experiences changes in velocity, as when attached to a vibrating surface, the movement of the magnet within the coil is proportional to force acting on the

sensor. The current in the coil, induced by the moving magnet, is proportional to velocity, which in turn is proportional to the force. This type of device is known as “self-generating” and produces a low impedance signal; therefore, no additional signal conditioning is generally needed.

Electro-mechanical velocity sensors require the spring suspension system to be designed with a relatively low natural frequency. These devices have good sensitivity, typically above 10 Hz, but their high-frequency response is limited (usually around 1500 Hz) by the inertia of the system. Some devices may obtain a portion, or all, of their damping electrically. This type must be loaded with resistance of a specific value to meet design constraints. These are usually designed for use with a specific data collection instrument and must be checked and modified if they are to be used with other instruments. Figure 25.7 shows a plot of the sensitivity vs. frequency for an electro-mechanical velocity transducer.

While electro-mechanical velocity transducers can be designed to have good dynamic range within a specific frequency range, there are several functional limitations. Because a damping fluid is typically used to provide most of the damping, this type of transducer is limited to a relatively narrow temperature band, below the boiling point of the damping liquid. The mechanical reliability of these sensors is also limited by the moving parts within the transducer, which may become worn or fail over time. This has resulted in this type of transducer being replaced by piezoelectric sensors in machine condition monitoring applications. The orientation of the sensor is also limited to only the vertical or horizontal direction, depending on the type of mounting used. Finally, as a damped system, such as an electro-mechanical velocity transducer, approaches its natural frequency, a shift in phase relationships may occur (below 50 Hz). This phase shift at low frequencies will affect analysis work.

FIGURE 25.7 Output sensitivity vs. frequency for an electro-mechanical velocity transducer.

25.6.3 Acceleration Transducers

By far the most commonly used transducers for measuring vibration are accelerometers (see [Chapter 15](#)). These devices contain one or more piezoelectric crystal elements (natural quartz or man-made ceramics), which produce voltage when stressed in tension, compression or shear. This is the piezoelectric effect. The voltage generated across the crystal pole faces is proportional to the applied force.

Accelerometers have a linear response over a wide frequency range (0.5 Hz to 20 kHz), with specialty sensors linear up to 50 kHz. This wide linear frequency range and the broad dynamic amplitude range make accelerometers extremely versatile sensors. Figure 25.8 shows the sensitivity vs. frequency relationship for a typical accelerometer.

In addition, the signal can be electronically integrated to give velocity and displacement measurements. This type of transducer is relatively resistant to temperature changes, reliable (having no moving parts), produces a self-generating output signal meaning no external power supply is needed unless there are onboard electronics, is available in a variety of sizes, is usually relatively insensitive to nonaxial vibration

FIGURE 25.8 Typical accelerometer sensitivity vs. frequency.

(<3% of main axis sensitivity), and can function well in any orientation. Signals from this type of transducer contain significantly more vibration components than other types. This means that there is a large amount of information available in the raw vibration signal.

Installation of accelerometers requires as rigid a mount as possible. Permanent installation with studs or bolts is usually best for high speed machinery where high-frequency measurements are required. The close coupling between the machine and the sensor allows for direct transmission of the vibration to the sensor. Stud mounting requires a flat surface to give the best amplitude linearity and frequency response. This type of mounting is expensive and may not be practical if large numbers of measurements are being recorded with a portable instrument. Magnetic mounts have the advantage of being easily movable and provide good repeatability in the lower frequency range, but have limited high-frequency sensitivity (4 to 5 kHz). Hand-held measurements are useful when conducting general vibration surveys, but usually result in significant variation between measurements. The hand-held mount is least expensive but only offers frequency response below 1 kHz. Figure 25.9 shows a plot of the response curves for the same accelerometer with different mounts. For machine condition monitoring and fault diagnostics applications, there will typically be a combination of all three mounting methods used, depending on the equipment being monitored and the monitoring strategy employed.

As with the other types of vibration sensor, accelerometers have certain limitations. Because of their sensitivity and wide dynamic range, accelerometers are also sensitive to environmental input not related to the vibration signal of interest. Temperature (ambient and fluctuations) may cause distortion in the recorded signal. General purpose accelerometers are relatively insensitive to temperatures up to 250°C. At higher temperatures, the piezoelectric material may depolarize and the sensitivity may be permanently altered. Temperature transients also affect accelerometer output. Shear-type accelerometers have the lowest temperature transient sensitivity. A heat sink or mica washer between the accelerometer and a hot surface may help reduce the effects of temperature.

Piezoelectric crystals are sensitive to changes in humidity. Most accelerometers are epoxy bonded or welded together to provide a humidity barrier. Moisture migration through cables and into connections must be guarded against. Large electro-magnetic fields can also induce noise into cables that are not double shielded.

If an accelerometer is mounted on a surface that is being strained (bent), the output will be altered. This is known as base strain, and thick accelerometer bases will minimize this effect. Shear-type accelerometers are less sensitive because the piezoelectric crystal is mounted to a center post not the base.

Accelerometers are designed to remain constant for long periods of time; however, they may need calibrating if damaged by dropping or high temperatures. A known amplitude and frequency source (or another accelerometer that has a known calibration) should be used to check the calibration of accelerometers from time to time.

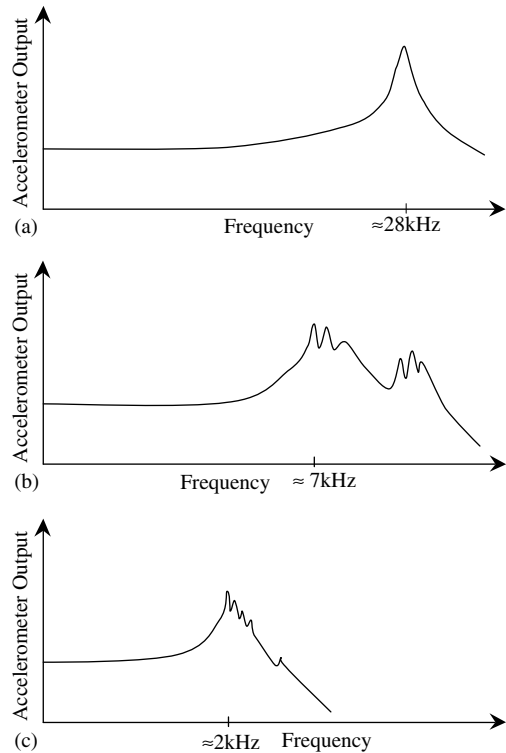

FIGURE 25.9 Accelerometer response vs. frequency for various types of mounts (a — stud; b — magnet; c — hand held).

25.7 Transducer Location

The placement (location) of a vibration transducer is a critical factor in machine condition monitoring and fault diagnostics. Using several locations and directions when recording vibration information is recommended. As always, it depends on the application and whether or not the expense is warranted. If the vibration component which relates to a given fault condition is not recorded, no amount of analysis will extract it from the signal. When selecting sensor locations consider the following:

- Mechanical independence
- The vibration transmission path
- Locations where natural frequency vibrations may be excited (flexible components or attachments)

- A transducer is a device that senses a physical quantity and converts it into an electrical output signal, which is proportional to the measured variable.
- The selection, placement, and proper use of the correct transducer are important steps in the implementation of a condition monitoring and fault diagnostics program.
- The transducer must be correct for the task, properly mounted, in good working order (properly calibrated), and fully understood in terms of operational characteristics.
- Traditional vibration sensors fall into three main classes: noncontact displacement transducers, velocity transducers, and accelerometers.
- Transducers are selected to optimize sensitivity over the frequency range that is expected to be recorded.
- Using several locations and directions when recording vibration information is recommended.
- When selecting sensor locations, one must consider mechanical independence, the vibration transmission path, and locations where natural frequency vibrations may be excited.

25.8 Recording and Analysis Instrumentation

25.8.1 Vibration Meters

Vibration meters are generally small, hand-held (portable), inexpensive, simple to use, self-contained devices that give an overall vibration level reading (see [Chapter 15](#)). They are used for walk-around surveys and measure velocity and/or acceleration. Generally, these devices have no built-in diagnostics capability, but the natural frequency of an accelerometer can be exploited to look for specific machinery faults. As an example, rolling element bearings generally emit “spike” energy during the early stages of deterioration. These are sharp impacts as rollers strike defects (pits, cracks) in the races. A spike energy meter is an accelerometer that has been tuned to have its resonant frequency excited by these impacts, thus giving a very early warning of deteriorating bearings.

25.8.2 Data Collectors

Most vibration data collectors available today for use in machine condition monitoring and fault diagnostics are microcomputer based. They are used together with vibration sensors to measure vibration, to store and transfer data, and for frequency domain analysis. Considerably more data can be recorded in a digital form, but the cost of these devices can also be considerable. Another

advantage of most data collectors is the ability to use these devices to conduct on-the-spot diagnostics or balancing. They are usually used with a PC to provide permanent data storage and a platform for more detailed analysis software. Data collectors are usually used on general-purpose equipment.

25.8.3 Frequency-Domain Analyzers

The frequency-domain analyzer is perhaps the key instrument for diagnostic work. Different machine conditions (unbalance, misalignment, looseness, bearing flaws) all generate characteristic patterns that are usually visible in the frequency domain. While data collectors do provide some frequency domain analysis capability, their main purpose is data collection. Frequency-domain analyzers are specialized instruments that emphasize the analysis of vibration signals. As such, they are often treated as a laboratory instrument. Generally, analyzers will have superior frequency resolution, filtering ability (including antialiasing), weighting functions for the elimination of leakage, averaging capabilities (both in the time and frequency domains), envelope detection (demodulation), transient capture, large memory, order tracking, cascade/waterfall display, and zoom features. Dual-channel analysis is also common.

25.8.4 Time-Domain Instruments

Time-domain instruments are generally only able to provide a time domain display of the vibration waveform. Some devices have limited frequency-domain capabilities. While this restriction may seem limiting, the low cost of these devices and the fact that some vibration characteristics and trends show up well in the time domain make them valuable tools. Oscilloscopes are the most common form. Shaft displacements (orbits), transients and synchronous time averaging (and negative averaging) are some of the analysis strategies that can be employed with this type of device.

25.8.5 Tracking Analyzers

Tracking analyzers are typically used to record and analyze data from machines that are changing speed. This usually occurs during run-up and coast-down of large machinery or turbo-machinery. These measurements are typically used to locate machine resonances and unbalance conditions. The tracking rate is dependent on filter bandwidth, and there is a need for a reference signal to track speed (tachometer input). These devices usually have variable input sensitivity and a large dynamic range.

- Vibration meters are generally small, hand-held (portable), inexpensive, simple to use, self-contained devices that give an overall vibration level reading.
- Most vibration data collectors available today for use in machine condition monitoring and fault diagnostics are microcomputer based. They are used together with vibration sensors to measure vibration, to store and transfer data, and for frequency domain analysis.
- Frequency domain analyzers are specialized instruments that emphasize the analysis of vibration signals, and as such they are perhaps the key instrument for diagnostic work.
- Time domain instruments are generally only able to provide a time domain display of the vibration waveform.
- Tracking analyzers are typically used to record and analyze data (locate machine resonances and unbalance conditions) from machines that are changing speed. This usually occurs during run-up and coast-down of large machinery or turbo-machinery.

25.9 Display Formats and Analysis Tools

Vibration signals can be displayed in a variety of different formats. Each format has advantages and disadvantages, but generally the more processing that is done on the dynamic signal, the more specific information is highlighted and the more extraneous information is discarded. The broad display formats that will be discussed here are the time domain, the frequency domain, the modal domain, and the quefrequency domain. Within each of these display formats, several different analysis tools (some specific to that display format) will be described.

25.9.1 Time Domain

The time domain refers to a display or analysis of the vibration data as a function of time. The principal advantage of this format is that little or no data are lost prior to inspection. This allows for a great deal of detailed analysis. However, the disadvantage is that there is often too much data for easy and clear fault diagnosis. Time-domain analysis of vibration signals can be subdivided into the following sections.

25.9.1.1 Time-Waveform Analysis

Time-waveform analysis involves the visual inspection of the time-history of the vibration signal. The general nature of the vibration signal can be clearly seen and distinctions made between sinusoidal, random, repetitive, and transient events. Nonsteady-state conditions, such as run-up and coast-down, are most easily captured and analyzed using time waveforms. High-speed sampling can reveal such defects as broken gear teeth and cracked bearing races, but can also result in extremely large amounts of data being collected — much of which is likely to be redundant and of little use.

25.9.1.2 Time-Waveform Indices

A time-waveform index is a single number calculated in some way based on the raw vibration signal and used for trending and comparisons. These indices significantly reduce the amount of data that is presented for inspection, but highlight differences between samples. Examples of time-waveform-based indices include the peak level (maximum vibration amplitude within a given time signal), mean level (average vibration amplitude), root-mean-square (RMS) level (peak level/ $\sqrt{2}$; reduces the effect of spurious peaks caused by noise or transient events), and peak-to-peak amplitude (maximum positive to maximum negative signal amplitudes). All of these measures are affected adversely when more than one machinery component contributes to the measured signal. The crest factor is the ratio of the peak level to the RMS level (peak level/RMS level), and indicates the early stages of rolling-element-bearing failure. However, the crest factor decreases with progressive failure because the RMS level generally increases with progressive failure.

25.9.1.3 Time-Synchronous Averaging

Averaging of the vibration signal synchronous with the running speed of the machinery being monitored is called time-synchronous averaging. When taken over many machine cycles, this technique removes background noise and nonsynchronous events (random transients) from the vibration signal. This technique is extremely useful where multiple shafts that are operating at only slightly different speeds and in close proximity to one another are being monitored. A reference signal (usually from a tachometer) is always needed.

25.9.1.4 Negative Averaging

Negative averaging works in the opposite way to time-synchronous averaging. Rather than averaging all the collected data, a baseline signal is recorded and then subtracted from all subsequent signals to reveal changes and transients only. This type of signal processing is useful on equipment or components that are isolated from other sources of vibrations.

25.9.1.5 Orbits

As described above, orbits are plots of the X direction displacement vs. the Y direction displacement (phase shifted by 90°). This display format shows journal bearing relative motion (bearing wear, shaft misalignment, shaft unbalance, lubrication instabilities [whirl, whip], and seal rubs) extremely well, and hence is a powerful monitoring and diagnostic tool, especially on relatively low-speed machinery.

25.9.1.6 Probability Density Functions

The probability of finding the instantaneous amplitude value from a vibration signal within a certain amplitude range can be represented as a probability density function. Typically, the shape of the probability density function in these cases will be similar to a Gaussian (or normal) probability distribution. Fault conditions will have different characteristic shapes. Figure 25.10 shows two probability density functions. One is characteristic of normal machine operating conditions, and the other represents a fault condition. A high probability at the mean value with a wide spread of low probabilities is characteristic of the impulsive time-domain waveforms that are typical for rolling-element-bearing faults. This type of display format can be used for condition trending and fault diagnostics.

FIGURE 25.10 Normalized vibration amplitude vs. probability density (normal and faulty bearings).

25.9.1.7 Probability Density Moments

Probability density moments are single-number indices (descriptors), similar to the time-waveform indices except they are based on the probability density function. Odd moments (first and third, mean and skewness) reflect the probability density function peak position relative to the mean. Even moments (second and fourth, standard deviation and kurtosis) are proportional to the spread of the distribution. Perhaps the most useful of these indices is the kurtosis, which is sensitive to the impulsiveness in the vibration signal and therefore sensitive to the type of vibration signal generated in the early stages of a rolling-element-bearing fault. Because of this characteristic sensitivity, the kurtosis index is a useful fault detection tool. However, it is not good for trending. As a rolling-element-bearing fault worsens, the vibration signal becomes more random, the impulsiveness disappears, and the noise floor increases in amplitude. The kurtosis then increases in value during the early stages of a fault, and decreases in value as the fault worsens.

25.9.2 Frequency Domain

The frequency domain refers to a display or analysis of the vibration data as a function of frequency. The time-domain vibration signal is typically processed into the frequency domain by applying a Fourier transform, usually in the form of a fast Fourier transform (FFT) algorithm. The principal advantage of this format is that the repetitive nature of the vibration signal is clearly displayed as peaks in the frequency spectrum at the frequencies where the repetition takes place. This allows for faults, which usually generate specific characteristic frequency responses, to be detected early, diagnosed accurately, and trended over time as the condition deteriorates. However, the disadvantage of frequency-domain analysis is that a significant amount of information (transients, nonrepetitive signal components) may be lost during the transformation process. This information is nonretrievable unless a permanent record of the raw vibration signal has been made.

25.9.2.1 Band-Pass Analysis

Band-pass analysis is perhaps the most basic of all frequency-domain analysis techniques, and involves filtering the vibration signal above and/or below specific frequencies in order to reduce the amount of information presented in the spectrum to a set band of frequencies. These frequencies are typically where fault characteristic responses are anticipated. Changes in the vibration signal outside the frequency band of interest are not displayed.

25.9.2.2 Shock Pulse (Spike Energy)

The shock-pulse index (also known as spike energy; Boto, 1979) is derived when an accelerometer is tuned such that the resonant frequency of the device is close to the characteristic responses frequency caused by a specific type of machine fault. Typically, accelerometers are designed so that their natural frequency is significantly above the expected response signals that will be measured. If higher frequencies are expected, they are filtered out of the vibration signal. High-speed rolling-element bearings that are experiencing the earlier stages of failure (pitting on interacting surfaces) emit vibration energy in a relatively high, but closely defined, frequency band. An accelerometer that is tuned to 32 kHz will be a sensitive detection device. This type of device is simple, effective, and inexpensive tool for fault detection in high-speed rolling-element bearings. The response from this type of device is load-dependent and may be prone to false alarms if measurement conditions are not constant.

25.9.2.3 Enveloped Spectrum

Another powerful analysis tool that is available in the frequency domain and can be effectively applied to detecting and diagnosing rolling-element-bearing faults is the enveloped spectrum (Courrech, 1985). When the vibration signal time waveform is demodulated (high-pass filtered, rectified, then low-pass filtered) the frequency spectrum that results is said to be enveloped. This process effectively filters out the impulsive components in signals that have high noise levels and other strong transient signal components, leaving only the components that are related to the bearing characteristic defect frequencies. This method of analysis is useful for detecting bearing damage in complex machinery where the vibration signal may be contaminated by signals from other sources. However, the filtering bands must be chosen with good judgment. Recall also, the impulsive nature of the fault signal at the characteristic defect frequency leaves as the fault deteriorates.

25.9.2.4 Signature Spectrum

The signature spectrum (Braun, 1986) is a baseline frequency spectrum taken from new or recently overhauled machinery. It is then later compared with spectra taken from the same machinery that represent current conditions. The unique nature of each machine and installation is automatically taken into account. Characteristic component and fault frequencies can be clearly seen and comparisons made manually (by eye), using indices, or using automated pattern recognition techniques.

25.9.2.5 Cascades (Waterfall Plots)

Cascade plots (also known as waterfall plots) are successive spectra plotted with respect to time and displayed in a three-dimensional manner. Changing trends can be seen easily, which makes this type of display a useful fault detection and trending tool. This type of display is also used when a transient event, such as a coast-down, is known to be about to occur. Cascade plots can also be linked to the speed of a machine. In this case, the horizontal axis is labeled in multiples of the rotational speed of the machine. Each multiple of the rotational speed is referred to as an "order."

"Order tracking" is the name commonly used to refer to cascade plots that are synchronously linked to the machine rotational speed *via* a tachometer. As the speed of the machine changes, the responses at specific frequencies change relative to the speed, but are still tracked in each time-stamped spectra by the changing horizontal axis scale.

25.9.2.6 Masks

Like negative averaging in the time domain, masks are baseline spectra that are used with an allowable tolerance limit to “filter out,” or block, specific frequencies. This technique is similar to band-pass analysis and requires a good knowledge of the full range of each machine’s operating limits (varying load or speed).

25.9.2.7 Frequency-Domain Indices

It has been noted that frequency spectra are more sensitive to changes related to machine condition (Mathew, 1987). Because of this sensitivity, several single number indices based on the frequency spectra have been proposed. Like the time-waveform indices, frequency-domain indices reduce the amount of information in frequency spectra to a single number. Because they are based on the frequency spectra, they are generally more sensitive to changes in machine condition than time domain indices. They are used as a means of comparing original spectra or previous spectra to the current spectra. Several frequency domain indices are listed below:

- Arithmetic mean (Grove, 1979):

$$20 \log \left\{ \left(\frac{1}{N} \sum_{i=1}^N A_i \right) / 10^{-5} \right\}$$

A_i = amplitude of i th frequency spectrum component

N = total number of frequency spectrum components

- Geometric mean (Grove, 1979):

$$\frac{1}{N} \left\{ \sum_{i=1}^N 20 \log \left(\left(\frac{A_i}{\sqrt{2}} \right) / 10^{-5} \right) \right\}$$

- Matched filter RMS (Mathew and Alfredson, 1984):

$$10 \log \left\{ \frac{1}{N} \sum_{i=1}^N \left(\frac{A_i}{A_{i(\text{ref})}} \right)^2 \right\}$$

$A_{i(\text{ref})}$ = amplitude of i th component in the reference spectrum

- RMS of spectral difference (Alfredson, 1982):

$$\left\{ \frac{1}{N} \sum_{i=1}^N (L_{ci} - L_{oi})^2 \right\}^{1/2}$$

L_{ci} = amplitude (dB) of i th component

L_{oi} = amplitude (dB) of i th reference component

- Sum of squares of difference (Mathew and Alfredson, 1984):

$$\left\{ \frac{1}{N} \sum_{i=1}^N [(L_{ci} + L_{oi}) \times |L_{ci} - L_{oi}|]^{1/2} \right\}$$

25.9.3 Modal Domain

Modal analysis is not traditionally listed as a machine condition monitoring and fault diagnostics tool, but is included here because of the ever-increasing complexity of modern machinery. Often, unless the

natural (free and forced response) frequencies of machinery, their support structure, and the surrounding buildings are fully understood, a complete and accurate assessment of existing machinery condition is not possible. A complete overview of modal analysis will not be provided here, but a specific approach to modal analysis (operational deflection shape [ODS] analysis) will be described.

ODS analysis is like other types of modal analysis in that a force input is provided to a structure or machine and then the response is measured. The response at different frequencies defines the natural frequencies of the structure or machine. Typically, an impact or constant frequency force is used to excite the structure. In the case of ODSs, the regular operation of the machinery provides the excitation input. With vibration sensors placed at critical locations and a reference signal linking together all the recorded signals, a simple animation showing how the machine or structure deflects under normal operation can be generated. These animations, along with the frequency information contained in each individual signal, can provide significant insights into how a machine or structure deforms under a dynamic load. This information, in turn, can be a useful addition to other data when attempting to diagnose problems.

25.9.4 Quefrency Domain

A quefrency-domain (Randall, 1981, 1987) plot results when a Fourier transform of a frequency spectra (log scale) is generated. As the frequency spectra highlight periodicities in the time waveform, so the quefrency “cepstra” highlights periodicities in a frequency spectra. This analysis procedure is particularly useful when analyzing gearbox vibration signals where modulation components in spectrum (sidebands) are easily detected and diagnosed in the cepstrum.

- Generally, the more processing that is done on the dynamic signal, the more specific useful information is highlighted and the more extraneous information is discarded.
- The primary display formats used in machine condition monitoring are the time domain, the frequency domain, the modal domain, and the quefrency domain.
- The time domain refers to a display or analysis of the vibration data as a function of time, allowing for little or no data to be lost prior to inspection.
- Time domain analysis includes: waveform analysis, time waveform indices, time synchronous averaging, negative averaging, orbit analysis, probability density functions, and probability density moments.
- The frequency domain refers to a display or analysis of the vibration data as a function of frequency, where the time domain vibration signal is typically processed into the frequency domain by applying a Fourier transform, usually in the form of a FFT algorithm.
- The principal advantage of frequency-domain analysis is that the repetitive nature of the vibration signal is clearly displayed as peaks in the frequency spectrum at the frequencies where the repetition takes place. This allows for faults, which usually generate specific characteristic frequency responses, to be detected early, diagnosed accurately, and trended over time as the condition deteriorates.
- Frequency-domain analysis includes the use of band pass analysis, shock pulse (spike energy), envelope spectrum, signature spectrum, cascades (waterfall plots), masks, and frequency-domain indices.
- Quefrency-domain analysis involves a Fourier transform of a frequency spectra (log scale). As the frequency spectra highlight periodicities in the time waveform, so the quefrency “cepstra” highlights periodicities in a frequency spectra.

25.10 Fault Detection

In many discussions of machine condition monitoring and fault diagnostics, the distinction between fault detection and fault diagnosis is not made. Here, they have been divided into separate sections in order to highlight the differences and clarify why they should be treated as separate tasks. Fault detection can be defined as the departure of a measurement parameter from a range that is known to represent normal operation. Such a departure then signals the existence of a faulty condition. Given that measurement parameters are being recorded, what is needed for fault detection is a definition of an acceptable range for the measurement parameters to fall within. There are two methods for setting suitable ranges: (1) comparison of recorded signals to known standards and (2) comparison of the recorded signals to acceptance limits.

25.10.1 Standards

One of the best known sources of standards is the International Organization for Standardization (ISO). These standards are technology oriented and are set by teams of international experts. ISO Technical Committee 108, Sub-Committee 5 is responsible for standards for condition monitoring and diagnostics of machines. This group is further divided into a number of working groups who review data and draft preliminary standards. Each working group has a particular focus such as terminology, data interpretation, performance monitoring, or tribology-based machine condition monitoring.

While ISO is perhaps the most widely known standardization organization, there are several others that are focused on specific industries. Examples of these include the International Electrical Commission, which is primarily product oriented, and the American National Standards Institute (ANSI), which is a nongovernment agency. There are also different domestic government agencies that vary from country to country. National defense departments also tend to set their own standards.

25.10.1.1 Standards Based on Machinery Type

Because different machines that are designed to perform approximately the same task tend to behave in a similar manner, it is not surprising that many standards are set based on machinery type. Figure 25.11 shows a generic plot separating vibration amplitude vs. rotating speed into different zones. For a specific type, size, or class of machine, a plot like this can be used to distinguish gross vibration limits relative to the speed of operation. Machines are usually divided into four basic categories:

1. *Reciprocating machinery*: These machines may contain both rotating and reciprocating components (e.g., engines, compressors, pumps).
2. *Rotating machinery (rigid rotors)*: These machines have rotors that are supported on rolling element bearings (usually). The vibration signal can be measured from the bearing housing because the vibration signal is transmitted well through the bearings to the housing (e.g., electric motors, single-stage pumps, slow-speed pumps).

FIGURE 25.11 Normalized vibration amplitude vs. probability density (zone A — new machine; zone B — acceptable; zone C — monitor closely; zone D — damage occurring).

- 3. *Rotating machinery (flexible rotors)*: These machines have rotors that are supported on journal (fluid film) bearings. The movement of the rotor must be measured using proximity probes (e.g., large steam turbines, multistage pumps, compressors). These machines are subject to critical speeds (high vibration levels when the speed of rotation excites a natural frequency). Different modes of vibration may occur at different speeds.
- 4. *Rotating machinery (quasi-rigid rotors)*: These are usually specialty machines in which some vibration gets through the bearings, but it is not always trustworthy data (e.g., low-pressure steam turbines, axial flow compressors, fans).

25.10.1.2 Standards Based on Vibration Severity

It is an oversimplification to say that vibration levels must always be kept low. Standards depend on many things, including the speed of the machinery, the type and size of the machine, the service (load) expected, the mounting system, and the effect of machinery vibration on the surrounding environment. Standards that are based on vibration severity can be divided into two basic categories:

- 1. *Small-to-medium sized machines*: These machines usually operate with shaft speeds of between 600 and 12,000 rpm. The highest broadband RMS value usually occurs in the frequency range of 10 to 1000 Hz.
- 2. *Large machines*: These machines usually operate with shaft speeds of 600 to 1200 rpm. If the machine is rigidly supported, the machine’s fundamental resonant frequency will be above the main excitation frequency. If the machine is mounted on a flexible support, the machine’s fundamental resonant frequency will be below the main excitation frequency.

While general standards do exist, there are also a large number of standards that have been developed for specific machines. Figure 25.12 shows a table with generic acceptance limits based on vibration severity.

25.10.2 Acceptance Limits

Standards developed by dedicated organizations are a useful starting point for judging machine condition. They give a good indication of the current condition of a machine and whether or not a fault exists. However, judging the overall condition of machinery is often more involved. Recognizing the changing machinery condition requires the trending of condition indicators over time. The development and use of acceptance limits that are close to the normal operating values for specific machinery will detect even slight changes in condition. While these acceptance limits must be tight enough to allow even small changes in condition to be detected, they must also tolerate normal operating variations without

Vibration Amplitude Increasing ↓	Vibration Severity for Separate Classes of Machines			
	Class I	Class II	Class III	Class IV
	A	A		
	B	B	A	A
	C	C	B	B
	D	D	C	C
			D	D

FIGURE 25.12 Acceptance limits based on vibration severity levels (zone A — new machine; zone B — acceptable; zone C — monitor closely; zone D — damage occurring).

generating false alarms. There are two types of limits:

1. *Absolute limits* represent conditions that could result in catastrophic failure. These limits are usually physical constraints such as the allowable movement of a rotating part before contact is made with stationary parts.
2. *Change limits* are essentially warning levels that provide warning well in advance of the absolute limit. These vibration limits are set based on standards and experience with a particular class of machinery or a particular machine. Change limits are usually based on overall vibration levels.

It is important to note that the early discovery of faulty conditions is a key to optimizing maintenance effort by allowing the longest possible lead-time for decision making. As well as the overall vibration levels being monitored, the rates of change are also important. The rate of change of a vibration level will often provide a strong indication of the expected time until absolute limits are exceeded. In general, relatively high but stable vibration levels are of less concern than relatively low but rapidly increasing levels.

An example of how acceptance limits may be used to detect faults and trend condition is provided when the gradual deterioration of rolling-element bearings is considered. Rolling-element bearings generate distinctive defect characteristic frequencies in the frequency spectrum during a slow, progressive failure. Vibration levels can be monitored to achieve maximum useful life and failure avoidance. Typically, the vibration levels increase as a fault is initiated in the early stages of deterioration, but then decrease in the later stages as the deterioration becomes more advanced. Appropriately, set acceptance levels will detect the early onset of the fault and allow subsequent monitoring to take place even after the overall vibration level has dropped. However, rapid bearing deterioration may still occur due to a sudden loss of lubrication, lubrication contamination, or a sudden overload. The possibility of these situations emphasizes the need for carefully selected acceptance limits.

It should also be noted that changes in operating conditions, such as speed or load changes, could invalidate time trends. Comparisons must take this into consideration.

25.10.2.1 Statistical Limits

Statistical acceptance limits are set using statistical information calculated from the vibration signals measured from the equipment that the limits will ultimately be used with. As many vibration signals as possible are recorded, and the average of the overall vibration level is calculated. An alert or warning level can then be set at 2.5 standard deviations above or below the average reading (Mechefske, 1998). This level has been found to provide optimum sensitivity to small changes in machine condition and maximum immunity to false alarms. A distinct advantage to using this method to set alarm levels is the fact that the settings are based on actual conditions being experienced by the machine that is being monitored. This process accommodates normal variations that exist between machines and takes into account the initial condition of the machine.

25.10.3 Frequency-Domain Limits

Judging vibration characteristics within the frequency spectra is sometimes a more accurate method of detecting and trending fault conditions. It can also provide earlier detection of specific faults because, as mentioned previously, the frequency domain is generally more sensitive to changes in the vibration signal that result from changes in machine condition. The different specific methods are listed and described below.

25.10.3.1 Limited Band Monitoring

In limited band monitoring, the frequency spectrum is divided into frequency bands. The total energy or highest amplitude frequency is then trended within each band. Each band has its own limits based on experience. Generally, ten or fewer bands are used. Small changes in component-specific frequency

ranges are more clearly shown using this strategy. Bandwidths and limits must be specific to the machine, sensor type, and location. Narrowband monitoring is the same as limited band monitoring, except it has finer definition of the bands.

25.10.3.2 Constant Bandwidth Limits

When limited band monitoring is practiced and the bands have same width at high and low frequencies, the procedure is called constant bandwidth monitoring (see Figure 25.13). This technique is useful for constant speed machines where the frequency peaks in the spectra remain relatively fixed.

25.10.3.3 Constant Percentage Bandwidth Limits

Constant percentage bandwidth monitoring involves using bandwidths that remain a constant percentage of the frequency being monitored (see Figure 25.14). This results in the higher frequency bands being proportionally wider than the lower frequency bands. This allows for small variations

FIGURE 25.13 Constant bandwidth acceptance limits.

FIGURE 25.14 Constant percentage bandwidth acceptance limits.

in speed without the frequency peaks moving between bands, which may have different acceptance limits.

- Fault detection can be defined as the departure of a measurement parameter from a range that is known to represent normal operation. Such a departure signals the existence of a faulty condition.
- ISO Technical Committee 108, Sub-Committee 5 is responsible for standards for Condition Monitoring and Diagnostics of Machines.
- Standards are based on machinery type or vibration severity.
- The development and use of acceptance limits that are close to normal operating values for specific machinery will detect even slight changes in condition.
- Statistical acceptance limits are set using statistical information calculated from the vibration signals measured from the equipment that the limits will ultimately be used with.
- Judging vibration characteristics within the frequency spectra is sometimes a more accurate method of the early detecting and trending of fault conditions because the frequency domain is generally more sensitive to changes in the vibration signal that result from changes in machine condition.
- Frequency domain limits include limited band monitoring, constant bandwidth limits, and constant percentage bandwidth limits.

25.11 Fault Diagnostics

Depending on the type of equipment being monitored and the maintenance strategy being followed, once a faulty condition has been detected and the severity of the fault assessed, repair work or replacement will be scheduled. However, in many situations, the maintenance strategy involves further analysis of the vibration signal to determine the actual type of fault present. This information then allows for a more accurate estimation of the remaining life, the replacement parts that are needed, and the maintenance tools, personnel, and time required to repair the machinery. For these reasons, and many more, it is often advantageous to have some idea of the fault type that exists before decisions regarding maintenance actions are made.

There are obviously a large number of potential different fault types. The description of these faults can be systemized somewhat by considering the type of characteristic defect frequencies generated (synchronous to rotating speed, subsynchronous, harmonics related to rotating speed, nonsynchronous harmonics, etc.). Such a systemization requires a focus on frequency-domain analysis tools (primarily frequency spectra). While this organization strategy is effective, it inherently leaves out potentially valuable information from other display formats. For this reason, the various faults that usually develop in machinery are listed here in terms of the forcing functions that cause them and specific machine types. In this way, a diagnostic template can be developed for the different types of faults that are common in a given facility or plant. Further reading on machinery diagnostics can be found in these references: Wowk (1991), Taylor (1994), Eisenmann and Eisenmann (1998), Goldman (1999), and Reeves (1999).

25.11.1 Forcing Functions

Listed and described below are a variety of forcing functions that can result in accelerated deterioration of machinery or are the result of damaged or worn mechanical components. The list is not meant to be exhaustive and is in no particular order.

25.11.1.1 Unbalance

Unbalance (also referred to as imbalance) exists when the center of mass of a rotating component is not coincident with the center of rotation. It is practically impossible to fabricate a component that is perfectly balanced; hence, unbalance is a relatively common condition in a rotor or other rotating component (flywheel, fan, gear, etc.). The degree to which an unbalance affects the operation of machinery dictates whether or not it is a problem.

The causes of unbalance include excess mass on one side of the rotor, low tolerances during fabrication (casting, machining, assembly), variation within materials (voids, porosity, inclusions, etc.), nonsymmetry of design, aerodynamic forces, and temperature changes. The vector sum of all the different sources of unbalance can be combined into a single vector. This vector then represents an imaginary heavy spot on the rotor. If this heavy spot can be located and the unbalance force quantified, then placing an appropriate weight 180° from the heavy spot will counteract the original unbalance. If left uncorrected, unbalance can result in excessive bearing wear, fatigue in support structures, decreased product quality, power losses, and disturbed adjacent machinery.

Unbalance results in a periodic vibration signal with the same amplitude each shaft rotation (360°). A strong radial vibration at the fundamental frequency, $1X$, ($1 \times$ rotational speed) is the characteristic diagnostic symptom. If the rotor is overhung, there will also be a strong axial vibration at $1X$. The amplitude of the response is related to the square of the rotational speed, making unbalance a dangerous condition in machinery that runs at high rotational speeds. In variable speed machines (or machines that must be run-up to speed gradually), the effects of unbalance will vary with the shaft rotational speed. At low speeds, the high spot (location of maximum displacement of the shaft) will be at the same location as the unbalance. At increased speeds, the high spot will lag behind the unbalance location. At the shaft first critical speed (the first resonance), the lag reaches 90° , and at the second critical and above, the lag reaches 180° .

A special form of unbalance is caused by a bent shaft or bowed rotor. These two conditions are essentially the same; only the location distinguishes them. A bent shaft is located outside the machine housing, while a bowed rotor is inside the machine housing. This condition is seen on large machines (with heavy rotors) that have been allowed to sit idle for a long time. Gravity and time cause the natural sag in the rotor to become permanent.

The vibration spectrum from a machine with a bent shaft or bowed rotor is identical to unbalance, largely because it is an unbalanced condition. Bent shafts and bowed rotors are difficult to correct (straighten), so they need to be balanced by adding counterweights as described above. The best way to avoid this condition is to keep the shaft/rotor rotating slowly when the machine is not in use.

25.11.1.2 Misalignment

While misalignment can occur in several different places (between shafts and bearings, between gears, etc.), the most common form is when two machines are coupled together. In this case, there are two main categories of misalignment: (1) parallel misalignment (also known as offset) and (2) angular misalignment. Parallel misalignment occurs when shaft centerlines are parallel but offset from one another in the horizontal or vertical direction, or a combination of both. Angular misalignment occurs when the shaft centerlines meet at an angle. The intersection may be at the driver or driven end, between the coupled units or behind one of the coupled units. Most misalignment is a combination of these two types.

Misalignment is another major cause of excessive machinery vibration. It is usually caused by improper machine installation. Flexible couplings can tolerate some shaft misalignment, but misalignment should always be minimized.

The vibration caused by misalignment results in excessive radial loads on bearings, which in turn causes premature bearing failure. Elevated $1X$ vibrations with harmonics (usually up to the third, but sometimes up to the sixth) in the frequency spectrum are the usual diagnostic signatures. The harmonics

TABLE 25.1 Characteristics that Can Help Distinguish between Unbalance and Misalignment

Unbalance	Misalignment
High 1X response in frequency spectra	High harmonics of 1X relative to 1X
Low axial vibration levels	High axial vibration levels
Measurements at different locations are in phase	Measurements at different locations are 180° out of phase
Vibration levels are independent of temperature	Vibration levels are dependent on temperature (change during warm-up)
Vibration level at 1X increases with rotational speed. Centrifugal force increases as the square of the shaft rotational speed	Vibration level does not change with rotational speed. Forces due to misalignment remain relatively constant with changes in shaft rotational speed

allow misalignment to be distinguished from unbalance. High horizontal relative to vertical vibration amplitude ratios (greater than 3:1) may also indicate misalignment.

One final note regarding misalignment is that the heat of operation causes metal to expand resulting in thermal growth. Vibration readings should be taken when the equipment is cold and again after normal operating temperature has been reached. The changes in alignment due to thermal growth may be minimal, but should always be measured since they can lead to significant vibration levels.

Because unbalance and misalignment are perhaps the two most common causes of excessive machinery vibrations and they have similar characteristic indicators, Table 25.1 has been included to help distinguish between them.

25.11.1.3 Mechanical Looseness

While there are many ways in which mechanical looseness may appear, there are two main types: (1) a bearing loose on a shaft and (2) a bearing loose in a housing. A bearing that is loose on a shaft will display a modulated time signal with many harmonics. The time period of modulation will vary and the time signal will also be truncated (clipped). A bearing that is loose in its housing will display a strong fourth harmonic, which can sometimes be mistaken for the blade-pass frequency on a four-blade fan. These faults may also look like rolling-element-bearing characteristic defect frequencies, but always contain a significant amount of wideband noise.

Another way to diagnose mechanical looseness is by tracking the changes in the vibrations signal as the condition worsens. In the early stages, mechanical looseness generates a strong 1X response in the frequency spectrum along with some harmonics. At this stage, the condition could be mistaken for unbalance. As the looseness worsens, the amplitude of the harmonics will increase relative to the 1X response (which may actually decrease). The overall RMS value of the time waveform may also decrease. Further deterioration of the condition results in fractional harmonics ($\frac{1}{2}$, $\frac{1}{3}$, $1\frac{1}{2}$, $2\frac{1}{2}$) increasing in amplitude. These harmonics are most visible in signals taken when the machine is only lightly loaded. These harmonics show up because of the clipping described above.

25.11.1.4 Soft Foot

Another condition that is in fact a type of mechanical looseness, but often masquerades as misalignment, unbalance, or a bent shaft, is soft foot. Soft foot occurs when one of a machine’s hold-down bolts is not tight enough to resist the dynamic forces exerted by the machine. That part of the machine will lift off and set back down as a function of the cyclical forces acting on it. All the diagnostic signs associated with mechanical looseness will be present in the vibration signal.

If the foundation (hold-down points) of a machine does not form a plane, then tightening the hold-down bolts will cause the casing and/or rotor to be distorted. This distortion is what leads to the misalignment, unbalance, and bent shaft vibration signatures. In order to check for a soft foot,

the vibration level must be monitored while each hold-down bolt is loosened and then retightened. The appearance and/or disappearance of the diagnostic indicators mentioned above will determine if soft foot is the problem. When a machine's vibration levels cannot be reduced by realignment or balancing, soft foot could well be the cause.

25.11.1.5 Rubs

Rubs are caused by excessive mechanical looseness or oil whirl. The result is that moving parts come into contact with stationary parts. The vibration signal generated may be similar to that of looseness, but is usually clouded with high levels of wideband noise. This noise is due to the impacts. If the impacts are repetitive, such as occurring each time a fan blade passes, there may be strong spectral responses at the striking frequency.

In many cases, rubs are the result of a rotor pressing too hard against a seal. In these cases, the rotor will heat up unsymmetrically and develop a bowed shape. Subsequently, a vibration signal will be generated that shows unbalance. To diagnose this condition, it will be noted that the unbalance is absent until the machine comes up to normal operating temperature.

25.11.1.6 Resonances

The analysis of resonance problems is beyond the scope of this chapter. However, some basic description is provided here because of the high likelihood that at some time a resonance will be excited by repetitive or cyclic forces acting on or nearby a machine. A resonance is the so-called "natural frequency" at which all things tend to vibrate. A machine's natural resonant frequency is dictated by the relationship $\omega_n = (k/m)^{1/2}$, where ω_n is the natural frequency, k is the spring stiffness, and m is the mass. Most systems will have more than one resonance frequency. These resonances (also called modes) can be excited by any forcing function that is at or close to that frequency. The response amplitude can be 10 to 100 times that of the forcing function. The term "critical speed" is also used to refer to resonances when the machine rotating speed equals the natural frequency.

The amount of response amplification depends on the damping in the system. A highly damped system will not show signs of resonance excitation, while a lightly damped system will be prone to resonance excitations. Resonances can be diagnosed by monitoring the vibration level while the speed of rotation of the machine is changed. A resonance will cause a dramatic increase in the 1X vibration levels as the speed is slowly changed. Most machines are designed to operate well away from known resonance frequencies, but changes to the machine (support structure, piping connections, etc.) and proximity to other machines may excite a resonance.

25.11.1.7 Oil Whirl

Oil whirl occurs when the fluid in a lightly loaded journal bearing does not exert a constant force on the shaft that is being supported and a stable operating position is not maintained. In most journal bearing designs, this situation is prevented by using pressure dams or tilt pads to insure that the shaft rides on an oil pressure gradient that is sufficient to support it. During oil whirl, the shaft pushes a wedge of oil in front of itself and the shaft then migrates in a circular fashion within the bearing clearance at just less than one half the shaft rotational speed. The rotor is actually revolving around inside the bearing in the opposite direction from shaft rotation.

Because of the inherent instability of oil whirl, in many situations where oil whirl occurs, the time waveform will show intermittent whirl events. The shaft makes a few revolutions while whirl is present and then a few revolutions where the whirl is not present. This "beating" effect is often evident in the time waveform and can be used as a diagnostic indicator.

Persistent oil whirl usually requires a replacement of the bearing. However, temporary measures to mitigate the detrimental effects include changing the oil viscosity (changing the operating temperature or the oil), running the machine in a more heavily loaded manner, or introducing a misalignment that will load the bearing asymmetrically. This last course of action is of course not recommended for more than relatively short-term relief.

25.11.1.8 Oil Whip

Oil whip occurs when a subsynchronous instability (oil whirl) excites a critical speed (resonance), which then remains at a constant frequency regardless of speed changes. Oil whip often occurs at two times the critical speed because, at that speed, oil whirl matches the critical speed. Figure 25.15 shows a waterfall (cascade) plot of a mass unbalance that excites oil whirl and oil whip. Note how the oil whip “locks on” to the critical speed resonance.

25.11.1.9 Structural Vibrations

Structural vibrations can range dramatically in amplitude and frequency. Large-amplitude, low-frequency vibrations can be excited in multistory buildings during an earthquake or by the wind. These vibrations are usually the result of a building resonance being excited. While these sources of structural vibration are important, the source that we are concerned with here is that of machinery operating as part of a building’s utility system, as part of the production plant, or construction equipment close-by. Fans, blowers, compressors, piping systems, elevators, and other building service machines all produce vibrations in a building and, if they are not properly isolated they can cause disruption and/or damage to other machines or processes operating close-by. The same is true of heavy machinery operating within a plant (stamping machines, presses, forges, etc.) and construction equipment. High-impact and repetitive vibrations can excite resonances large distances from the source of the excitation.

25.11.1.10 Foundation Problems

Machine foundations provide rigidity and inertia so that the machine stays in alignment. The energy generated by a machine in the form of vibrations is transmitted, reflected, or absorbed by the foundation. Especially on larger machines, the foundation is paramount to successful dynamic behavior. Maximum energy is transmitted through the foundation to the earth when the mechanical impedance of the foundation is well matched to that of the source of vibration. That is, the source of vibration and the foundation should have the same natural frequency. If this is the case, all frequencies of vibration below

FIGURE 25.15 Waterfall (cascade) plot of a mass unbalance that excites oil whirl and oil whip.

the natural frequency will be transmitted by the foundation to earth. A poor match will mean that more energy is reflected or absorbed by the foundation, which could effect the operation of the machine attached. Changing foundations can grossly affect amplitude and phase measurements, which means that vibration measurements can be used to easily detect a changing foundation or hold-down system.

25.11.2 Specific Machine Components

25.11.2.1 Damaged or Worn Rolling-Element Bearings

Rolling-element bearings produce very little vibration (low level random signal) when they are fault free, and have very distinctive characteristic defect frequency responses (see Eschman, 1985, for the equations for calculation of defect frequencies) when faults develop. This, and the fact that most damage in rolling-element bearings occurs and worsens gradually, makes fault detection and diagnosis on this component relatively straightforward. Faults due to normal use usually begin as a single defect caused by metal fatigue in one of the raceways or on a rolling element. The vibration signature of a damaged bearing is dominated by impulsive events at the ball or roller passing frequency. Figure 25.16 shows the characteristic time waveform and frequency spectra at various stages of damage. As the damage worsens, there is a gradual increase in the characteristic defect frequencies followed by a drop in these amplitudes and an increase in the broadband noise. In machines where there is little other vibration that would contaminate or mask the bearing vibration signal, the gradual deterioration of rolling-element bearings can be monitored by using the crest factor or the kurtosis measure (see above for definitions).

A key factor in being able to accurately detect and diagnose rolling-element-bearing defects is the placement of the vibration sensor. Because of the relatively high frequencies involved, accelerometers should be used and placed on the bearing housing as close as possible to, or within, the load zone of the stationary outer race.

Specific applications can also pose significant challenges to fault diagnosis. Very low-speed machines have bearings that generate low energy signals and require special processing to extract useful bearing condition indications (Mechefske and Mathew, 1992a). Machines that operate at varying speeds also pose a problem because the characteristic defect frequencies are continuously changing (Mechefske and Liu, 2001). Bearings located close to, or within, gearboxes are also difficult to monitor because the high energy at the gear meshing frequencies masks the bearing defect frequencies (Randall, 2001).

FIGURE 25.16 Characteristic time waveform and frequency spectra at various stages of damage in a rolling-element bearing.

25.11.2.2 Damaged or Worn Gears

Because gears transmit power from one rotating shaft to another, significant forces are present within the mating teeth. While gears are designed for robustness, the teeth do deflect under load and then rebound when unloaded. The local stresses are high at the tooth interface and root, which leads to fatigue damage. Proper design and perfect fabrication of gears (with perfect form and no defects) would result in relatively low vibration levels and a long life. However, the presence of nonperfect gears gives rise to excessive vibration (Smith, 1983).

The time waveform, the frequency spectral, and the cepstral patterns generated by gear vibrations all contain critical information needed to diagnose defects (see Figure 25.17). In relatively simple gearboxes, the time waveform can be used to distinguish impacts due to cracked, chipped, or missing teeth (McFadden and Smith, 1984, 1985). The frequency spectra and cepstra are powerful tools when the gearbox contains several sets of mating gears, which is most often the case.

Even a significant defect on one tooth (or even a missing tooth) often does not produce an abnormally strong frequency spectral response at $1X$. However, the defect will modulate the gear mesh frequency (number of teeth times the shaft rotational speed) and appear as $1X$ sidebands of the gear mesh frequency. That is, smaller spectral responses that appear a distance of $1X$ (and multiples of $1X$ for more severe gear faults) above and below the gear mesh frequency. Because these sidebands occur at multiples of $1X$ and a spectral plot can become quite cluttered with response lines, cepstral analysis is well suited to distinguish the frequency components that are strong fault indicators. Often, a change in the response at two times the gear mesh frequency is a good indicator of developing gear problems. The amplitude of the gear mesh frequency, and its multiples, vary with load. This makes it important to sample the vibration signal at the same load conditions. When unloaded, excessive gear backlash may also cause an increase in the amplitude of the gear mesh frequency.

Because each gear tooth meshes with an impact, structural resonances may be excited in the gears, shafts, and housing. Proper design of a gearbox will minimize this effect, but resonances in gearboxes cause accelerated gear wear and should be monitored.

Gears provide an excellent example of how machines must wear-in during early use. New gears will have defects that are quickly worn away in the machine's early life. Vibration levels will become steady and only increase gradually later in the machine's life as the gears wearout. These gradual increases in vibration level are normal. Sudden changes in vibration levels (at gear mesh frequency, two times gear mesh frequency, or sidebands), especially decreases, are very significant. A drop in the vibration level usually means a decrease in stiffness, and that more of the transmission forces are being absorbed due to bending of the gear teeth. Catastrophic failure is imminent. Premature gear failures are usually a symptom of other problems such as unbalance, misalignment, bent shaft, looseness, improper lubrication, or contaminated lubrication.

25.11.3 Specific Machine Types

25.11.3.1 Pumps

There are two principal types of pumps: (1) centrifugal pumps and (2) reciprocating pumps. Reciprocating pumps will be discussed in a later section. The sources of vibration in pumps are widely

FIGURE 25.17 Frequency and quefrency plots (damaged gear).

varied. In addition to the standard mechanical problems (unbalance, misalignment, worn bearings, etc.), problems that are particular to pumps include vane-pass frequency generating conditions (starvation, impeller loose on the shaft, impeller hitting something) and cavitation.

Starvation occurs when not enough liquid is not present to fill each vane on the impeller every revolution of the shaft. Pump starvation can be confused with unbalance (see Chapter 34). However, it can be distinguished by the varying amplitude 1X vibration at constant speed and the reduced load on the driving motor.

When the vanes on the impeller are striking something, the vane-pass frequency (the number of vanes times the rotational speed) is excited. Because the striking causes a force on the shaft, an unbalance is also present. The frequency spectrum will show a response at 1X and vane-pass frequency. The time waveform will show a high-frequency response (vane pass) riding on a frequency response at 1X. The vane-pass frequency is in phase with the shaft speed. If the impeller is loose on the shaft, the vane-pass frequency will be modulated by the shaft speed.

Cavitation occurs when there is sufficient negative pressure (suction) acting on the liquid in the system that it becomes a gas (it boils). This usually takes place in localized parts of the system. Cavitation usually occurs in a pump when the suction intake is restricted and the liquid vaporizes when coming off the impeller. As the fluid moves past the low pressure region, the gas bubble collapses. If the collapsing bubble is close to a solid surface, it will aggressively erode the surface. Cavitation may be caused by a local decrease in atmospheric pressure, an increase in fluid temperature, an increase in fluid velocity, a pipe obstruction, or abrupt change in direction. The vibration signal that results will have significant vibration levels at 1X with harmonics and strong spectral responses at vane-pass frequency. High-frequency broadband noise is also common. An increase in the system pressure can reduce cavitation.

Hydraulic unbalance will result if there has been poor design of suction piping (elbow close to inlet) or poor impeller design (unsymmetrical). The vibration signal will contain high 1X axial vibration components. Impeller unbalance is a specific form of mechanical unbalance as discussed above. High 1X vibration levels will result. Pipe stresses result from inadequate pipe support and cause stress on the pump casing. This may also cause misalignment. Pipe resonances can also be excited by vane-pass frequency pressure pulsations.

Diagnosis of pump problems can be improved by installing a pressure transducer in the discharge line of the pump. The measured pressure fluctuations can be processed in the same way as vibration signals. The frequencies measured represent the pressure fluctuations and the amplitude is the zero-to-peak pressure change.

25.11.3.2 Fans

Fans account for a significant number of field vibration problems due to their function and construction. Fans move air or exhaust gases that are often laden with grease, dust, sand, ash, and other corrosive and erosive particles (also see Chapter 34). Under these conditions, fans blades gain and lose material resulting in the need to regularly rebalance. The level of balance must also be relatively fine because fans often have large fan-blade diameters and operate at relatively high speeds. Fans are usually mounted on spring/damper systems to help isolate vibrations, but they are also constructed in a relatively flexible manner, which adds to the demands for fine balancing. Along with fine balancing requirements, typical problems include looseness, misalignment, bent shaft, and defective bearings.

Fans also generate a strong response at blade-pass frequency (number of blades times the shaft rotational speed). This frequency response is present during normal operation, but it can become elevated if the blades are hitting something, the fan housing is excessively flexible, or an acoustical resonance is present. Acoustical resonances are relatively common where large volumes of air are being moved through large flexible ducts and/or the fan blades are of an air-foil design.

25.11.3.3 Electric Motors

Electric motors can be divided into two groups: (1) induction motors and (2) synchronous motors. A full description will not be given here as to the differences. Like any machine, electric motors are subject to a

full range of mechanical problems, and vibrations signals can be used to detect and diagnose these problems. Apart from the conditions described elsewhere in this section, there are some problems that occur only in electric motors. For the sake of brevity, these problems and the vibration signals that typically accompany them are summarized in Table 25.2.

25.11.3.4 Steam and Gas Turbines

Steam and gas turbines (and high-speed compressors) require special mention because of the high speeds and temperatures involved. Problems on steam turbines are usually limited to looseness, unbalance, misalignment, soft foot, resonance, and rubs. As discussed above, each of these conditions has a set of characteristic vibration responses that allow for relatively straightforward diagnosis. However, because of the high speeds, this type of machinery is usually designed to be lighter and less rigid than other rotating machines. Excessive vibration can therefore lead to catastrophic failure very quickly. Because of this, high-speed turbines and compressors are designed to closer tolerances than other types of machines, and extra care is taken when balancing rotors. These machines also frequently operate above their first critical speed and sometimes between their second and third critical speeds. At these speeds, the rotor becomes quite flexible and the support bearings become very important in that they must provide the appropriate amount of damping.

Because steam and gas turbines are supported on journal bearings, most monitoring and diagnostics work will be based solely on proximity probe signals. While this is not a problem in and of itself, accelerometer signals should also be taken in order to cover the higher frequencies, which are excited by conditions such as looseness and rubs.

25.11.3.5 Compressors

Compressors act in much the same way as pumps, except that they are compressing some type of gas. They come in many different sizes, but only two principal types: (1) screw-type and (2) reciprocating compressors. Reciprocating compressors will be discussed in a later section. Screw-type compressors have a given number of lobes or vanes on a rotor and generate a vane-passing frequency. Screw compressors with multiple rotors can also generate strong 1X and harmonics up to vane-pass frequency. The close tolerances involved result in relatively high vibration levels, even when the machine is in good condition. As with pumps, signals taken from pressure transducers in the discharge line can be useful for diagnostics.

25.11.3.6 Reciprocating Machines

Reciprocating machines (gas and diesel engines, steam engines, compressors, and pumps) all have one thing in common — a piston that moves in a reciprocating manner. These machines generally have high overall vibration levels and particularly strong responses at 1X and harmonics, even when in good condition. The vibrations are caused by compressed gas pressure forces and unbalance. Vibrations at $\frac{1}{2}X$ may be present in four-stroke engines because the camshaft rotates at one half the crankshaft speed.

TABLE 25.2 Mechanical Problems Particular to Electric Motors

Condition	Vibration Indicator
Motor out of magnetic center	High spectral response at 60 Hz
Motors with broken rotor bars	High spectral response at motor running speed and/or second harmonic
Motor with turn-to-turn shorts in the windings	Motor runs at a slower than expected speed (high slit frequency)
Motor out of magnetic center with broken rotor bars or turn-to-turn shorts in the windings	Side bands of slip frequency times the number of poles centered around the motor running speed and harmonics of the running speed

Many engines operate at variable speeds, which will allow the strong forcing functions to excite resonances of the components and the mounting structure, if it is not designed in a robust manner. Excessive vibrations in reciprocating machines usually occur due to operational problems such as misfiring, piston slap, compression leaks, and faulty fuel injection. These problems result in elevated $\frac{1}{2}X$ vibrations, if only one cylinder is affected, and a decrease in efficiency and power output. Gear and bearing problems may also occur in reciprocating machines, but the characteristic defect frequencies for these faults are significantly higher.

25.11.4 Advanced Fault Diagnostic Techniques

Much of the discussion in the previous sections has highlighted the fact that many machine defects generate distinctive vibration signals. This fact has been exploited recently with the development of a variety of different automatic fault diagnostics techniques (Mechefske and Mathew, 1992b; Mechefske, 1995). The details of these systems will not be provided here, but the goal of automatic diagnostics is to augment and assist, rather than replace, the vibration signal analyst. If characteristic defect indicators can be detected and extracted from a vibration signal without the intervention of a signal analyst, the analyst will have more time for other duties and will also have access to information that may not have been uncovered through normal signal processing and analysis.

There are, however, still many situations where machine defects do not generate distinctive vibration signals or when the vibration signals are masked by large amounts of noise or vibrations from other machinery. In such cases, advanced diagnostic algorithms incorporating new signal processing techniques are currently being developed and implemented. Artificial neural networks (Timusk and Mechefske, 2002) have been found to provide an excellent basis for detecting and diagnosing faults. Wavelet analysis (Lin et al., 2004) and short-time Fourier transforms (STFTs) have also been shown to effectively allow both time domain and frequency domain information to be displayed on the same plot. This provides an opportunity to clearly see short duration transient events as well as detect faults in machinery that is operating in nonsteady-state conditions.

- Analysis of the vibration signal to determine the actual type of fault present will allow for more accurate estimation of the remaining life, the replacement parts that are needed, and the maintenance tools, personnel, and time required to repair the machinery.
- A diagnostic template can be developed for the different types of faults that are common in a given facility or plant by listing various faults that usually develop in machinery in terms of the forcing functions that cause them and specific machine types.
- Common forcing functions include unbalance, misalignment, mechanical looseness, soft foot, rubs, resonances, oil whirl, oil whip, structural vibrations, and foundation problems.
- Specific machine components that need to be monitored include damaged or worn rolling-element bearings and gears.
- Specific machine types that can be treated as common groups include pumps, fans, electric motors, steam and gas turbines, compressors, and reciprocating machines.

Summary

Despite the high level of technology built into every aspect of modern metal cutting operations, the phenomenon of tool wear still hampers the reliability and complete automation of machining processes. Tool wear is the loss of material on the edge of the cutting tool. This chapter concerns sensor-based tool condition monitoring (TCM), and specifically those methods that are based on vibration related properties such as force, acceleration, and acoustic emission (AE). References are made to systems proposed in the literature and also to commercially available hardware. The chapter focuses on turning operations. The mechanics of turning are briefly discussed. Various methods of obtaining vibration signals from turning operations are described. The vibration signal has to be processed in order to estimate the level of wear in the cutting edge of the tool, and several state-of-the-art approaches are discussed. Effective methods of constructing a model relating sensor data and the tool wear, using processed vibration signals, are described. The chapter concludes by indicating some important points that should be considered when using vibration-based systems for TCM, and some interesting topics for future research in this field of study. Chapters 25 and Chapter 27 present further information on the present subject.

26.1 Introduction

Millions of products are manufactured daily by a variety of processes. A basic method to form bulk metal into a desired final shape is through the process of metal cutting, also referred to as machining. Metal cutting is essentially the removal of excess material from a workpiece by moving a working tool over the

surface of the workpiece at a certain depth, speed, and feed rate. Conventional machining operations are turning, milling, and drilling.

Despite the high level of technology built into every aspect of modern metal cutting operations, the phenomenon of tool wear still hampers the reliability and complete automation of machining processes. Tool wear is the loss of material on the edge of the cutting tool. Although tool wear can be minimized, it cannot be eliminated. Unfortunately, excessive or even a small quantity of tool wear may cause a defect in a machined component, and therefore it is always necessary to be aware of the extent of the current tool wear before machining can commence. Economic losses due to tool wear occur as a result of the scrapping of expensive parts and the nonoptimal use of tool inserts. A conservative approach is often taken, and the insert is recycled long before it should have been. Furthermore, secondary damage due to tool wear can be extreme and even catastrophic. For this reason, many approaches to tool condition monitoring (TCM) have been proposed through the years. There exist sensorless and sensor-based TCM approaches. Sensorless approaches are generally tool-life equations and not monitoring methods. Thus, sensorless approaches attempt to determine the optimal tool life under certain machining conditions. These are often extended versions of the famous Taylor equation, which is described by

$$vT^n = C \quad (26.1)$$

where v is the cutting speed, T is the tool life, and n and C are constants that must be determined experimentally for a given tool and workpiece combination.

This chapter is focused on sensor-based TCM, and specifically those methods that are based on vibration related properties such as force, acceleration, and acoustic emission (AE). These sensor types are known to be most effective for TCM. Furthermore, discussions will be focused on the application of TCM in turning operations, though reference will be made to other machining operations as well. Besides vibration-based approaches, other sensor based TCM methods are:

- Use of noncontact capacitive sensors
- Vision systems
- Measurement of the motor current
- Surface roughness monitoring
- Ultrasonic monitoring
- Temperature monitoring
- Laser scatter methods
- Audible emission monitoring

The reader is also referred to other excellent overviews of sensor-assisted TCM, published by Dan and Mathew (1990), Byrne et al. (1995), Scheffer and Heyns (2001a), and Dimla (2000). A TCM database was also published by the CIRP, supervised by Teti (1995), which includes more than 500 research papers focusing only on TCM.

26.2 Mechanics of Turning

26.2.1 General Terms

A typical turning operation is schematically shown in [Figure 26.1](#). The cutting tool moves parallel to the workpiece and spindle, and hence reduces the diameter of the shaft. The most important machining parameters are:

- Cutting speed (usually expressed in m/min)
- Feed rate (usually expressed in mm/rev)
- Depth of cut (usually expressed in mm)

The force response on the tool tip due to the turning operation consists of three components: F_x , F_y , and F_z . These forces consist of a static and a dynamic part, as shown in [Figure 26.2](#). The static forces are governed by the static pressure between the tool and workpiece, and are a function of the machining

FIGURE 26.1 Turning operation.

parameters. The dynamic forces are governed by forced and free vibrations due to excitation from the cutting operation. Analytical models exist that can describe the static forces for basic machining operations (Merchant, 1945). The dynamic behavior is more difficult to model theoretically, although there is also continuous research in this area (Kapoor et al., 1998).

One of the main difficulties of monitoring tool wear with vibration is to identify the frequency range that is influenced by tool wear, since machining processes entail various mechanisms that produce vibrations that are not related to tool wear. The frequency range of vibrations produced during ordinary machining operations usually falls between 0 and 10 kHz. From the literature, it can be concluded that the frequency range sensitive to tool wear depends entirely on the type of machining operation, and must be determined experimentally for each individual case. There are two important vibration frequencies present during cutting:

- The natural frequencies of the tool holder and its components
- The frequency of chip formation

Dynamic tests should be conducted to identify the dynamic properties of tool holders (Scheffer and Heyns, 2002a). However, the interaction of the working tool engaged into the rotating workpiece complicates the situation, and as a result the dynamic behavior during cutting could be different from the expected behavior obtained from off-line tests. Scheffer and Heyns (2004) compared continuous cantilever models with modal hammer tests for different tool holder overhang lengths. The natural frequency of the first mode as a function of overhang length is plotted in Figure 26.3 (for a specific tool holder). It can be seen that a continuous fixed-free cantilever beam model corresponds well with the results obtained with hammer tests.

FIGURE 26.2 Static and dynamic forces.

The chip formation frequency can be calculated with simple equations that take the machining conditions into account (Lee et al., 1989). The tool holder natural frequencies and chip formation frequency are independent. Generally, tool wear has a larger effect on the vibration amplitudes at the tool holder natural frequencies but can influence chip formation frequencies as well.

26.2.2 Chatter Vibrations

Another phenomenon important to machining operations is tool chatter vibrations. These are self-excited vibrations resulting from the generation of different chip thicknesses during machining. Initially, cutting forces excite a structural mode of the machine–workpiece system. This leaves a wavy surface finish on the workpiece. During the next revolution, another wavy surface is produced in the same way. Depending on the phase shift between these two waves, the maximum chip thickness can grow and oscillate at a particular frequency that is close to that of a structural mode. This is called the regenerative chatter frequency. Chatter cause a poor surface finish and can also lead to tool breakage.

The analysis and prediction of chatter has been the subject of research for many years. Morimoto et al. (2000) developed a piezoelectric shaker/actuator to regenerate the vibrations of the cutting process. In this way, unwanted vibrations such as chatter can be attenuated. The system is also helpful to determine the dynamic properties of the machine tool. Koizumi et al. (2000) used a very interesting approach called the correlation integral in the time domain to identify chatter onset. Lago et al. (2002) designed a sensor and actuator integrated tool for turning and boring to control chatter. The tool holder shank vibrations are sent to the actuator *via* a digital controller. An adaptive feedback control system is used to perform broadband vibration attenuation up to 40 dB at different frequencies simultaneously.

26.2.3 Tool Wear

26.2.3.1 Tool Failure Mechanisms

Tool wear is caused by mechanical loads, thermal loads, chemical reactions, and abrasive loads. The load conditions are in turn influenced by the cutting conditions and materials. The different loads can cause certain wear mechanisms that may occur in combination. These mechanisms have either a physical or chemical characteristic that causes loss or deformation of tool material. Tool wear mechanisms can be classified into several types, summarized as follows (Du, 1999):

- Abrasive wear resulting from hard particles cutting action
- Adhesive wear associated with shear plane deformation
- Diffusion wear occurring at high temperatures
- Fracture wear due to fatigue

Other wear mechanisms are plastic deformation and oxidation, which are not very common in industry. It is estimated that 50% of all tool wear is caused by abrasion, 20% by adhesion, 10% by chemical reactions and the remaining 20% by the other mechanisms (Kopac, 1998). Abrasion is basically the grinding of the cutting tool material. The volume of abrasive wear increases linearly with the cutting forces. Higher hardness of the tool material can reduce the amount of abrasive wear. During adhesion, the high pressures and temperatures on the roughness peaks on the tool and the workpiece cause

FIGURE 26.3 Frequency of first tool holder mode. (Source: Scheffer, C. and Heyns, P.S., *Mech. Syst. Signal Process*, Elsevier, 2004. With permission.)

welding. These welding points are broken many times every second due to the workpiece movement and as a result cause removal of the tool material (Kopac, 1998). Diffusion wear occurs at even higher cutting speeds, where very high temperatures are present (especially when using hard metal tools).

26.2.3.2 Tool Failure Modes

Tool wear will generally occur as a combination of a number of wear modes, with one mode predominant. The dominant mode will depend on the dominant wear mechanism, which in its turn is influenced by the machining conditions and the choice of tool and workpiece material. For a given tool and workpiece combination, the dominant wear mode can be determined at different cutting speeds using the product of the cutting speed and the undeformed chip thickness (Dimla, 2000). The common wear modes are:

- Nose wear
- Flank wear
- Crater wear
- Notch wear
- Chipping
- Cracking
- Breakage
- Plastic deformation

Figure 26.4 is a graphical representation of the different tool failure modes. The consequences of tool wear are deviations in shape and roughness of the machined part that cause the part to be discarded because it is out of tolerance. Most wear modes cause an increase in cutting forces, although this is not always the case for all tool and workpiece combinations. The most widely researched tool failure modes for turning with single point tools are flank wear, breakage (fracture), and crater wear. Flank and crater wear are accepted as normal tool failure modes, because the other failure modes can be avoided by selecting the proper machining parameters. The growth of flank and crater wear is directly related to the total cutting time, unlike some of the other failure modes, which can occur unexpectedly even with a new tool.

FIGURE 26.4 Tool failure modes. (Source: Scheffer, C. and Heyns, P.S. 2001a. COMA '01, University of Stellenbosch. With permission.)

26.2.3.3 Tool Wear Measurement

Wear measurements of tool inserts are done through the implementation of an appropriate international standard, ISO 3685. Flank wear is quantified in terms of VB, which is the mean of the wear height on the tool flank. The length of flank wear is also measured in terms of b . Crater wear is quantified in terms of the crater depth, K . The parameters are depicted in Figure 26.5, which is a scanning electron microscope (SEM) picture of a worn turning insert.

26.2.3.4 Tool Wear Stages

It is assumed by most authors that tool wear consists of an initial, a regular, and a fast wear stage (Zhou et al., 1995). Some authors divide tool wear into five distinct stages (Bonifacio and Diniz, 1994):

1. Initial stage of wear
2. Regular stage of wear
3. Microbreakage stage of wear
4. Fast wear stage
5. Tool breakage

It has been established by various researchers that the initial and fast (before tool breakage) stages occur more rapidly than the regular stage. Bonifacio and Diniz (1994) explain that, during the fast wear stage with coated carbide tools, the tool loses its coating and the tool substrate (which has less resistance) begins to perform the cut and wears faster. During the initial stage, the tool edge loses its sharp edge rapidly, after this the process stabilizes for a given time. Flank wear in relation to total cutting time will typically appear as depicted in Figure 26.6.

The geometrical growth and rate of wear is unique for every tool insert, even those used with the same machining parameters. Wear measurements conducted on the shop floor of a piston manufacturer by Scheffer and Heyns (2004) are shown in Figure 26.7. It was found that the tools last between 1000 and 6000 components, which makes the optimal use of the tool extremely problematic if the wear is not monitored on-line. The reason for this behavior is mainly attributed to fluctuating conditions on the shop floor, for example, the rate at which components are manufactured. If the time allowed for the tool to cool down between workpieces is not constant, large variations in the tool life can be expected.

FIGURE 26.5 Tool wear parameters.

FIGURE 26.6 Flank wear in relation to cutting time.

FIGURE 26.7 Typical variations in tool life. (Source: Scheffer, C. and Heyns, P.S., *Mech. Syst. Signal Process*, Elsevier, 2004. With permission.)

26.3 Vibration Signal Recording

The information from vibration sensors can be treated in numerous ways. The overall aim of a tool condition monitoring system (TCMS) is to utilize the best processing techniques to extract the relevant information from sensor signals. Generally, a TCMS consists of the steps depicted in Figure 26.8. Various methods that could be used in each step will be discussed in more detail.

26.3.1 Direct and Indirect Systems

TCMSs can be divided in two categories, namely, direct and indirect. Direct methods are concerned with a measurement of volumetric loss at the tool tip, while indirect methods use a pattern in sensor data to detect a failure mode (Byrne et al., 1995). Direct methods do not utilize vibration and will not be discussed here. In general, direct methods are sensitive to dirt and cutting chips, and consequently they are not commonly accepted in industry. Indirect methods have found more acceptance in industry due to the fact that most indirect methods are easily interpreted, cost-effective, and often more reliable than direct methods. Also, for some applications, it might not be possible to use a direct monitoring method due to the nature of the process.

26.3.2 Sensor Requirements for Tool Wear Monitoring

Machine tools represent very hostile environments for sensors. Sensors used for TCM (also see Chapter 15) must meet certain requirements, such as (Byrne et al., 1995) the following:

- Must measure as close as possible to the point of metal removal
- Must not cause a reduction in the stiffness of the machine tool
- Must not cause a restriction of the working space of the machine
- Should be wear and maintenance free, easy to replace, and of low cost
- Must have resistance to dirt, chips, and electromagnetic and thermal influences
- Should function independent of tool and workpiece
- Must provide reliable signal transmission, e.g., from rotating to fixed machine components

26.3.3 Force Measurement

Worn tools cause an increase in the cutting force components. It is also known that both the dynamic and static components generally increase with tool wear due to frictional effects. The three components of the cutting force each responds uniquely to varying machining parameters and the different wear modes. Depending on the type of process that is investigated and the specific experimental setup, results among researchers vary. This can be attributed to dynamic effects of the machine tool and the measurement equipment. There are a number of different sensor configurations to collect forces from machining operations and these are described below.

26.3.3.1 Direct Measurement Dynamometers

Tool holder dynamometers are by far the most popular method for collecting cutting forces. These sensors utilize the piezoelectric effect and can measure quasistatic and dynamic cutting forces very accurately. However, dynamometers are very expensive and bulky instruments and are not practical for a

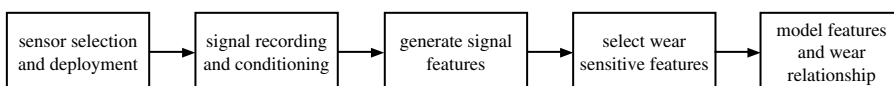

FIGURE 26.8 TCMS steps.

typical shop floor. Furthermore, their usable frequency range is limited to approximately 1 kHz. An example of a tool holder dynamometer is shown in Figure 26.9.

Tarmal and Opavsky (2000) investigated the dynamics of a conventional force dynamometer for machining operations. It was found that the dynamometer has significant amplitude distortion in the frequency range that is quoted as the operating range by the manufacturer. The authors suggest that the dynamic characteristics of the dynamometer (while clamped as it would be during measurements) be identified with a modal test and the effect of dynamometer dynamics be compensated for after measurements are made to obtain the true cutting force.

26.3.3.2 Indirect Force Sensors

There are numerous small force sensors available for the purpose of force measurement on machine tools. These measure forces in load-carrying components of the machine tool and are thus not direct force measurement devices. The advantages of these sensors are their size, low cost, and significantly higher operational frequency range. A disadvantage is that a suitable position for the sensor can only be determined experimentally. These sensors are suitable for tool breakage monitoring in rough machining or detection of other catastrophic events such as collisions. An example of a three-component force sensor is shown in Figure 26.10.

26.3.3.3 Piezoelectric Strain Sensors

The use of piezoelectric strain sensors for wear monitoring of synthetic diamond tool inserts was reported by Scheffer and Heyns (2000a). These sensors are ultrasensitive to changes in cutting forces if they are installed in an appropriate location. The best location for the sensor must once again be determined experimentally, but generally it should be installed on a load-carrying component of the machine as close as possible to the tool tip, for example, on the tool holder itself (Scheffer and Heyns, 2001b). An example of a piezoelectric strain sensor that can be used on machine tools is shown in Figure 26.11.

26.3.3.4 Resistance Strain Gauges

A quite simple method to estimate both the static and dynamic components of cutting forces without any distortion is to use resistance strain gauges (see Chapter 15). These comply with most of the requirements for TCM sensors, and they can accurately follow the static and dynamic response of a system up to

50 kHz. Scheffer and Heyns (2002a) developed a sensor-integrated tool holder using strain gauges. It was shown that the system is robust, cost-effective, and fit for an industrial TCMS. The physical layout of the strain gauges on a boring bar is shown in Figure 26.12. The system was calibrated with a special device to directly obtain the three cutting forces from the strain gauge signals.

26.3.3.5 Customized Force Sensors

There are a number of customized force sensors available that can be used with specific machining operations. These are:

- Force measuring plates, pins, and bearings
- Special force measuring bolts
- Force and torque measuring rings that fit on spindles

26.3.4 Acceleration Measurement

Piezoelectric accelerometers can measure the machine vibration caused by oscillations of cutting forces. It is well known that high-frequency vibrations (higher than 1 kHz) yield large acceleration levels, giving accelerometers an advantage over force-based monitoring. Accelerometers fulfill the environmental requirements for tool wear monitoring because they are resistant to the aggressive media present during machining. Accelerometers are also less expensive than force dynamometers and can measure vibration levels within a very wide frequency range, typically 5 Hz to 10 kHz.

Various authors have shown that acceleration levels change with tool wear. Li et al. (1997) found that the coherence function of two crossed accelerations can be used as an easy and effective way to identify tool wear and chatter. They found that with progressive tool wear, the autospectra of the two accelerations and their coherence function increase gradually in magnitude around the first natural frequencies of the cross-bending vibration of the tool shank. As the tool approaches a severe wear stage, the peaks of the coherence function increase to values close to unity. Scheffer et al. (2003) reported on the use of an accelerometer for wear monitoring during hard turning. It was found that certain frequencies show repeatable amplitude increase with increasing tool wear. These frequencies corresponded to the tool holder natural frequencies. Some authors, for example, Bonifacio and Diniz (1994), also found that a wear sensitive frequency will increase with increasing tool wear and then suddenly decrease near the end of tool life. This can be attributed to an increased damping effect due to plastic deformation and microbreakage of the cutting edge.

26.3.5 Acoustic Emission Measurement

Cutting processes produce elastic stress waves that propagate through the machine structure. Different sources in the cutting process generate these stress waves known as acoustic emission (AE). Sources of AE

in metal cutting are:

- Friction on the tool face and flank
- Plastic deformation in the shear zone
- Crack formation and propagation
- Impact of the chip at the workpiece
- Chip breakage

A typical AE sensor for use on machine tools is shown in Figure 26.13.

The fact that crack formation generates AE makes AE ideal for tool breakage detection. Collection of the AE requires special hardware that can bandpass filter the signals to the AE range (between approximately 50 and 250 kHz). Furthermore, amplification is required and an analogue root-mean-square (RMS) circuit with a short time constant is generally also included to collect the AE_{RMS} . The different steps required to collect AE are depicted in Figure 26.14 (adapted from Jemielniak, 2000).

Araujo et al. (2000) investigated sliding friction as a possible source of AE during metal cutting. The AE_{RMS} values in different frequency ranges were collected for different widths of cut and also with the tool rubbing against the workpiece without cutting. It was found that the level of AE remains almost constant for all width of cut conditions, and hence it was concluded that the main mechanism for AE during metal cutting is the sliding friction between the tool and workpiece. Consequently, an increase or decrease of AE can be expected with tool wear depending on the effect on the sliding friction due to that tool wear. Furthermore, it is believed that the cutting temperatures will affect the AE due to thermal expansion effects. Chiou and Liang (2000) investigated AE with tool wear and chatter effects in turning. A model is presented that can predict the chatter AE_{RMS} amplitude with certain levels of flank wear. Good correlation was found between the model and the experimental results. Kim et al. (1999) reported on the use of AE to monitor the tool life during a gear shaping process. The AE_{RMS} is collected and used in a software program to predict the remaining tool life.

Li (2002) presented an overview of using AE for TCM in turning operations. It is stated the AE is heavily dependent on cutting conditions and, as a result, methods should be employed to handle this problem effectively. Some methods are proposed that include advanced signal processing, sensor fusion and modeling techniques. Many other AE-based tool wear and breakage monitoring systems have been implemented successfully in research. One problem still lies with an appropriate interpretation of the AE frequency spectrum. In most studies, an explanation for the choice of certain frequencies and their advantages are not given or not investigated. In fact, Jemielniak (2000) found that using the average value of AE (or AE_{RMS}) is the most suitable. A similar conclusion was made by Scheffer et al. (2003), who compared different processing methods of the AE signal during hard turning.

26.3.6 Sensor Comparisons

Future research should be directed towards directly comparing different sensors for tool wear monitoring. Choi et al. (1999) developed a single sensor for parallel measurement of force and AE. A finite element analysis was carried out to determine the optimal position for the sensor away from the tool holder because the sensor obstructed the working space of the machine. The approach was successful for breakage detection but no wear estimations are reported. Barrios et al. (1993) compared AE, vibration, and spindle current for TCM during milling. It was found that the spindle current is the most sensitive sensor for detecting tool wear, with AE the least sensitive. However, contradictory results are reported in other publications, and hence more research would be required to determine ultimately which sensor is the best for which machining operation. Govekar et al. (2000) compared force and AE methods for TCM, and concluded that the best result is achieved when sensory information is combined. Dimla and Lister (2000a) compared the use of force and vibration signals for TCM and also combined the information in a single decision-making technique (Dimla and Lister, 2000b). Similar comparative studies were reported by Scheffer et al. (2003).

26.4 Signal Processing for Sensor-Based Tool Condition Monitoring

Using the sensor information from the different sensor systems described in the previous section, a decision must be made with respect to the tool condition. This decision is generally referred to as the data classification. It is often better to combine sensory information to solve a complex problem such as TCM. Such a combined approach is referred to as sensor fusion. Sick (2002) proposed a generic sensor fusion architecture for TCM, which summarizes the various sensor fusion levels of a TCMS. These are:

- Analogue preprocessing
- Digital preprocessing
- Feature extraction
- Wear model
- Decision making

Fusion of sensor information can occur at any of these levels. Analogue and digital preprocessing are activities such as signal amplification, conditioning, filtering, calibration, and temperature compensation. The feature extraction step is probably the most important step, because here the sensor signals must be condensed and reduced to only a few appropriate wear sensitive values. Many different methods are available to achieve this. The wear model level establishes a relationship between the chosen features and the tool condition. In many cases, neural networks (NNs) are used in this step, and sensor fusion takes place within the NN. A decision level can also be included where a final decision is made with respect to the tool condition, for instance a “competing experts” formulation if a TCMS is used in conjunction with a tool-life equation. Discussions on the various techniques follow.

26.4.1 Feature Extraction

Most decision-making techniques for process monitoring are based on signal features. Through appropriate signal processing, features can be extracted from signals that show consistent trends with respect to tool wear. Features are mainly derived through processing in the time, frequency, or joint time-frequency domain or statistical analysis.

26.4.1.1 Time Domain

Features extracted from the time domain are usually fundamental values such as the signal mean or RMS. Other techniques include the shape of enveloping signals, threshold crossings, ratios between

time-domain signals, peak values, and polynomial approximations of time-domain signals. Examples of time-domain features from an interrupted cutting operation are shown in Figure 26.15.

It has been found that some of the time-domain features show good correlation with tool wear and are easy to implement (Scheffer, 1999). Bayramoglu and Döngel (1998) investigated the use of several different force ratios (calculated from the static cutting forces). It was found that certain force ratios can be used to monitor tool wear under a wide range of cutting conditions. Most commercial TCMS rely on time-domain information. However, time-domain features are known to be sensitive to disturbances and should be complemented with features from another domain.

26.4.1.2 Frequency Domain

The power or energy of certain frequency bands in the fast Fourier transform (FFT) is often suggested as a feature for TCM. It is very challenging to identify spectral bands that are sensitive to tool wear. It is even more difficult to determine exactly why these frequencies are influenced by tool wear. Power in certain bands will often increase due to higher excitation forces because of the increase in friction when the tool starts to wear. Sometimes a peak in the FFT will also shift due to changing process dynamics as a result of tool wear. An early frequency-domain approach is reported by Jiang et al. (1987), in which frequency-band energy is determined from the power spectral density (PSD) function as a feature for tool wear.

Some authors suggest that two frequency ranges be identified from the original signal (Bonifacio and Diniz, 1994). The one range must be sensitive to tool wear, the other must be insensitive. For instance, if the measurement was made from 0 to 8 kHz, it must be split (using appropriate filters) into a 0 to 4 kHz signal and a 4 to 8 kHz signal. If the lower range is more sensitive to tool wear, a ratio between the two ranges can be calculated. If this ratio exceeds a certain pre established value, it can be concluded that the end of the tool life has been reached. This can also apply for a ratio between the signal recorded from a fresh tool to that compared with a worn tool. Examples of frequency-domain features from cutting forces are shown in Figure 26.16.

One difficulty with frequency-domain approaches is that the dynamics of the operation and measurement hardware is not always fully understood. The fact that measurement hardware dynamics instead of process dynamics are often measured was also recently identified by Warnecke and Siems (2002). The response of a force dynamometer is influenced by its clamping condition, which may cause it to experience nonlinearities at relatively low frequencies. There are also some uncertainties when using these instruments, relating to their calibration and other varying parameters. A model for expressing the uncertainties when collecting cutting forces with a dynamometer was proposed by Axinte et al. (2001). These uncertainties might be responsible for the scatter of force components often reported in the

FIGURE 26.15 Simple time-domain features.

FIGURE 26.16 Frequency-domain features.

literature. An interesting study is also reported by Bähre et al. (1997), concerning determination of the natural frequencies of the machine tool components using the finite element method (FEM). These are taken into account for interpretation of the vibration/AE signal.

26.4.1.3 Statistical Processing

In the case of statistical features, signals are assumed to have a probabilistic distribution, and consequently, useful information can be extracted from the statistics of the distribution. Hence, the signal is regarded as a random process. Generally, machining processes are nonstationary but are assumed to be stationary for the short periods during which features are calculated. Several statistical features have been investigated for TCM and can be applied to several machining operations. The main features are those that describe the probability distribution of a random process (variance, standard deviation, skewness, kurtosis, etc.) and coefficients of time-series models. There are also miscellaneous other statistical features, such as cross-correlations, the coherence function, and the harmonic mean.

One useful approach is the use of autoregressive (AR) and autoregressive moving average (ARMA) coefficients. AR coefficients computed for a signal represent its characteristic behavior. When the signal changes during the cutting operation due to tool wear, the model coefficients also change and can then be utilized to monitor the progressive tool wear. Baek et al. (2000) report on the use of an eighth order AR model for tool breakage detection during end milling. It was found that the AR approach is somewhat more accurate than the frequency band energy method. Yao et al. (1990) used the ARMA method to decompose the dynamic cutting force signals, and wear-sensitive frequencies were identified. This assisted in identifying the importance of certain vibration modes with respect to TCM.

The use of statistical process control (SPC) methods is also reported by some authors. Jun and Suh (1999) considered the X-bar and exponentially weighted moving average (EWMA) for tool breakage detection in milling. Jennings and Drake (1997) used statistical quality control charts for TCM. Different statistical parameters are calculated and examples of one-, two- and three-variable control charts are given.

26.4.1.4 Time–Frequency Domain

The most common time–frequency domain processing method in TCM applications is wavelet analysis. A comprehensive discussion on the advantages and disadvantages of wavelet analysis for TCM is described by Sick (2002). It is often stated that wavelets are used because they provide information about the localization of an event in the time as well as in the frequency domain. However, locating discrete frequency-related events in the time domain is rarely of importance with respect to tool wear (which is a gradually increasing phenomenon). In contrast, tool breakage will have a large localized effect in the time domain, but this can be monitored more effectively using time-domain techniques. Furthermore, wavelets are time variant and the exact contribution of a particular frequency at any given time can never be determined accurately due to Heisenberg's uncertainty principle.

Despite the above arguments, the use of wavelet analysis for TCM is reported in several publications. Lee and Tarng (1999) use the discrete wavelet transform for cutter breakage detection in milling and find that the technique is reliable even under changing machining conditions. Luo et al. (2002) published results of a TCMS using wavelet analysis of vibration signals. In this case, the wavelet is used as a filter to enhance wear-sensitive features in the signals. However, the results are not compared with conventional digital filtering. A comparative study between wavelets and digital filtering for tool wear monitoring was carried out by Scheffer (2002). It was found that, although the wavelet packets act as automated filters, a very similar (if not better) result could be achieved with appropriate digital filtering. The use of wavelets increase the complexity of the TCMS, which is a disadvantage for shop-floor implementations. Furthermore, the results from digital filtering can be physically related to the machining operation and tool wear, whereas the behavior of wavelet packets is more difficult to interpret.

Another method of time–frequency analysis that can be applied for TCM is spectrograms (e.g., the Gabor distribution). Spectrograms are very useful to identify stationarity in dynamic signals, and for detection of disturbances that may be time-localized in signals. The use of the Choi–Williams time–frequency distribution for TCM during multimilling is described by James and Tzeng (2000).

Wear-sensitive regions on the time–frequency distribution are calculated and used as inputs to a NN for wear classification. An example of a change in the dominant chip curl frequency during hard turning is shown in Figure 26.17. It is obvious that, due to some disturbance (perhaps tool wear), the dominant dynamic force frequency “jumps” from 27 to 9 Hz.

26.4.2 Feature Selection

Various authors attempt to generate features that are sensitive to tool wear but insensitive to changing machining parameters. For most operations, the machining parameters can be included in the wear model and hence the sensitivity of the features is not such an important issue. There are also other techniques to normalize sensor data with respect to machining parameters, for instance the use of a theoretical model (Sick, 1998). This is very useful if the machining conditions change so often that not enough data can be collected for training or calibrating a model. Numerous techniques exist to select the most wear-sensitive features or to reduce the input feature matrix to a lower dimension. The main techniques for feature selection and reduction are listed below:

- Principal component analysis (PCA)
- Statistical overlap factor (SOF)
- Genetic algorithm (GA)
- Partial least squares (PLS)
- Automatic relevance determination (ARD)
- Analysis of variance (ANOVA)
- Correlation coefficient
- Simulation error calculations

Al-Habaibeh et al. (2000) presented a TCMS for a parallel kinematics machine tool for high-speed milling of titanium. An interesting approach to feature selection is employed, called self-learning automated sensors and signal processing selection (ASPS). This approach is based on an on-line self-learning methodology, whereby a certain feature will be selected automatically based on a correlation with tool wear. A linear regression is performed on each feature in the sensory feature matrix to detect the sensitivity of each feature with respect to tool wear. A very interesting cost analysis is then performed to determine if the installation of a sensor justifies its costs.

Ruiz et al. (1993) proposed the use of a discrimination power for feature selection in a TCM application. The method is similar to that of the SOF. An automated version is proposed that also checks for linear correlation between features. It is difficult to assess the success rate of the automated procedure because the experiments/simulations are not described in enough detail. Lee et al. (1998) describe the use of ANOVA to determine the best force ratio for TCM statistically. Several ratios between the three main cutting forces are computed and the influence of controllable parameters (e.g., machining conditions) on these ratios are investigated by means of ANOVA.

Du (1999) describes the use of a blackboard system, which is a knowledge-based approach for feature selection and decision-making. An advantage is the fact that a physical interpretation of a feature can be linked to phenomena in the machining operation. The method is also flexible, but suffers from the disadvantage of requiring a large quantity of data and expertise to establish the knowledge-based rules.

FIGURE 26.17 Time-frequency distribution of cutting force signal. (Source: Scheffer, et al., *Int. J. Mach. Tools Manuf.*, Elsevier, 2003. With permission.)

FIGURE 26.18 Comparison of correlation coefficient and SOF for feature selection. (Source: Scheffer, C. and Heyns, P.S., *Mech. Syst. Signal Process*, Elsevier, 2004. With permission.)

Mdlazi et al. (2003) compared the performance of ARD and PCA for feature selection for two damage detection case studies. It was found that the performance of the methods is similar, but one might perform better on a particular data set. Generally speaking, the PCA yields better results for damage detection problems. Scheffer and Heyns (2002b) compared several feature selection methods for TCM, such as SOF, PCA, GA, ANOVA, and the linear correlation coefficient. It was found that the correlation coefficient approach and the SOF should be preferred for TCM applications. PCA could also be of assistance, but the feasibility of PCA for on-line applications is still questionable. The correlation coefficient and SOF is expressed as percentages in Figure 26.18 (from Scheffer and Heyns, 2004) for 30 different wear monitoring features in a turning tool wear case study. Ideally, a feature with a high level of correlation and SOF should be selected.

As a last step, engineering judgment is required for proper feature selection because automated methods will often select features that are dependant on one another, thus not achieving the goals of sensor fusion. The following rules can be used as a guideline for selecting features for TCM:

- Select features from the static and dynamic parts of force signals.
- Select features measured in different directions.
- Use time- and frequency-domain features.
- Features based on simple signal processing methods are preferred.
- There should be a reasonable physical explanation for the behavior of a feature with respect to tool wear.

26.5 Wear Model/Decision-Making for Sensor-Based Tool Condition Monitoring

26.5.1 Trending, Threshold

A very simple decision-making technique is to trend features and to establish threshold values. When a certain feature or set of features crosses a threshold value, an estimation of the tool condition can be made. Unfortunately, these threshold values can only be determined experimentally. The difficulty with this method is to determine the correct threshold value, especially under diverse cutting conditions. Furthermore, the method is extremely sensitive to disturbances. The trend of the mean feed force with increasing flank wear is shown in Figure 26.19, and two thresholds are shown as examples. It is clear that this technique is not very reliable due to the large variance in the trend.

FIGURE 26.19 Example of trend and thresholds.

26.5.2 Neural Networks

The use of NNs as a secondary, more sophisticated signal processing and decision-making technique is often found in TCM applications. The simultaneous utilization of many features and the robustness towards distorted sensor signals are two of the most attractive properties of NNs. Neural networks also assist in the fusion of sensor information for TCM. In other words, combining features from acceleration, AE, and force signals in a NN can result in a method that can predict the tool condition with increased accuracy (Silva et al., 1998). The successful implementation of NNs is dependent on the proper selection of the network structure, as well as the use of the correct training and testing methods.

It is important to make a distinction between supervised and unsupervised NN paradigms. Unsupervised NNs are trained with input data only, and are usually used for discrete classification of different stages of tool wear. Supervised NNs are trained with input and output data, and these are used for continuous estimations of tool wear. Furthermore, a distinction should be made between dynamic and static NNs. In the case of dynamic NNs, temporal (time) information is included in the network with the aim to model a time series. This can be done explicitly by using a time-based feature as an input to the network, or implicitly by using recurrent networks or networks with tapped delay lines (TDLs). Dynamic networks are preferred for TCM because tool wear is time-dependent (tool wear is a monotonically increasing parameter that is partly a function of machining time).

26.5.2.1 Unsupervised Networks

There are two basic network paradigms for unsupervised classifications, namely adaptive resonance theory (ART) and the self-organizing map (SOM). ART is based on competitive learning, addressing the stability–plasticity dilemma of NNs. The main advantage is its ability to adapt to changing conditions. ART networks also have self-stability and self-organization capabilities. The SOM is actually a data-mining method used to cluster multidimensional data automatically. A high-dimensional feature matrix can be displayed on a two-dimensional grid of neurons that are arranged in clusters with similar feature values. Clusters for new and worn tools can be formed, and these are used for automatic classification of the tool condition. A SOM is depicted schematically in Figure 26.20.

There are many practical advantages for using unsupervised networks. One is the fact that the machining operation is not interrupted for tool wear measurements during the training phase. There is also the advantage of practical implementation if machining conditions change very often and appropriate training samples for supervised learning cannot be collected. Furthermore, the numerous different combinations of tool and workpiece materials and geometries can make supervised learning impossible. Normally, unsupervised NNs are used to identify discrete wear classes and cannot be used for a continuous estimation of tool wear.

Silva et al. (2000) investigated the adaptability of the SOM and ART for tool wear monitoring during turning with changing machining conditions. It was found that, with appropriate training, the methods have enough adaptive capabilities to be employed in industrial applications. Govekar and Grabec (1994) use the SOM for drill wear classification, where the SOM is used as a kind of empirical modeler. It was found that the adaptability of the SOM and its ability to handle noisy data makes the technique viable for on-line TCM. Scheffer and Heyns (2000b, 2001b) showed how a TCMS can be adaptable using SOMs. Different network sizes were compared with define discrete classes of new and worn tools. Larger networks yielded more continuous results. The TCMS using SOMs was applied to monitoring synthetic diamond tools for an industrial turning operation. It was found that the SOM can be used for industrial applications, especially if tool wear measurements are not available.

FIGURE 26.20 Schematic representation of the SOM.

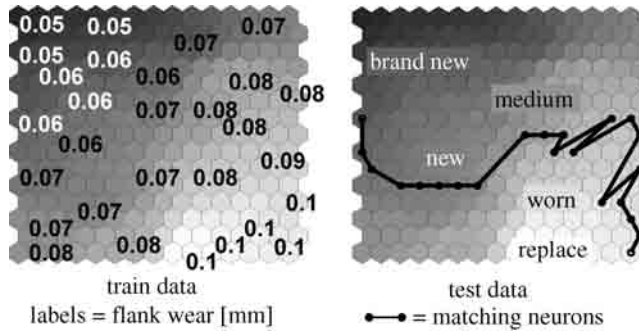

FIGURE 26.21 Unsupervised approach to wear monitoring with the SOM. (Source: Scheffer, C. and Heyns, P.S., *South African Inst. Tribol.* 2002. With permission.)

Different NN paradigms were compared on a wear monitoring application for aluminum turning by Scheffer and Heyns (2002b). It was shown that the SOM is useful to identify discrete wear classes, as shown in Figure 26.21. If an exact value of the tool wear is required, supervised networks will yield better results but will require proper training samples.

26.5.2.2 Supervised Networks

Common supervised NNs used for TCM are the multilayer perceptron (MLP), multilayer feedforward (FF) network, recurrent neural network (RNN), supervised neuro-fuzzy system (NFS-S), time delay neural network (TDNN), single layer perceptron (SLP) and the radial basis function (RBF) network. The use of an SLP for TCM is described by Dimla et al. (1996), using the perceptron learning rule for training. The SLP is useful to identify discrete classes of the tool condition. FF networks are usually trained with the backpropagation algorithm. However, backpropagation should not always be the preferred choice because other methods are known that outperform this technique in terms of training time and generalization. The size of the hidden layers in multilayer networks should be optimized for performance. Many contradictory statements about the use of MLP networks can be found in the literature. One of the main problems is the selection of the number of input features, size of the network, and the number of training examples that should be used.

A multilayer feedforward (FF) network is shown schematically in Figure 26.22. Normally, a nonlinear activation function should be used in the first layer, and linear neurons in the subsequent layers. In the case of the FF networks, the backpropagation algorithm is often used for training. Backpropagation is an optimization algorithm based on steepest gradient descent.

The use of FF networks with the backpropagation training rule is reported by authors such as Zhou et al. (1995), Das et al. (1996), and Zawada-Tomkiewicz (2001). Cutting conditions can also be included in such networks. Lou and Lin (1997) describe the use of a FF network using a Kalman filter to avoid the training problems encountered with backpropagation for a TCM application. The proposed method is less sensitive to the network initializations that often cause convergence problems with backpropagation.

Monitoring a dynamic system such as a cutting process should be done with a dynamic modeling technique such as dynamic NN paradigms, for example, recurrent networks, TDNNs, or explicit

FIGURE 26.22 Multilayer FF network.

FIGURE 26.23 Recurrent networks: feedback connection (left) and Elman network (right). (Source: Scheffer, C. and Heyns, P.S., *South African Inst. Tribol.* 2002. With permission.)

inclusion of temporal information in static networks. Recurrent NNs have feedback connections from their output to their input. There are various types of recurrent NNs that are useful for specific applications. Elman networks are quite interesting. Generally, they are two-layer networks with feedbacks from the first layer output to the first layer input. This type of network can be used to learn and model temporal patterns. A recurrent network and an Elman network are shown schematically in Figure 26.23.

Liu and Altintas (1999) report on the use of a FF network using a combination of TDLs and recurrent connections. Machining conditions are also included. It is stated that the system was integrated into an industrial TCMS, but was never put to use due to lack of "... robust, practical cutting force sensors ...". (Liu and Altintas 1999). Scheffer and Heyns (2002b) report on the use of an Elman NN for TCM. It was found that the Elman network has a very smooth response and yielded better results than static NN paradigms. It should be mentioned that the Elman network requires more time for training, but because this is done off-line, training time should not be a criterion for evaluating NNs.

Neuro-fuzzy systems (NFS-S) attempts to combine the learning ability of NNs with the interpretation ability of fuzzy logic. A TCMS using an NFS-S can be generated almost automatically because the fuzzy rules can be learned by the NN. A combination of supervised and unsupervised training is used for NFS-S. An in-process NFS-S system to monitor tool breakage was designed and implemented successfully by Chen and Black (1997), concentrating on end milling operations. Xiaoli et al. (1997) as well as Chungchoo and Saini (2002) also propose some of the advantages of using an NFS-S for TCM.

RBF networks are often preferred because of the convergence properties of the training algorithm. In essence, convergence can be guaranteed and is often achieved much faster than in MLPs. The accuracy of RBFs depends on the choice of the centers for the basis functions, and should be treated with care. Pai et al. (2001) reported on the use of a resource allocation network (RAN) for TCM. The RAN is a RBF network utilizing sequential learning. The RAN is compared with the MLP for wear estimation during face milling. It was found that the RAN has faster learning ability but the MLP is more robust.

TDNNs have delay elements in the feedforward connections, called TDLs. One advantage of TDNNs over RNNs is that stability problems are avoided. An investigation towards the inclusion of one and two phase delays for a TCM application was reported by Venkatesh et al. (1997). Different network sizes were also investigated, and it was found that the NNs with temporal memory generally perform better than those without memory. It is also stated that new algorithms should be investigated for training. Sick and Sicheneder (1997) also describe the use of TDNNs for TCM in turning. The TDNN is compared with the MLP and a significant improvement was found when using

TDNNs. In another instance, Sick et al. (1998) compare the SOM, NFS-S, and MLP networks for wear estimation. The following critical questions are used to evaluate the different NN paradigms (Sick et al., 1998):

- Are the generalization capabilities of the NN sufficient (tested on previously unseen data)?
- What rate of correct classification can be achieved for different wear stages?
- Are the results repeatable (e.g., with a new initialization)?

In the case study presented by Sick et al. (1998), the best results were found with MLPs. It is stated, however, that the results can be improved when using TDNNs, and such results are reported in Sick (1998).

A novel combined approach is suggested by Sick (1998) to handle the effect of machining parameters. An empirical model is used to normalize the data with respect to machining parameters before the data are entered into the NN. Thus, machining parameters are not included in the NN itself. This approach solves the extrapolation limitations encountered when an NN is tested with data recorded with machining parameters it was not trained with. Although many authors test their NNs' paradigms in such a way, NNs cannot be expected to extrapolate. NNs should instead be tested with previously unseen data recorded with same machining parameters it was trained with (hence an interpolation effect). This is a problem because training and testing patterns for each condition must be supplied. However, if data can be normalized with respect to machining parameters, training is only required for the normalized condition. This was in effect achieved by Sick (1998). A difficulty still lies with establishing an appropriate model, and in many cases it will also require a large number of experimental tests. A possible solution lies in the incorporation of numerical models, for example, finite element models.

Scheffer (2002) presented another approach to tool wear monitoring of turning operations, using a combination of static and dynamic NNs. Static networks are trained off-line to model selected features from cutting forces. A dynamic NN that uses explicit temporal information is then trained on-line with the particle swarming optimization algorithm (PSOA). The training goal of the dynamic NN is to minimize the errors between the outputs of the static NNs and the on-line measurements. The method was tested on various turning operations and was also tested on an industrial shop floor. It was found that the method is more accurate and reliable than other NN paradigms and can be used with cost-effective hardware (Scheffer and Heyns 2002a, 2004). The method is depicted schematically in Figure 26.24.

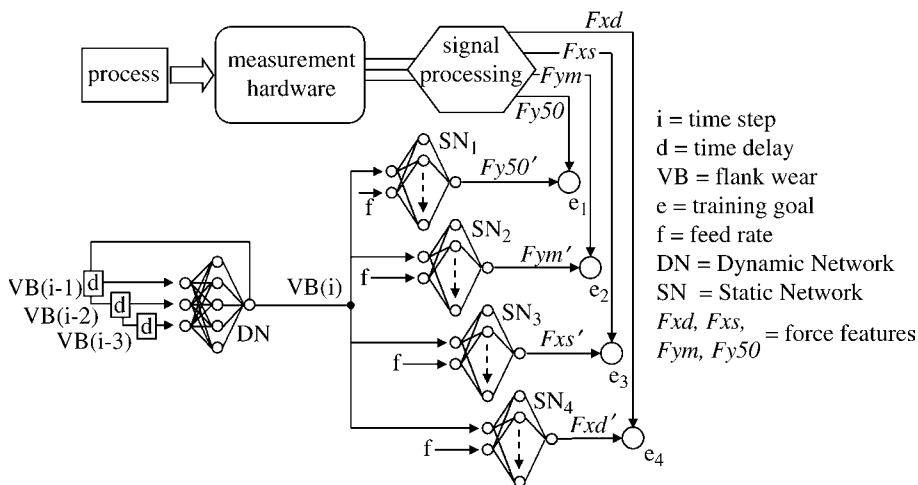

FIGURE 26.24 Combined static and dynamic NN approach for turning. (Source: Scheffer, C. and Heyns, P. S., *Mech. Syst. Signal Process*, Elsevier, 2004. With permission.)

26.5.3 Fuzzy Logic

Many authors have investigated the use of fuzzy logic to classify tool wear. It has been shown that fuzzy logic systems demonstrate great potential for use in intelligent manufacturing applications. While NN models cannot directly encode structured knowledge, it is often stated that fuzzy systems can directly encode structured knowledge in a numerical framework. Additionally, fuzzy systems are capable of estimating functions of a system with only a partial description of the system's behavior.

Du et al. (2002) propose a very interesting method called transition fuzzy probability, which was applied to a boring operation. This formulation can deal with the uncertainty of process conditions. The method performs well because TCM has two uncertainties: that of occurrence and that of appearance. The transition fuzzy probability solves this issue through the use of temporal information, similar to dynamic NNs. The method was shown to outperform a backpropagation NN, although very few details are given. It would be interesting to compare this method with dynamic NNs such as TDNNs.

Fu et al. (1997) combined force, vibration, and AE in a fuzzy classifier for TCM during milling. Time- and frequency-domain features were used, and it was found that combining the sensory information achieved the best result. This is done within the fuzzy classifier. Li and Elbestawi (1996) and Kuo and Cohen (1998) combine fuzzy modeling steps with NNs at different levels for TCM. The latter combined force, vibration and AE in a multisensor approach with satisfactory results.

26.5.4 Other Methods

There are also a number of other decision-making and modeling methods that have been applied to TCM, and these include:

- Knowledge-based expert systems (Du, 1999)
- Pattern recognition algorithms (Kumar et al., 1997)
- Dempster–Shafer theory of evidence (Beynon et al., 2000)
- Hidden Markov models (Ertunc and Loparo, 2001; Ertunc et al., 2001)

Of these four approaches, only hidden Markov models have the potential possibly to outperform NNs and fuzzy systems. However, not enough comparable research has been conducted in this area, and is it certainly a worthwhile topic for future research.

26.6 Conclusion

Techniques for achieving TCM with vibration-based properties were presented in this chapter. The sensing methods that have proved to be effective for TCM are force, acceleration, and AE. The sensors employed must comply with certain requirements such as robustness and cost-effectiveness. Sensors must be installed as close as possible to the point of metal removal in order to avoid signal-to-noise ratio problems. Various techniques exist to condition and process the signals in analogue and digital formats. The aim of signal processing is to generate wear sensitive features from the vibration signals. This could be done by time, frequency, joint time–frequency, and statistical analysis. Feature selection can be automated with a variety of procedures, but care must be taken when using these to avoid selection of linearly dependent data.

The selected features can be used to establish a model of tool wear. Numerous research papers have shown that NNs should be used due to the many advantages of NN modeling. The training and testing procedures of NNs are of utmost importance if the system is considered for industrial implementation. Care must be taken not to overtrain the networks because they will lose their ability to generalize. Furthermore, NNs cannot be expected to perform well if they are tested with previously unseen machining parameters. They should also be trained with the minimum and maximum tool wear that is

expected. Future work should be directed towards incorporating numerical machining models into the wear monitoring system to normalize the data with respect to machining parameters. If this can be achieved, the amount of training data required for an effective TCMS will be reduced, which in turn will provide a better solution to TCM for the manufacturing industry.

Summary

An overview of fault detection and diagnosis of helicopter gearboxes is presented in this chapter. Between oil analysis and vibration monitoring, the two predominant methods of gearbox monitoring, vibration monitoring is much more studied and relied upon because of its ability to reflect a wider variety of faults. In order to cover the concepts used in vibration monitoring, a method of diagnosis is discussed that relies on the knowledge of the gearbox structure and characteristics of the features of vibration for component fault isolation. Since a necessary part of vibration monitoring is selection of accelerometer locations on the housing, a method is also described whereby the suitability of accelerometer locations is quantified based on the structure of the gearbox and the monitoring effectiveness of the locations. Finally, a case study is included to illustrate the application of the concepts presented in the chapter to fault detection and diagnosis, as well as the ranking of suites of accelerometer locations. Some topics related to this chapter are covered in [Chapter 15](#), [Chapter 25](#), and [Chapter 26](#).

27.1 Introduction

Present helicopter power trains are significant contributors to both flight safety incidents and maintenance costs. For example, for large and medium civil transport helicopters in the period 1956 to 1986, gearboxes were the principal cause of 22% of the accidents with potential loss of life and aircraft (Astridge, 1989). To prevent such incidents, routine maintenance is scheduled at a significant ratio of the total maintenance cost for the helicopter. Rapid and reliable detection and diagnosis (isolation) of faults¹ in helicopter gearboxes is therefore necessary to prevent major breakdowns due to progression of undetected faults, and for enhancing personnel safety by

¹Determining whether the overall machinery is healthy is referred to as fault detection, whereas diagnosis is analogous to isolating the source of failure.

preventing catastrophic failures. Fault detection and diagnosis is also necessary for reducing maintenance costs by eliminating the need for routine disassembly of the gearbox, and for saving time during inspection.

Detection and diagnosis of helicopter gearbox faults, like most rotating machinery, is based on oil analysis and vibration monitoring. Oil analysis, which is used to detect the presence of metallic debris, is performed by: (1) magnetic plugs (chip detectors), (2) oil filters, and (3) spectrometric oil analysis (SOA) (Lurton, 1994). Among these, magnetic plugs are the most popular because of their in-flight utility and their ability to quantify the severity of wear by measuring the rate of detected debris. However, magnetic plugs can only collect ferromagnetic particles, and their capture efficiency may be poor. Oil filters used in helicopter gearboxes range between 3 and 150 μm , with finer meshes of 3 μm more common in the recent years. SOA, which is a ground-based technique, is useful for detecting fine debris, typically below 10 μm in size, caused by wear conditions such as rubbing, cutting, and corrosion wear, and fine surface fatigue such as micropitting. Therefore, development of a reliable method of identifying common forms of fatigue such as spalling or wear that generate particles greater than 10 μm in size is of particular interest. The effectiveness of SOA is also affected by the level of filtering performed on the used oil, which often leaves the oil free of particles (Lurton, 1994). The need for improving wear detection has motivated development and use of other analysis methods such as image processing of oil filters, ferrography, thermography, and ultrasonic analysis (Thornton, 1994).

The other method of gearbox fault detection and diagnosis, and by far the more popular one, is based on vibration monitoring. The basic principle behind vibration monitoring is that, under normal operating conditions, each component in the gearbox produces vibrations at specific frequencies related to the component's rotational frequency. In the case of a component fault, the vibration generated by the faulty component is different from the normal vibration, and will be reflected at the component's rotational frequency and its harmonics. As such, monitoring the changes of vibration should theoretically give an indication of the fault. In practice, however, changes in the measured vibration as a

FIGURE 27.1 Layout of various components in a typical helicopter (OH-58A) gearbox.

result of component faults are not always distinct due to the attenuation of vibration by the housing and other components it travels through, as well as the noise in the signal. To provide a more tangible framework for the concepts in vibration monitoring, the layout of a typical helicopter gearbox is shown in Figure 27.1, with the location of the accelerometers on its test stand shown in Figure 27.2.

In order to enhance identification of vibration changes by component faults, the raw vibration is generally processed to obtain “features” that characterize the vibration at the frequencies associated with the gearbox components. Accordingly, the main focus of research in vibration monitoring has been the identification of individual features that consistently reflect specific gearbox faults (Dyer and Stewart, 1978; McFadden and Smith, 1986; Mertaugh, 1986; Zakrajsek et al., 1995). A typical set of vibration features obtained from each vibration measurement is shown in Figure 27.3 (Stewart Hughes Ltd., 1986). Among them, envelope band and tone energies, cepstra, and synchronous-time averaged signals, are associated with various bearing frequencies and gear mesh tones. Envelope band and tone energies, which are the sum of the harmonics of the bearings’ fundamental rolling-element frequencies within a filtered bandwidth, could be used for early detection of failure in rolling-element bearings (Barkov and Barkova, 1995). Similarly, a cepstrum, which is the power spectrum of the logarithm of a power spectrum, is often used because of its insensitivity to transmission path effects for identification of families of uniformly spaced sidebands in gearbox vibration spectra (Randall, 1982). Synchronous-time averaging is a signal processing technique that isolates the fundamental and harmonics of the gear meshing frequency, and is a primary analysis technique for detection of gear and shaft faults (McFadden and Smith, 1986).

The traditional approach to fault diagnosis has relied on human expertise to relate vibration features to faults. In this approach, a diagnostician first identifies abnormalities in vibration features, then relates them to component faults, considering both the proximity of the accelerometer producing the feature to various components and the information about the type of fault characterized by the feature. Using this information, the diagnostician hypothesizes faults in specific components and then verifies or discards the hypothesis by examining features from other accelerometers in the proximity of the suspect component. The disadvantages of this approach arise from: (1) the difficulty in identifying abnormality in features which are contaminated with noise, and (2) the tediousness of examining the numerous features obtained from all of the accelerometers. Owing to the large number of features

FIGURE 27.2 Location and orientation of the accelerometers on the OH-58A test stand.

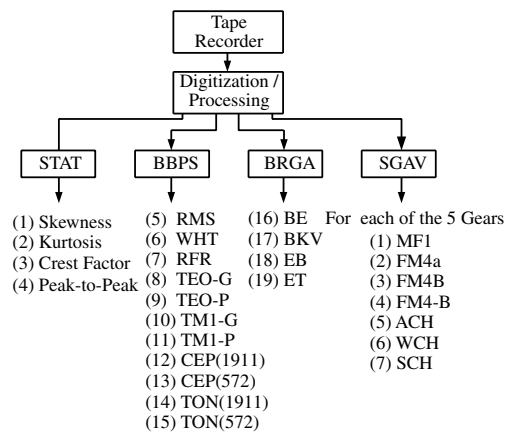

FIGURE 27.3 A typical set of vibration features extracted from each accelerometer.

associated with a gearbox², the diagnostician cannot often pay equal attention to all the features and is likely to ignore information that contradicts the hypothesis.

The most efficient method for integration of features is pattern classification. To this end, artificial neural networks have been widely investigated and shown to provide excellent results (Solorzano et al., 1991; Chin et al., 1993; Kazlas et al., 1993; Chin et al., 1995). Neural networks offer the following advantages in diagnosis: (1) as pattern classifiers, they can efficiently cope with noise in features, (2) through training, they can form the signatures of individual faults in the multidimensional space of features, and (3) they can process vibration features in parallel, so diagnosis is not hindered by the enormity of feature space. The main disadvantage of supervised neural networks, however, is their need for prior training, which requires a comprehensive set of features during normal operation and at various fault instances. While training data can be obtained experimentally through accelerated fatigue tests (Lewicki et al., 1992) or seeded fault studies (Naval Command, Control, and Ocean Surveillance Center, 1995), their cost is considered too high, limiting the utility of supervised neural networks in fault diagnosis. The lack of training data poses a similar restriction for statistical pattern classifiers which need *a priori* statistics of the features.

In the absence of training data required by supervised neural networks, the monitoring system can be formatted as in Figure 27.4 to take advantage of unsupervised pattern classification. The strategy depicted in Figure 27.4 considers fault detection independent of abnormality scaling of features, so it can be performed before or in parallel to this stage, based on the overall deviation of all of the features from their normal state. An example of abnormality scaling based on unsupervised pattern classification is described in the Section 27.2.

For fault diagnosis, the proposed system should have detailed information about the relation between the individual features and component faults. One format for providing that information is expert diagnostic software, which can be developed at two different levels. At one level, “shallow expert systems” can be developed to compile a human diagnostician’s knowledge relating measurements to faults, often as “if ...then” rules, similar to those already developed for simpler rotating machinery (Liddle and Reilly, 1993). The main obstacle in such a development will be the design of a robust inference engine that can resolve conflicting conclusions from the large pool of suspect features. At another level, “deep expert systems” can be developed to represent the diagnostic knowledge derived from the physics of the process. In deep expert systems, measurements need to be related to component faults by a model of the energy flow via the structural connections between components and sensors. A suitable format for defining the relation between components and sensors is the fuzzy set theory, which can address the approximate nature of vibration modeling. An example of a deep expert diagnostic system for helicopter gearboxes is the structure-based connectionist network (SBCN) (Jammu et al., 1998) described in Section 27.3, which takes advantage of the integration capability of neural networks while avoiding the need for supervised training. The salient feature of this connectionist network is that its weights can be determined *a priori*, based on the proximity of components to various accelerometers and the type of faults characterized by individual features. Although this system has been developed on a very approximate model of vibration flow between the gearbox components and accelerometers, it has produced promising results when used for fault diagnosis of helicopter gearboxes (Jammu et al., 1998).

A side benefit of a model of the structural connections between gearbox components and sensors is its use in sensor location selection (Wang et al., 1999). An important issue in helicopter gearbox diagnostics is the determination of the number of accelerometers to be used for monitoring and their location on the gearbox housing. Accelerometers are generally located by experts, based on their

FIGURE 27.4 Generic structure of an unsupervised diagnostic system.

²The large number of frequencies (tones) associated with the various components of the gearbox necessitates a huge number of features (often in excess of a hundred) to be obtained for vibration readings from each of the several accelerometers.

proximity to gearbox components, orientation, and ease of mounting on the housing. However, this approach often leads to too many accelerometers and too high a demand for on-line monitoring on the on-board computer. Another problem with the extra accelerometers is the cost of extra mountings, cabling, and signal conditioning equipment. Sensor location selection based on a gearbox model is discussed in Section 27.4.

27.2 Abnormality Scaling

The abnormality-scaling module described here relies solely on the value of each feature during normal operation. Accordingly, it is referred to as the *single category-based classifier* (SCBC) to signify its independence from feature values associated with faulty conditions (Jammu et al., 1996). In order to perform abnormality scaling, the SCBC compares features with their normal values, and if they are sufficiently different, assigns values between zero and one to characterize their degree of deviation from their normal values. The schematic of the SCBC, which is implemented by a connectionist network, is shown in Figure 27.5. The inputs to SCBC are the raw features from signal processing, $s_i(t)$, $i = 1, \dots, n$, and its outputs are abnormality-scaled features, $f_i(t)$, with values between zero and one. The value of zero indicates normality, and the other extreme of one denotes complete abnormality. The individual weights of the SCBC network, w_i , represent the normal values of the features, which are initially set equal to the first corresponding feature value supplied to the SCBC.

Classification in the SCBC is performed by first measuring the Euclidean distance of each feature, $s_i(t)$, from its weight value, w_i , and normalizing it into the range $[0, 1]$ using a *matching factor*, ϕ_i , defined as (Figure 27.6)

$$\phi_i(t) = 1 - \exp\left(\frac{-(s_i(t) - w_i)}{w_i}\right)^2 \quad (27.1)$$

A ϕ_i value of zero indicates that the feature value matches the weight value precisely, and a value of one denotes that it deviates from it considerably. Note that the exponential function used here is not unique, and that other functions that can map the Euclidean distance into the range $[0, 1]$ can also be used for the *matching factor*. Since during normal operation of the gearbox, noise in the features usually causes them

FIGURE 27.5 Schematic of the SCBC network.

FIGURE 27.6 Matching and abnormality-scaling in SCBC.

to deviate from their normal values, a threshold, θ , is considered to account for deviations by noise. The threshold, θ , is used to hard-limit $\phi_i(t)$ in SCBC as

$$\phi_i(t) = \begin{cases} 0 & \text{(normal)} & \text{if } \phi_i(t) < \theta \\ \phi_i(t) & \text{(hard-limited)} & \text{otherwise} \end{cases} \quad (27.2)$$

In the above relationship, the threshold θ is obtained as

$$\theta = \frac{1}{n} \sum_{i=1}^n \left(1 - \exp \frac{-[\max(s_i) - \mu_i]^2}{\mu_i^2} \right) \quad (27.3)$$

where $\max(s_i)$ denotes the maximum value of the i th feature in a set of κ samples of this feature recorded during normal operation, and μ_i represents its mean, estimated as

$$\mu_i = \frac{1}{\kappa} \sum_{t=1}^{\kappa} s_i(t) \quad (27.4)$$

The matching factor, defined by Equation 27.1, suppresses any positive value in $[0, \infty]$ into the range $[0, 1]$. As such, only very large deviations in the feature values will be scaled to the value of one. Since large deviations in feature values are uncommon for gearboxes, the value of matching factor is further scaled to yield abnormality-scaled feature values $f_i(t)$ as (Figure 27.6)

$$f_i(t) = f_{\min} + \exp(\alpha * \phi_i(t)) \quad (27.5)$$

where f_{\min} represents the minimum abnormality value assigned to any feature that violates the threshold, θ , and α controls the slope of the exponential curve. Since $f_i(t)$ is defined to have a value between zero and one, it is set to one when $f_i(t)$ in Equation 27.5 exceeds the value of one.

After each round of classification of the vibration features, the weight values in the SCBC are updated so as to cope with noise and small variations in the operating conditions. Adaptation is carried out in two stages. In the first stage, called *primary adaptation*, a network weight is adapted if the feature associated with it is classified as normal. In the second stage, referred to as *contrast enhancement* (CE) (Carpenter and Grossberg, 1987), the rest of the weights are adapted to achieve homogeneity in the abnormality-scaled values, thus increasing the likelihood of all of them being classified as normal or abnormal. Homogeneity, however, needs to exist only within specific feature groups, because gearbox faults do not necessarily cause abnormality in all of the features. For example, a gear fault will be reflected only by the features related to the gear, and is not expected to cause abnormality in bearing features. In order to preserve the functionality of individual feature groups (i.e., general features, gear features, and bearing features), CE is performed exclusively for each feature group.

Adaptation in SCBC is performed as follows. Let w_I represent the weight which is presently being updated and w_i the remaining weights in the group. In *primary adaptation*, the weight value w_I is modified according to the relationship

$$w_I = w_I + \delta w_I \quad (27.6)$$

where

$$\delta w_I = \begin{cases} \eta[s_I(t) - w_I] & \text{if } f_I(t) = 0 \\ 0 & \text{otherwise} \end{cases} \quad (27.7)$$

with the parameter η denoting the learning rate.

For CE, if the majority of features are classified as normal, then the weight values associated with the features classified as abnormal will be adjusted such that the likelihood of all of the features being

classified as normal is increased for the same feature. CE is performed as

$$w_i = w_i + \delta w_i \quad \text{for all } i \neq I \quad (27.8)$$

where

$$\delta w_i = \begin{cases} \eta \Lambda[s_i(t) - w_i] & \text{if } f_i(t) = 0 \\ -\eta \Lambda[s_i(t) - w_i] & \text{otherwise} \end{cases} \quad (27.9)$$

In CE, the amount by which the weight values are adjusted is controlled by a *neighborhood function*, Λ (Kohonen, 1989), which is assigned a value between zero and one. A value of zero is used for inputs with no noise, and a value at the other extreme of one is used for unreliable features with large amounts of noise. Usually, in practice, the value of Λ is set less than 0.5. For each round of *primary adaptation* (Equation 27.6 and Equation 27.7), I is varied to include all the features in the group. If the j th group of features contains m_j features, then primary adaptation is applied by varying I from one to m_j , to cover all the weight values w_I in the j th feature group. For each I , the remaining weight values, w_i , in the group ($i = 1$ to m_j and $i \neq I$) are adapted using CE according to Equation 27.8 and Equation 27.9.

The adaptation algorithm presented in Equation 27.6 to Equation 27.9 is biased towards the most recent feature vector if only this vector were used for adaptation, whereas adaptation should be ideally performed using all of the feature vectors that pertain to the current operating conditions. However, as the number of available feature vectors for the operating condition progressively increases, adaptation based on all of the features becomes computationally demanding. As a compromise, in SCBC only the β most recent feature vectors are utilized for each adaptation sweep, such that adaptation is performed iteratively over the β most recent feature vectors. The learning rate, η , is progressively reduced for each adaptation iteration (Equation 27.7 and Equation 27.9). Abnormality scaling formulae are summarized in Table 27.1.

TABLE 27.1 Summary of the Abnormality-Scaling Formulae

Classification in the single category-based classifier is performed by first measuring the Euclidean distance of each vibration feature, $s_i(t)$, from its weight value w_i , and normalizing it into the range $[0, 1]$ using a *matching factor*, ϕ_i , defined as

$$\phi_i(t) = 1 - \exp\left(\frac{-(s_i(t) - w_i)^2}{w_i}\right)$$

The matching factor is then hard-limited by a threshold, θ , as

$$\phi_i(t) = \begin{cases} 0 & \text{(normal)} & \text{if } \phi_i(t) < \theta \\ \phi_i(t) & \text{(hard-limited)} & \text{otherwise} \end{cases}$$

In the above relationship, the threshold, θ , is obtained as

$$\theta = \frac{1}{n} \sum_{i=1}^n \left(1 - \exp\left(\frac{[\max(s_i) - \mu_i]^2}{\mu_i^2}\right)\right)$$

where $\max(s_i)$ denotes the maximum value of the i th feature in a set of κ samples of this feature, recorded during normal operation, and μ_i represents its mean, estimated as

$$\mu_i = \frac{1}{\kappa} \sum_{t=1}^{\kappa} s_i(t)$$

The vibration feature is then abnormality-scaled as

$$f_i(t) = f_{\min} + \exp(\alpha * \phi_i(t))$$

where f_{\min} represents the minimum abnormality value assigned to any feature that violates the threshold, θ , and α controls the slope of the exponential curve.

27.3 The Structure-Based Connectionist Network

The SBCN (Jammu et al., 1998) is developed to take advantage of the integration capability of neural networks, but to avoid the need for supervised training. It defines the weights of the network according to the structural knowledge of the gearbox and the type of fault represented by various vibration features. In the SBCN, the structural influences, which represent the proximity effect of faults on accelerometers, are determined based on the root-mean-square (RMS) value of the frequency response of a simplified lumped-mass model of the gearbox.

Fault diagnosis in SBCN is performed by propagating the abnormality-scaled vibration features from SCBC to produce outputs representing the fault possibility values for each gearbox component as (Figure 27.7)

$$p_k(t) = \sum_{i=1}^n f_i(t)v_{ik} \quad (27.10)$$

In the above equation, $p_k(t)$ represents the fault possibility value for the k th component of the gearbox, $f_i(t)$ denotes the abnormality-scaled value of a feature and v_{ik} represents the weighting factor determined based on the lower and upper bounds of fuzzy influence weights (l_{ik} , u_{ik}) as

$$v_{ik} = l_{ik} + (u_{ik} - l_{ik})f_i(t) \quad (27.11)$$

Note that Equation 27.10 represents propagation of inputs through the weights of the SBCN, similar to a regular connectionist network with v_{ik} as weights (Hertz et al., 1991). The difference is that the weights of the SBCN vary within the range (l_{ik} , u_{ik}) according to the magnitude of the corresponding input, $f_i(t)$. According to Equation 27.11, a higher abnormality-scaled feature value produces a higher weight value, v_{ik} , emulating the reasoning by the human expert who pays more attention to the features that exhibit higher abnormality values. In SBCN, in order to make uniform the interpretation of the fault possibility values $p_k(t)$, they are normalized to have values between zero and one as

$$c_k(t) = \frac{p_k(t)}{\sum_{i=1}^n u_{ik}} \quad (27.12)$$

Accordingly, a $c_k(t)$ equal to one denotes a definite fault, whereas a value of zero represents normality. In this system, fault diagnosis is performed hierarchically. First, the faulty subsystem within the gearbox is identified by using the structural influences as v_{ik} . Then, the faulty components within the suspect subsystem(s) are isolated using the product of structural and featural influences as v_{ik} .

The connection weights of the SBCN are defined based on the influences between the component faults and vibration features. Ideally, the structural influences should represent the strength of component vibration at the particular frequency (frequencies) represented by the feature. For this, the attenuation property of the “travel path” between each component and accelerometer needs to be modeled as a function of the moment of inertia, stiffness, and damping of the components in the path (Badgley and Hartman, 1974; Smith, 1983; Lyon, 1995). In order to appreciate the difficulties associated with vibration modeling of gearboxes, the vibration model of a simple gearbox is considered

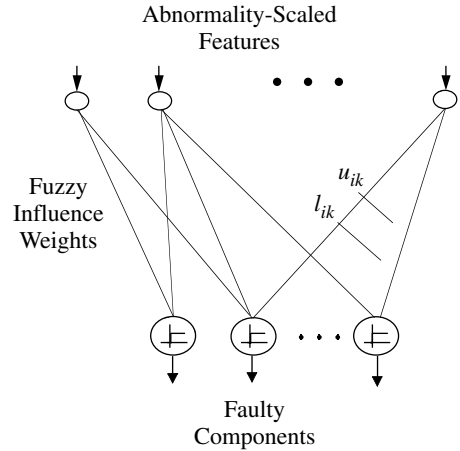

FIGURE 27.7 The structure-based connectionist network (SBCN) with its fuzzy weights for isolating faulty components.

(Choy and Qian, 1993):

$$[M][\ddot{X}] + [\dot{G}_v][\dot{X}] + [G_A][X] + [C_b][\dot{X} - \dot{X}_c] + [K_b][X - X_c] + [K_s][X - X_r] = [F(t)] + [F_G(t)] \quad (27.13)$$

where X represents the generalized displacement vectors in the lateral x , y , and z , and rotational θ_x , θ_y , and θ_z directions, M denotes the inertia matrix, G_v represents gyroscopic forces, G_A denotes the rotor angular acceleration, C_b and K_b represent the damping and stiffness matrices of bearings, respectively, $[X - X_c]$ denotes the casing vibration, $[X - X_r]$ represents the shaft residual bow, and K_s denotes the shaft bow stiffness matrix. The excitation force $[F(t)]$ is due to mass imbalance, and $[F_G(t)]$ represents the nonlinear gear mesh force, which in the x direction has the form (Choy and Qian, 1993)

$$F_{Gxk} = \sum_{i=1, i \neq k}^n K_{tki} [-R_{ci}\theta_{ci} - R_{ck}\theta_{ck} + (X_{ci} - X_{ck})\cos(\alpha_{ki}) + (Y_{ci} - Y_{ck})\sin(\alpha_{ki})][\cos(\alpha_{ki}) + \text{SIGN}(\mu)\sin(\alpha_{ki})] \quad (27.14)$$

where F_{Gxk} denotes the gear mesh force in the x direction on the $(n - 1)$ th gear due to its mesh with $(n - 1)$ other gears, K_{tki} represents the nonlinear gear mesh stiffness between the k th gear and i th gear, R_{ci} denotes the radius of the i th gear, α_{ki} represents the orientation angle between the k th and i th gears, and μ denotes the coefficient of friction. Mathematical relationships similar to Equation 27.14 can be defined to represent the force in the y direction as well as torsional gear mesh forces. Furthermore, the vibration of the casing due to the vibration of the gear–shaft system needs to be represented by a separate set of coupled equations of motion similar to Equation 27.13. The above equations need to be integrated numerically in order to estimate the vibration signal recorded on the housing, but the following difficulties exist. (1) The values of stiffness and damping coefficients for the components are not readily available. (2) The cross-coupling terms in the stiffness matrices in the x , y , and z directions cannot be easily defined (Mitchell and Davis, 1985; Choy and Qian, 1993). (3) It is difficult to take into account the multitude of travel paths and the associated models of attenuation for the many component–accelerometer pairs in the gearbox. For example, K_{tki} , the gear mesh stiffness, which is obtained by considering the gear tooth as a nonuniform cantilever beam (Lin et al., 1988; Boyd and Pike, 1989), is a function of the cross section of the tooth at the point of loading as well as load variation due to changes in the direction of load application (Mark, 1987; Lin et al., 1988; Choy and Qian, 1993), friction between the meshing teeth (Rebbechi et al., 1991), contact ratio (Cornell and Westervelt, 1978), the type of gears (spur, helical, etc.) (Mark, 1987; Lin et al., 1988; Boyd and Pike, 1989), and gear errors such as profile, transmission, and manufacturing errors (Smith, 1983; Mark, 1987). Similarly, the stiffness of bearings is a time-varying, nonlinear function of bearing displacement and the number of rolling elements in the load zone, as well as the bearing type (roller, ball, etc.), axial preload, clearance, and race waviness (Harris, 1966; While, 1979; Walford and Stone, 1983). All these factors make it very difficult to obtain an accurate and computationally inexpensive vibration attenuation model for gearboxes.

In order to avoid the difficulties associated with accurate modeling of vibration transfer, a simplified method is described here that accounts separately for the two main aspects of vibration change by faulty components: (1) the proximity effect of the faulty component on the accelerometer generating the feature (structural influence), and (2) the frequency related information represented by the feature (featural influence). The main simplification in this method is in the definition of structural influences as the average strength of the vibration signal across all frequencies measured by an accelerometer due to a component fault. To compute this average vibration, several simplifications have been adopted:

1. A lumped-mass model of the gearbox is used to model vibration.
2. Only the average static values for the stiffness coefficients are used, to cope with the absence of accurate values for stiffness coefficients.
3. Damping ratios of bearings and shafts are neglected (Lin et al., 1988).
4. A damping ratio of 0.1 is used for all the gears as an approximation to actual gear ratios estimated between 0.03 and 0.17 (Kasuba and Evans, 1981).

5. The cross-coupling terms in the stiffness matrix are neglected.
6. Only the shortest vibration travel path between each component–accelerometer pair is considered.

Using the above simplifications, the average vibration registered by an accelerometer due to a faulty i th component can be simulated by applying an excitation source y at the i th component in the lumped-mass model (Figure 27.8). In order to represent all frequencies in the excitation source, y can be selected to consist of unit amplitude sine waves of all frequencies. The displacement of various components in the travel path due to an excitation exerted at the i th component can be obtained for a typical N -mass path as (James et al., 1994)

$$\begin{bmatrix} a_{11} & a_{12} & 0 & \cdots & 0 \\ a_{21} & a_{22} & a_{23} & \cdots & 0 \\ \vdots & \vdots & \vdots & \cdots & \vdots \\ 0 & \cdots & 0 & a_{N-1,N-1} & a_{NN} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_N \end{bmatrix} = \begin{bmatrix} y \\ 0 \\ \vdots \\ 0 \end{bmatrix} \quad (27.15)$$

where $[x_1, x_2, \dots, x_N]^T$ represent the displacements of the N components in the path, y denotes the magnitude of excitation at the first component, and the coefficients a_{ij} are defined as

$$\begin{aligned} a_{nn-1} &= -j\omega c_{n-1} - k_{n-1} & a_{nn} &= -m_n \omega^2 + j\omega(c_{n-1} + c_n) + (k_{n-1} + k_n) \\ a_{nn+1} &= -j\omega c_n - k_n \end{aligned} \quad (27.16)$$

In the above equation, m_n denotes the mass of the n th component, k_n and c_n represent the stiffness and damping coefficients between the n th and $(n+1)$ th components, respectively, and ω denotes frequency.

In SBCN, the average vibration representing the overall vibration transferred from the component to the accelerometer is characterized by the RMS value of vibration across all frequencies. RMS values of vibration are readily obtained from Equation 27.15 by numerical integration of the square of displacements across all frequencies. In these calculations, to avoid unnecessary numerical problems at the natural frequencies of the components with negligible damping, the integration is carried out excluding the natural frequencies.

For the purpose of assigning structural influences, the RMS values are scaled so that the component directly adjacent to the accelerometer has the highest influence. Different functions can be used for defining the influences. For example, I_i can be defined as

$$I_i = \frac{\log(r_i)}{\log(r_N)} \quad (27.17)$$

where r_i represents the RMS value of vibration with the excitation source at the i th component, and r_N denotes the RMS value when the excitation is at the N th component. In both cases, the accelerometer is considered at the N th component. The influence for the other components is obtained in a similar fashion, by moving the excitation source to them in the travel path.

The RMS values, r_i , are only approximate estimates due to the simplifications made for their computation. Such approximate RMS values would, in turn, result in approximate influences. To

FIGURE 27.8 Illustration of the lumped-mass model of a vibration travel path consisting of N masses.

characterize the approximate nature of influences, they can be defined as fuzzy variables (Zadeh, 1975) by mapping the influences into the range associated with fuzzy variables, such as *nil*: (0, 0.1), *low*: (0.1, 0.4), *medium*: (0.4, 0.6), *high*: (0.6, 0.9) and *definite*: (0.9, 1).

Another body of knowledge commonly used by diagnosticians is that of the type of fault represented by a feature. To incorporate this knowledge, fuzzy featural influences can be defined according to the relation between the frequency content of each feature and the rotational frequencies of various components (McFadden and Smith, 1986; Stewart Hughes Ltd., 1986). For example, a feature such as envelope band energy (BE), which represents the energy at the bearings rotational frequencies and harmonics, is assigned a featural influence of “high” in relation to bearing faults.

The SBCN is designed to provide fault possibility values for gearbox components without any prior training. However, its design does not preclude the possibility of training when confronted with misclassifications, which are in the form of undetected faults, false alarms, and misdiagnoses. Among these, undetected faults are safety hazards that should be avoided at all costs, and false alarms and misdiagnoses, although not as crucial as undetected faults, should be minimized so as to improve the reliability of the diagnostic system. One of the features of the SBCN is its ability to benefit from connectionist learning (Hertz et al., 1991) to improve diagnostic performance after each misdiagnosis. For this purpose, an error-minimizing adaptation algorithm can be considered for adapting the fuzzy influence weights of SBCN so as to avoid reoccurrence of misdiagnosis. This algorithm reduces the error between the outputs of the SBCN $c_k(t)$ and the binary target $T_k(t)$ obtained after inspection. The binary target takes the value of zero for all the normal components and one for the faulty components. Sequential update rules for adapting the fuzzy influences in SBCN have the form

$$l_{ik} = \begin{cases} l_{ik} + \eta_3(T_k(t) - c_k(t))(1 - f_i(t))f_i(t) & \text{if } 0 < l_{ik} < 1 \\ l_{ik} & \text{otherwise} \end{cases} \quad (27.18)$$

$$u_{ik} = \begin{cases} u_{ik} + \eta_3(T_k(t) - c_k(t))f_i(t)^2 & \text{if } 0 < u_{ik} < 1 \\ u_{ik} & \text{otherwise} \end{cases} \quad (27.19)$$

where η_3 represents the learning rate. In this method, in order to allow uniform interpretation of the trained fuzzy influences with respect to their original values, adaptation is stopped when the weight values reach the bound of zero or one.

27.4 Sensor Location Selection

Suitable mounting locations for accelerometers on the housing are generally those that provide both close proximity to gearbox components and ease of mounting (also see Chapter 15). However, considering that only a limited number of accelerometers can be used, the candidate locations need to be selected so as to provide a comprehensive coverage of the components. The method presented here relies on indices to quantify the suitability of various mounting locations. It uses a *coverage index* to define the reach of each accelerometer, and an *overlap index* to represent the overlap of the locations in coverage of the gearbox components. The monitoring effectiveness of various combinations of accelerometer locations can then be estimated as a function of the coverage and overlap indices of the accelerometer locations (Wang et al., 1999).

27.4.1 Coverage Index

The coverage index denotes the reach of each accelerometer in monitoring various components of the gearbox. It can be computed based on an influence matrix such as that defined in the SBCN. It can be defined, for example, as the sum of the corresponding row of the influence matrix, as

$$C_j = \frac{1}{N} \sum_{i=1}^N \frac{u_{ij} + l_{ij}}{2} \quad (27.20)$$

where u_{ij} and l_{ij} represent the upper and lower limits, respectively, of the fuzzy influence coefficients between the gearbox component, i , and accelerometer, j , and N denotes the total number of gearbox components. According to this index, an accelerometer location with a higher coverage index should be considered a better candidate.

27.4.2 Overlap Index

The coverage index can be used to rank accelerometers individually. However, for a complex gearbox where more than one accelerometer is needed for monitoring, the sum of the coverage indices associated with all of the accelerometers in the suite will not provide a correct representation of their overall effectiveness because it will ignore the overlap among them.

Although the overlap between accelerometer pairs may be defined according to the influence coefficients, that definition will only consider the distance of the accelerometers from the components, and will ignore factors such as accelerometer orientation and gearbox size. In order to consider these other factors, the overlap index may be defined independent of the influence coefficients, based on an overlap matrix that represents the level of cocoverage between all of the accelerometer pairs. The individual components O_{jk} in this matrix can be defined as

$$O_{jk} = \frac{E_{jk}}{e^{aD_{jk}}}(1 + S_{jk}) \quad (27.21)$$

where O_{jk} denotes the overlap between the accelerometers, j and k , E_{jk} represents the similarity of orientation between the two accelerometers, a denotes a constant to account for the size of the gearbox, D_{jk} accounts for the physical distance between the two accelerometers, and S_{jk} represents a symmetry factor between the two accelerometers. The formulation of Equation 27.21 is based on the following understanding. The overlap in coverage of two accelerometers depends mainly on their orientation and location, that is, the more identical their orientation is and the closer they are mounted to each other, the higher is their expected level of overlap. In the above equation, the orientation factor, $E_{jk} \in [0, 1]$, is set to one when the accelerometers, j and k , have identical orientation. The distance factor, $D_{jk} \in [0, 1]$, is defined as the normalized shortest geometrical distance between the two accelerometers along the casing, where the term $e^{aD_{jk}}$ approximates the attenuation of vibration due to distance (Lindsay, 1960) and the constant a , with values ranging between zero and two, accounts for the effect of gearbox size on vibration attenuation. Although the main factors in the coverage overlap of two accelerometers are orientation and distance, the accelerometers that are symmetrically positioned are believed to have a larger overlap with each other. In order to account for this factor, a symmetry factor, $S_{jk} \in [0, 1]$, is also included in Equation 27.21, which is set to one when two accelerometers are perfectly symmetrical with respect to the housing. Based on Equation 27.21, the values of O_{jk} would ordinarily fall in the range $[0, 1]$, where the value of one indicates that the two accelerometers, j and k , have 100% overlap with each other and that one of them can be removed. Similarly, when O_{jk} is zero then the two accelerometers are assumed to be covering completely different components. It should be noted, of course, that some overlap between accelerometers is considered useful and is often factored in when selecting accelerometer locations.

The overlap coefficients only represent the level of overlap between pairs of accelerometers and not the specific components covered jointly by each accelerometer pair. As such, defining the level of overlap between several accelerometers is not as straightforward. At one extreme, one can assume that the coverage overlap of each accelerometer pair in the suite does not coincide with the coverage overlap of the other accelerometer pairs, so the total overlap, O_s , for the accelerometer suite can be computed as

$$O_s = \sum_{j=1}^m \min \left(\sum_{k=j+1}^m O_{jk} \frac{C_j + C_k}{2}, C_j \right) \quad (27.22)$$

where m denotes the number of accelerometers in the suite, and the min function ensures that the computed overlap will not exceed the total coverage of accelerometer j . At the other extreme, it can

be assumed that the overlaps of all of the accelerometer pairs coincide, and that the total overlap of the accelerometer suite can be defined as

$$O_s = \sum_{j=1}^m \max \left(O_{jk} \frac{C_j + C_k}{2} \text{ for all } k > j \right) \quad (27.23)$$

The latter formulation only considers the largest overlap between accelerometer j and the other accelerometers in the suite. It is also possible to use the average of the above two extremes as a compromise:

$$O_s = \sum_{j=1}^m \frac{1}{2} \left[\left(\min \left(\sum_{k=j+1}^m O_{jk} \frac{C_j + C_k}{2}, C_j \right) + \left(\max \left(O_{jk} \frac{C_j + C_k}{2} \text{ for all } k > j \right) \right) \right) \right] \quad (27.24)$$

It should be noted that, unlike the coverage index, the overlap index is suite related because the overlap of an accelerometer depends on the other accelerometers in the suite.

27.4.3 Monitoring Effectiveness

As mentioned earlier, the coverage index can be used to evaluate the effectiveness of individual accelerometers in monitoring, but its sum cannot be a sole measure of effectiveness of suites of accelerometers. For instance, a suite consisting of the top three accelerometer locations in terms of coverage may be inferior to another suite of three accelerometer locations with a lower total level of coverage but less overlap among the accelerometers. The best set of accelerometer locations is, therefore, one which provides the highest coverage of the gearbox components and the least overlap among the accelerometers. As such, the monitoring effectiveness (ME) of a suite can be expressed as

$$ME_s = \left(\sum_{j=1}^m C_j \right) - O_s \quad (27.25)$$

where m represents the number of accelerometers in the suite, C_i denotes the coverage of individual accelerometers in the suite, and O_s represents the total overlap among the accelerometers in the suite (Equation 27.24), estimated from Equation 27.22, Equation 27.23, or Equation 27.24. The indices used in sensor location are summarized in Table 27.2.

TABLE 27.2 Summary of Indices Used for Sensor Location Selection

Sensor location is performed according to the following indices:

Coverage index

$$C_j = \frac{1}{N} \sum_{i=1}^N \frac{u_{ij} + l_{ij}}{2}$$

where u_{ij} and l_{ij} represent the upper and lower limits of the fuzzy influence coefficients between the gearbox component, I , and accelerometer, j , and N denotes the total number of gearbox components.

Overlap index

$$O_{jk} = \frac{E_{jk}}{e^{aD_{jk}}} (1 + S_{jk})$$

where O_{jk} denotes the overlap between the accelerometers, j and k , E_{jk} represents the similarity of orientation between the two accelerometers, a denotes a constant to account for the size of the gearbox, D_{jk} accounts for the physical distance between the two accelerometers, and S_{jk} represents a symmetry factor between the two accelerometers.

According to the above indices, the monitoring effectiveness of an accelerometer suite is defined as

$$ME_s = \left(\sum_{j=1}^m C_j \right) - O_s$$

where m represents the number of accelerometers in the suite, C_j denotes the coverage of individual accelerometers in the suite and O_s represents the total overlap among the accelerometers in the suite.

27.5 A Case Study

This case study illustrates the application of the SBCN to an OH-58A main rotor gearbox (Figure 27.1; Jammu et al., 1996). Experimental vibration data for the OH-58A gearbox were collected at the NASA Lewis Research Center as part of a joint NASA/Navy/Army advanced lubricants program (Lewicki et al., 1992). Various component failures in the OH-58A transmission were produced during accelerated fatigue tests. The vibration signals were recorded by eight piezoelectric accelerometers (frequency range of up to 10 kHz) using an FM tape recorder. The signals were recorded once every hour, for about 1 to 2 min per recording (using a bandwidth of 20 kHz). Two magnetic chip detectors were also used to detect the debris caused by component failures. The location and orientation of the accelerometers are shown in Figure 27.2. The OH-58A gearbox was run under a constant load, and was disassembled and inspected periodically or when one of the chip detectors indicated a failure. A total of eleven failures occurred during these tests. They consisted of three cases of planet bearing pitting fatigue, three cases of sun gear pitting fatigue, two cases of top housing cover cracking, and one case each of spiral bevel pinion (SBP) pitting fatigue, mast bearing micropitting, and planet gear pitting fatigue.

In order to extract the vibration features, the vibration signals from the gearbox were digitized and processed by a commercially available signal analyzer (Stewart Hughes Ltd., 1986). Overall, 54 vibration features were extracted from each accelerometer for the OH-58A gearbox. Out of these features, 35 features were gear-related features (7 for each of the five gears). The remaining 19 features were indicators of either general faults (e.g., wear and out-of-balance), or general gear and bearing faults.

27.5.1 Structural and Featural Influences

The structural influences for the OH-58A gearbox were obtained through five primary vibration travel paths: (1) duplex bearing-spiral bevel mesh-triplex bearing, (2) duplex bearing-sun-planet mesh-ring gear, (3) mast roller bearing-main shaft-mast ball bearing, (4) ring gear-planet bearing-mast ball bearing, and (5) duplex bearing-sun planet mesh-mast ball bearing. The first travel path was in connection to accelerometers 4, 5, and 6, whereas all the other paths were connected to accelerometers 1, 2, 3, 6, 7, and 8. The RMS values of vibration were then computed using the lumped-mass model of these paths with excitation sources at each of the gearbox components. These RMS values were then used as the basis for defining the fuzzy structural influences between each component–accelerometer pair (Table 27.3).

The structural influences in Table 27.3 indicate that all of the components in the gearbox are covered by the accelerometers, and that some accelerometers have identical influences with respect to the components. Although these influences are not completely accurate due to their neglect of the orientation of accelerometers and various approximations (Jammu et al., 1998), they can still be used for

TABLE 27.3 Structural Influences between the Components of the OH-58A Gearbox and the Eight Accelerometers

Component/Accelerator	1	2	3	4	5	6	7	8
Triples bearing	—	—	—	H	H	—	—	—

Mast ball bearing	M	M	M	—	—	M	M	M
Sun gear	H	H	H	L	M	H	H	H
Planet bearing	H	H	H	L	M	H	H	H
Planet gear	H	H	H	L	M	H	H	H
Ring gear	H	H	H	L	M	H	H	H

The influences shown are: “—” nil, “L” low, “M” medium, and “H” high.

an overall assessment of the effectiveness of various accelerometers and their redundancy. For example, the influences in Table 27.3 are identical for accelerometers 1, 2, 3, 6, 7, and 8. This would indicate that one or more of these accelerometers can be discarded without any drastic effect on fault diagnostic effectiveness. However, it should be noted that the strategy used in SBCN relies on the averaging effect of accelerometers, and that it will not function without a certain level of overlap in accelerometer coverage.

The featural influences were defined for individual vibration features according to the type of fault they are supposed to represent. For example, bearing-related features such as envelope band and tone energy were assigned high in association with gearbox bearings. Similarly, the signal averaged features for the five gears in the OH-58A gearbox were assigned high with respect to these gears. Features that are indicators of faults in all rotating elements in the gearbox were assigned an influence of medium for gears as well as bearings.

The structural and featural influences constitute the basis of the SBCN connection weights. As discussed in Jammu et al. (1998), diagnosis in SBCN is performed hierarchically, first isolating the faulty subsystems and then faulty components. As such, only the average of the structural influences associated with each subsystem is used as the connection weights, v_{ik} , of SBCN to yield the fault possibility values, $p_k(t)$, associated with each subsystem, according to Jammu et al. (1998):

$$p_k(t) = \sum_{i=1}^n f_i(t)v_{ik} \quad (27.26)$$

In subsystem diagnosis, $f_i(t)$ denotes the average abnormality-scaled value of general features. In the second stage of fault diagnosis, at the component level, the combination of structural and featural influences are used as v_{ik} , and $f_i(t)$ consist of individual abnormality-scaled features.

27.5.2 Evaluation of Influences

As explained in Jammu et al. (1998), the structural influences representing the proximity effect of component faults on accelerometer readings were obtained from the RMS value of the frequency response of the lumped-mass model of the gearbox. In this case, however, the actual RMS values of the vibration were available at several fault instances for the OH-58A gearbox, which could also be used to yield a set of experimentally obtained structural influences. In order to evaluate the modeled influences, a comparison between these two sets of structural influences was conducted. The experimental influences were obtained by normalizing the experimental RMS values when a faulty component had been detected and using them as the basis for assigning the level of fuzzy influences (Table 27.4). The results in Table 27.4 indicate mixed agreement between experimental and structural influences. For example, the structural influences of sun gear, planet bearing, and planet gear on accelerometers 1, 2, and 3 are close to the experimentally obtained influences, but the influence of mast ball bearing on accelerometers 2 and 3

TABLE 27.4 Influences between Accelerometers and Gearbox Components Obtained from Experimental RMS Values of Vibration for the OH-58A Gearbox

Accelerator/Parts	Influences from RMS Values of Vibration				
	Spiral Bevel Pinion	Mast Ball Bearing	Sun Gear	Planet Bearing	Planet Gear
1	— (—)	— (—)	H (H)	M (H)	M (H)
2	M (—)	— (H)	M (H)	M (H)	M (M)
3	M (—)	— (H)	M (H)	H (H)	M (M)
4	L (H)	— (—)	H (L)	— (—)	M (—)
5	H (H)	— (—)	H (M)	H (M)	— (M)
6	L (—)	— (—)	L (H)	M (H)	L (H)
7	— (—)	— (—)	H (H)	M (H)	L (H)
8	— (—)	— (—)	M (H)	M (H)	M (H)

For comparison, the influences from the lumped-mass model are shown inside parentheses.

TABLE 27.5 Normalized Weight Values of the Supervised Connectionist Network

Accelerator	Subsystem		
	1	2	3
1	* (–)	* (M)	* (H)
2	* (–)	H (M)	H (H)
3	* (–)	* (M)	L (H)
4	H (H)	* (–)	* (L)
5	M (H)	* (–)	H (M)
6	M (M)	* (M)	H (H)
7	M (–)	L (M)	H (H)
8	* (–)	H (M)	M (H)

For comparison, the subsystem influences of the SBCN are included inside parentheses. A “*” indicates a negative weight value.

do not match. In this case, the mismatch between the two sets of influences may be due to (1) the limitation of the RMS value in reflecting the change in vibration as a result of various component faults (e.g., mast ball bearing micropitting), (2) variation in the level of change of the RMS values as a function of the type and size of the fault, and (3) lack of faults in every component of the OH-58A gearbox, which limits the ability to determine the influences for every gearbox component.

Defining influences based on an approximate model of the gearbox was motivated by the need to avoid supervised training of the SBCN. However, given that experimental data were available for the OH-58A gearbox, an evaluation of the structural influences could be performed by comparing them with the weights of a connectionist network structurally similar to SBCN, but trained by supervised learning. For this purpose, the OH-58A gearbox was divided into three subsystems (Figure 27.1), and the supervised network, having three output units for the three subsystems and eight input units for the eight accelerometers, was trained using least-mean-square (LMS) learning. The weights of this network were trained until the number of false alarms and misdiagnoses were reduced to zero. The trained weights were then normalized and converted into fuzzy variables for comparison with the structural influences obtained from the lumped-mass model of the gearbox. Table 27.5 includes the influences of the two networks, where the modeled influences (inside parentheses) represent the average of component influences within each subsystem (Table 27.3). The results in Table 27.3 indicate general agreement between the trained weights and modeled influences. Some of the trained weights had negative values (indicated by “*”), which is inevitable due to the use of LMS learning. However, all of these negative weights were quite small in magnitude, which makes them consistent with their modeled nil counterparts (denoted by “–”). As in the case of influences from the RMS values (Table 27.4), some of the mismatches in Table 27.5 are expected to be due to the limited number of faults represented in the experimental data. For example, the considerably different influence of subsystem 2 on accelerometer 1, or subsystem 3 on accelerometer 1, is attributed to the lack of specific faults in these subsystems that would lead to a more accurate influence on accelerometer 1.

The comparison between the modeled structural influences and those obtained from the supervised neural network indicates that the modeled influences are in good agreement with the trained influences, and that the lumped-mass modeling used here provides an acceptable set of structural influences for the SBCN.

27.5.3 Fault Detection Results

The fault detection network (FDN) in the proposed diagnostic system (Figure 27.4) is used first to identify the presence of faults in the gearbox. Fault diagnosis is then performed when the presence of a fault is prompted. A total of eight FDNs, one for each of the eight OH-58A accelerometers, were used. The inputs to each FDN were the 19 general features not specific to any particular gear or bearing. The initial weight

TABLE 27.6 Fault Detection Results for the OH-58A Gearbox

Day	Fault Detection Network: Predicted and Actual Failures				
	Test 1	Test 2	Test 3	Test 4	Test 5
1	— (—)	— (—)	— (—)	— (—)	— (—)
2	— (—)	— (—)	— (—)	— (—)	— (—)
3	— (—)	— (—)	1 (1)	— (—)	— (—)

6	— (1)	— (—)	— (—)	— (—)	— (—)
7	1 (1)	— (—)	— (—)	— (—)	— (—)
8	1 (1)	— (—)	— (—)	— (—)	— (1)
9	— (1*)	— (—)	— (1*)	— (—)	1 (1)
10			— (—)	1 (1)	— (1)
11			1 (1)	1 (1)	— (1*)
12			1 (1)	1 (1*)	
13			— (1*)	1 (—)	
14				1 (1)	
15				1 (1*)	

A “—” indicates normality and a “1” represents the presence of a fault. For reference, the expected faults determined by an expert are included inside the parentheses, with “*” indicating actual observation of the fault.

values of the FDNs were set as the values of the first set of features for each of the five tests, and were subsequently adapted using 50 adaptation sweeps for each training batch. The occurrence of a fault was prompted when any of the FDNs indicated a fault. The detection results for individual test sets obtained from the FDNs are shown in Table 27.6. A “—” in this table indicates normal conditions, whereas a “1” indicates the presence of a fault. The expected detection results are indicated inside parentheses. The results for test 1 indicate that the presence of faults was detected on days 5, 7, and 8, while faults were expected to be present from days 5 to 9. Of course, it should be noted that the gearbox was not inspected on a daily basis, so the actual condition of the gearbox is unknown for each day of the tests. In test 1, which was run for nine days, a fault was actually observed only on day 9 during a routine inspection of the gearbox (indicated by 1*). However, based on an inspection of the vibration features, it was estimated that the fault could have been present as early as day 5. For the other tests, the days when the faults were actually observed are also indicated by 1*. While it is discouraging to note that day 6 of test 1 was classified as normal though a fault was present on day 5, the results are in agreement with observations by experts who believe that sometimes increased noise levels immediately after the occurrence of faults mask the effect of faults on vibration features. For the other tests, the results indicate that except for an undetected fault in test 3 and a false alarm in test 4, excellent fault detection was obtained. It should also be noted that the fault on day 9 of test 3 was a hairline crack, which was perhaps undetectable through vibration monitoring. The quality of fault detection in the proposed system is particularly important to the overall diagnostic results, since it is only after a fault is detected that SBCN is engaged in diagnosis.

In summary, the detection results obtained (Table 27.6) indicate that the occurrences of most of the faults were identified. This provides assurance that the later stage of diagnostics would not be hampered by the detection phase.

27.5.4 Fault Diagnostic Results

In the proposed system, fault diagnosis is performed by the SBCN only after the presence of a fault is detected. In this system, fault diagnosis is performed in two hierarchies so as to take full advantage of the separation of the structural and featural influences. In the first hierarchy the gearbox is divided into subsystems (Figure 27.1) and the faults in individual subsystems are isolated by the SBCN based on the structural influences alone. For each subsystem, the weights of the SBCN are set equal to the average of the structural influences of the components within that subsystem (Table 27.5). The inputs to the SBCN

for this stage of the diagnosis consist of the averaged values of abnormality-scaled features from each accelerometer, and its outputs are the fault possibility values for each subsystem. In the second hierarchy, the faulty components within each subsystem are isolated. The inputs to the SBCN for this stage of the diagnosis are the abnormality-scaled vibration features, and the weights are the product of featural influences and structural influences of the subsystem containing each component. The averaging of fuzzy influences here was done by taking the average of upper bounds and lower bounds of individual influences separately, and then defining the fuzzy variable that would match the range. The product of fuzzy influences was determined by multiplying the upper bounds and lower bounds of fuzzy variables separately, and then defining the fuzzy variable for the resultant range.

27.5.4.1 Faulty Subsystem Isolation

The fault possibility values for the three subsystems of the OH-58A gearbox are shown in Table 27.7. The results in this table represent the hard-limited fault possibility values (threshold of 0.5) and include, for comparison, the actual condition of the gearbox reported from routine inspection inside parentheses. As before, a “*” indicates actual observation of the fault during inspection of the gearbox. The results in Table 27.7 indicate that in test 1, faults in subsystems 1 and 3 were correctly identified on days 5, 7, and 8. In test 3, the faults in subsystem 3 on days 3 and 4 were correctly identified, along with a possible fault in subsystem 1. The housing crack on day 9 of this test was left unidentified because it was never prompted during the detection phase. In any case, this particular fault (a housing crack) could not be isolated by the current SBCN due to absence of features that reflect this fault. Also for this test, faults in subsystems 2 and 3 were correctly identified on days 11 and 12. In Test 4, the fault in subsystem 3 was correctly diagnosed on days 10, 11, 12, 14, and 15. Moreover, on day 13 of test 4, even though the gearbox was supposed to be normal, the SBCN indicated faults in subsystem 3. This was due to the replacement of the three-planet assembly with a four-planet assembly, which changed the vibration characteristic of subsystem 3. In test 5, the fault in subsystem 3 was correctly identified on day 9. There was also a misdiagnosis in subsystem 1.

In summary, the diagnostic results from the gearbox subsystems indicate that all of the eight subsystem faults were correctly identified in the OH-58A gearbox and that four faults were misdiagnosed. Considering that these results were obtained by using structural influences alone as the connection weights of the SBCN, the results validate the utility of these influences and of lumped-mass modeling as a means of representing the vibration travel path of gearboxes for their model-based fault diagnosis.

TABLE 27.7 Faulty Subsystem Isolation Results for the OH-58A Gearbox

Day	Faulty Subsystems Isolation for OH-58A				
	Test 1	Test 2	Test 3	Test 4	Test 5
1	— (—)	— (—)	— (—)	— (—)	— (—)
2	— (—)	— (—)	— (—)	— (—)	— (—)
3	— (—)	— (—)	1, 3 (3)	— (—)	— (—)
4	— (—)	— (—)	1, 3 (3*)	— (—)	— (—)
5	1, 3 (1, 3)	— (—)	— (—)	— (—)	— (—)
6	— (1, 3)	— (—)	— (—)	— (—)	— (—)
7	1, 3 (1, 3)	— (—)	— (—)	— (—)	— (—)
8	1, 3 (1, 3)	— (—)	— (—)	— (—)	— (3)
9	— (1*, 3*)	— (—)	— (3)	— (—)	1, 3 (3)
10			— (—)	3 (3)	— (3)
11			2, 3 (2, 3)	3 (3)	— (3*)
12			2, 3 (2, 3)	3 (3*)	
13			— (2*, 3*)	3 (—)	
14				3 (3)	
15				3 (3*)	

The three subsystems in the table are the input subsystem (1), the output subsystem (2), and the transmission subsystem (3). For comparison, the actual faults are included inside parentheses with “*” indicating the observed faults.

27.5.4.2 Faulty Component Isolation

Fault possibility values associated with the components of the OH-58A gearbox obtained from the SBCN are included in Table 27.8. The results indicate that the diagnostics associated with individual components are not as accurate as those obtained for the subsystems. Briefly, for test 1, the SBP fault in subsystem 1 and the sun gear (SG) fault in subsystem 3 were correctly identified only on days 5 and 8, respectively, while other components were assigned higher fault possibility values on other days. For test 3, the three bearing faults in subsystems 2 and 3 (BRG2 and BRG3, respectively) were correctly identified on days 3, 4, and 12, but other components were also given high fault possibility values. In test 4, the bearing fault in subsystem 3 (BRG3) was correctly identified only on day 10, while the SG fault remained misdiagnosed. In test 5, the SG fault was correctly identified on day 9, while the planet gear (PG) fault was misdiagnosed.

In view of the promising results obtained at the subsystem level, which confirm the validity of the structural influences, the cause of diagnostic inaccuracies at the component level should be attributed mainly to the deficiency of gear and bearing specific features used in this study. The strong cross-coupling

TABLE 27.8 Faulty Component Isolation by SBCN for the OH-58A Gearbox

Days	Faulty Component Isolation for OH-58A

10 and 11	—	—	—	—	—*	—*	—	—

The components listed are SBP: spiral bevel pinion; SBG: spiral bevel gear; BRG1: bearings in subsystem (SS) 1; BRG2: bearings in SS2; SG: sun gear; PG: planet gear; RG: ring gear; and BRG3: bearings in SS3. As before, “*” indicates observation of the faulty component.

TABLE 27.9 Maximum Values of Correlation Coefficients between Features and Faults

Fault-Feature Correlation Coefficients		
Features/Faults	Gear Faults	Bearing Faults
Gear features	0.49 (1)	0.57 (0)
Bearing features	0.38 (0)	0.44 (1)

The values inside parentheses are the expected ideal values.

between these features is illustrated by the maximum values of the correlation coefficients between the gear and bearing features and gear and bearing faults in Table 27.9. The results indicate reasonable correlation values of 0.49 between the gear features and gear faults, and 0.44 between the bearing features and bearing faults. These numbers, however, are not as impressive when they are compared with the cross-correlation values of 0.57 between gear features and bearing faults, and 0.38 between bearing features and gear faults. The high cross-correlation values in Table 27.9 indicate that the gear and bearing features do not provide the resolution necessary for faulty component isolation. The manifestation of the resolution problem caused by the coupling between gear and bearing features is observed in the similar fault possibility values of 0.9 and 0.89 on day 5 of test 1, in Table 27.8, for the SBP and bearings in subsystem 1 (BRG1). Based on the results in Table 27.8, one can conclude that the unsupervised pattern classification scheme incorporated in this research cannot be a substitute for well-defined features, and that a more effective set of features with smaller cross-correlation values are needed for diagnosis at the component level.

27.5.5 Sensor Location Evaluation

The eight candidate accelerometer locations (see Figure 27.2 for their locations and orientations), which were actually used for vibration measurement during accelerated fatigue tests of the gearbox, were analyzed and ranked for their significance in monitoring. In order to obtain the overlap coefficients for the OH-58A gearbox, the values of the orientation factors, E_{jk} , distance factors, D_{jk} , and symmetry factors, S_{jk} , for the eight accelerometer locations were defined as

$$E_{jk} = \begin{bmatrix} 1 & 0.5 & 0.3 & 1 & 0.4 & 0.8 & 1 & 0.8 \\ 0.5 & 1 & 0.3 & 0.5 & 0.4 & 0.7 & 0.5 & 0.7 \\ 0.3 & 0.3 & 1 & 0.4 & 1 & 0.3 & 0.3 & 0.3 \\ 1 & 0.5 & 0.4 & 1 & 0.4 & 0.5 & 1 & 0.8 \\ 0.4 & 0.4 & 1 & 0.4 & 1 & 0.4 & 0.4 & 0.4 \\ 0.8 & 0.7 & 0.3 & 0.5 & 0.4 & 1 & 0.8 & 0.6 \\ 1 & 0.5 & 0.3 & 1 & 0.4 & 0.8 & 1 & 0.8 \\ 0.8 & 0.7 & 0.3 & 0.8 & 0.4 & 0.6 & 0.8 & 1 \end{bmatrix}, \quad aD_{jk} = \begin{bmatrix} 0 & 0 & 0 & 1.5 & 1.5 & 0.5 & 2.0 & 0.5 \\ 0 & 0 & 0 & 1.5 & 1.5 & 0.5 & 2.0 & 0.5 \\ 0 & 0 & 0 & 1.5 & 1.5 & 0.5 & 2.0 & 0.5 \\ 1.5 & 1.5 & 1.5 & 0 & 0.8 & 1.0 & 0.5 & 2.0 \\ 1.5 & 1.5 & 1.5 & 0.8 & 0 & 1.0 & 0.5 & 2.0 \\ 0.5 & 0.5 & 0.5 & 1.0 & 1.0 & 0 & 1.5 & 1.0 \\ 2.0 & 2.0 & 2.0 & 1.5 & 1.5 & 1.5 & 0 & 1.5 \\ 0.5 & 0.5 & 0.5 & 2.0 & 2.0 & 1.0 & 1.5 & 0 \end{bmatrix}$$

$$S_{jk} = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0.5 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0.5 & 0 \end{bmatrix}$$

TABLE 27.10 Best and Worst Accelerometer Suites within Each Suite Size

Suite Size	Best Suites	Worst Suites
1 accelerometer	5	3
2 accelerometers	(5, 8); (2, 5)	(4, 7); (1, 6)
3 accelerometers	(2, 5, 7); (4, 5, 8); (2, 4, 5)	(1, 6, 8); (1, 2, 6); (1, 2, 8)
4 accelerometers	(3, 4, 5, 8); (2, 4, 5, 8); (2, 4, 5, 7)	(1, 2, 7, 8); (1, 4, 7, 8); (1, 6, 7, 8)
5 accelerometers	(2, 3, 4, 5, 8); (2, 3, 5, 7, 8); (2, 3, 5, 6, 7)	(1, 4, 6, 7, 8); (1, 2, 6, 7, 8); (1, 2, 4, 7, 8)
6 accelerometers	(1, 2, 3, 4, 5, 7); (2, 3, 4, 5, 6, 8)	(1, 2, 4, 6, 7, 8); (1, 3, 4, 6, 7, 8)
7 accelerometers	(1, 2, 3, 4, 5, 6, 8)	(1, 2, 3, 4, 6, 7, 8)

Using the above values, the overlap coefficients for the eight locations were determined from Equation 27.21 as

$$O_{jk} = \begin{bmatrix} 1 & 0.50 & 0.3 & 0.2 & 0.089 & 0.485 & 0.271 & 0.485 \\ 0.500 & 1 & 0.3 & 0.112 & 0.089 & 0.425 & 0.135 & 0.425 \\ 0.300 & 0.300 & 1 & 0.089 & 0.223 & 0.182 & 0.081 & 0.182 \\ 0.223 & 0.112 & 0.089 & 1 & 0.180 & 0.184 & 0.446 & 0.108 \\ 0.089 & 0.089 & 0.223 & 0.180 & 1 & 0.147 & 0.089 & 0.054 \\ 0.485 & 0.425 & 0.182 & 0.184 & 0.147 & 1 & 0.179 & 0.441 \\ 0.271 & 0.135 & 0.081 & 0.446 & 0.089 & 0.179 & 1 & 0.268 \\ 0.485 & 0.425 & 0.182 & 0.108 & 0.054 & 0.441 & 0.268 & 1 \end{bmatrix} \quad (27.27)$$

Given the above values of coverage and overlap, the ME values were determined from Equation 27.24 for various suites from the eight candidate accelerometer locations of the OH-58A main rotor gearbox. The ME values can be used, for example, to select the best set of accelerometer locations given a number of accelerometers to be used. A sample set of accelerometer locations with the highest and lowest rankings (from the 254 possible suites of the eight OH-58A locations) are shown in Table 27.10. Note that, for some suite sizes, several combinations of accelerometer locations are selected as the “best” and “worst” suites, because in these cases the ME values were too close to render a suite better or worse than the others.

The ME values can also be used to assess the benefit of additional accelerometers, leading to larger suite sizes. To demonstrate this utility of monitoring effectiveness, the maximum ME value for each suite size was obtained (Figure 27.9). While additional accelerometers are expected to add to monitoring effectiveness, the added coverage they provide will diminish for larger suite sizes due to the increase in overlap between the accelerometers. This is clearly reflected in Figure 27.9 where the maximum ME value of the eight-strong accelerometer suite is the same as that of the seven-strong accelerometer suite, and the suite with five accelerometers has a maximum ME value of 0.90, only 10% less than that of the suite with eight accelerometers.

27.5.6 Sensor Location Validation

The validity of the ME values was evaluated by comparing the rankings they provided for various accelerometer suites to the rankings obtained

FIGURE 27.9 Maximum values of monitoring effectiveness for different accelerometer suite sizes.

empirically from a series of diagnostic tests. The suites were ranked into four evenly spaced categories. The suites with the highest monitoring effectiveness were ranked as one, and those with the lowest values were ranked into the fourth category. The empirical rankings were obtained from the SBCN according to the fault possibility values, $p_i \in (0, 1)$, of the individual gearbox subsystems (Jammu et al., 1998). For quantification purposes, a performance index, p_s , was obtained for each suite of accelerometers to represent the accuracy of the diagnostic results, as

$$p_s = \sum_{\text{faults}} p_i \quad (27.28)$$

where the summation was carried out over all the available faults that had occurred during the OH-58A experiments. Under ideal conditions and with a perfect accelerometer suite, the values of p_i should be all equal to one (i.e., the value of p_s should be equal to the number of faults). However, in practice, the fault possibility values are smaller than one due to imperfect signal conditioning, presence of noise, and so on. The understanding used here is that, everything else being the same, the value of p_s is only affected by the quality of the accelerometer suite when the vibration features from different suites are used as inputs to the diagnostic system. The value of p_s was computed for various accelerometer suites, and then normalized against the largest value of p_s obtained for the same suite size. These normalized p_s values were then used as the basis for ranking the suites. As with the monitoring effectiveness values, the suite with the highest normalized p_s value was assigned to the first category. It should also be noted that, in both cases, the rankings provide only a relative measure of effectiveness among suites of the same size, and that they should not be perceived as global measures. The normalized p_s values and the associated rankings for suites of seven accelerometers are included in Table 27.11, along with the ME values and their corresponding rankings. The results indicate remarkably close agreement between the estimated and empirical rankings and that, except for one mismatch, the rankings are identical. Similar analyses were performed for suites of other sizes. A summary of matches and mismatches for all the suites is given in Table 27.12. The results indicate that, out of the 254 possible suites, the estimated rankings of 174 suites match exactly the empirical rankings, and 103 mismatch by only one rank.

The results summarized in Table 27.12 indicate that the proposed selection method is effective in assessing the monitoring effectiveness of suites of accelerometers. The experimental data set, although one of the most complete sets available in the industry, is not comprehensive enough to render a complete evaluation of the method. The main limitation is the absence of faults in all of the components of the gearbox. This could result in an overestimation of the significance of accelerometers that cover faulty components during the experiments. Similarly, it could lead to devaluation of accelerometers which cover healthy components during the experiments. For example, there was only a single fault in subsystem 2 (mast bearing micropitting), therefore, accelerometer locations that covered this subsystem were given a lower empirical ranking than they actually deserved.

TABLE 27.11 Rankings Obtained from the Monitoring Effectiveness Values and from the Diagnostic Results for Suites of Seven Accelerometers

Accelerometers Included	Monitoring Effectiveness		Empirical	
	ME _s	Rank	p_s	Rank
2, 3, 4, 5, 6, 7, 8	0.983	1	0.888	1
1, 3, 4, 5, 6, 7, 8	0.791	2	0.702	2
1, 2, 4, 5, 6, 7, 8	0.705	2*	0.844	1
1, 2, 3, 5, 6, 7, 8	0.908	1	0.926	1
1, 2, 3, 4, 6, 7, 8	0.200	4	0.200	4
1, 2, 3, 4, 5, 7, 8	0.990	1	1.000	1
1, 2, 3, 4, 5, 6, 8	1.000	1	0.938	1
1, 2, 3, 4, 5, 6, 7	0.940	1	0.843	1

* indicates a mismatch between the rankings.

TABLE 27.12 Summary Comparison of Rankings Obtained from the Monitoring Effectiveness Values and from the Diagnostic Results for Suites of All sizes

Suites of	Match Exactly	Mismatch by		
		1	2	3
7	7	1	0	0
6	17	11	0	0
5	39	17	0	0
4	48	22	0	0
3	38	18	0	0
2	17	11	0	0
1	8	0	0	0
Total	174	80	0	0

27.6 Conclusion

Commercial fault detection systems developed for helicopter gearboxes, generally as part of a Health and Usage Monitoring System (HUMS)³, follow the traditional approach to fault detection and diagnosis. In these systems, the individual vibration signals obtained from each accelerometer are processed first to extract various features, and are then evaluated statistically or in comparison with established thresholds to identify possible abnormalities. The abnormal features are then scaled and weighted to provide a weighted average “figure of merit” that can be used for fault detection. Once a gearbox is identified as abnormal, diagnosis is performed by evaluating the synchronized time averaged features associated with individual shafts and gears — the signal average of a particular shaft contains the mounted gear meshing characteristics which can be used to determine the gear condition. In HUMS, statistical analysis is usually based on the mean and standard deviation of individual features, and thresholds are established based either on experience or according to base-lines determined from initial data points at the beginning of aircraft operation. It should be noted that the simplistic approach used by major HUMS producers for abnormality identification and fault detection and diagnosis is often due to the stringent restrictions imposed by the certification process⁴; otherwise, much development work has been conducted in the recent years that can be included in commercial systems.

A truly integrated mechanical diagnostic system should have the following characteristics: (1) be able to automatically correlate the information from various sensor suites including accelerometers, oil debris sensors, acoustic emission (AE) transducers, and so on, and to consolidate the results into a reliable solution; (2) be able to “predict” (prognose) a degrading mechanical condition based on trending of the “features” or condition indices; (3) be compatible with the maintenance policies and operational situations, (4) account for the fatigue life of the monitored components; (5) account for flight conditions (such as transmission torque) that would affect the diagnostic results; (6) be based on open systems architecture (both hardware and software) for future technology insertion; and (7) be lightweight (including cabling and sensors) such that no significant extra weight will be added to the aircraft.

Oil analysis will undoubtedly play a more critical role in fault detection and diagnosis. One logical step will be development of more reliable in-flight methods of chip detection based on optical technology and image processing (Lukas and Yurko, 1996). The chip detectors of the future are expected to benefit from the micro-electro-mechanical systems (MEMS) technology, making available microdetectors that can be

³A HUMS generally consists of structural usage monitoring, gearbox, engine, and rotor system fault detection and diagnosis, rotor track and balance, and the associated data processing and maintenance logistics.

⁴No HUMS has been certified by the FAA yet because of the relative newness of the technology and lack of data to verify it. Some HUM systems have been flying in the North Sea area, mostly manufactured by Teledyne-Stewart Hughes and GEC-Bristows, but they need to be developed further before they can be totally reliable.

located practically anywhere within the gearbox. Continued emphasis is also expected on postflight oil analysis such as ferrography, thermography, ultrasonic analysis, and passive electric current analysis (Saba 1996).

As for vibration monitoring, there will be continued need for algorithmic development to produce new features for reliable identification of component faults. In this domain, there will be more focus on acoustic monitoring and stress wave analysis. Accelerometers normally have a frequency response range of a few Hz to over 50 kHz. In acoustic monitoring, a much higher bandwidth is considered — microphones are currently available that have a flat response to over 100 kHz. This provides the possibility of measuring a cleaner signal in higher frequency ranges, which may prove useful in detecting certain bearing faults. Another advantage of microphones is that they do not need to be mounted on the surface of the housing, therefore, unlike accelerometers, they are not affected by mounting resonance. For stress wave monitoring, AE sensors are available that detect the stress waves generated by strain (elastic) energy spontaneously released by materials when they undergo deformation. This type of energy, which has a very broad bandwidth (DC to several MHz) due to the impulse nature of the strain release, propagates away from a crack tip and throughout the structure body. For crack growth monitoring, analysis is usually focused on the high frequency region (> 100 kHz) of the AE signal so that the effect of low frequency noise caused by airframe, gearbox, and/or drive shaft vibration is minimized. Stress wave monitoring through AE signals may, therefore, reveal the presence of cracks, as well as their location and severity (Teller and Kwun, 1994).

Another important area of research and development in fault diagnosis is sensor technology. A generic restriction in vibration monitoring is the limited number of mounting locations for accelerometers on the housing. This restriction, however, is expected to be alleviated with the advancement of the MEMS technology which will eventually make available miniaturized sensors that can be mounted practically anywhere on a housing, and perhaps inside it. These sensors are expected to have the added capability of processing the vibration signal and producing the features locally, so that the central processor can be dedicated solely to integration of features for fault detection and diagnosis.

Summary

Much research and development effort is going on to develop precision motion systems that are used in most production equipment. Market demands for better products (products with much higher performance, higher reliability, longer life, lower cost, and increasing miniaturization) are some of the main driving forces behind these efforts. There are several challenges ahead in order to meet these stringent requirements for precision motion systems. One of the main challenges is to suppress the mechanical vibrations in these motion systems. This chapter provides several possible approaches to this objective. The first approach will focus on a proper mechanical design, based on the determinacy of machine structure, to reduce the mechanical vibration in the motion systems to a minimum. In addition to a good design, a monitoring and suppression mechanism is necessary to cope with additional and usually unpredictable sources of vibration seeping in during the course of operations. An approach, utilizing an adaptive notch filter in the control system, is presented in the chapter, to continuously identify resonant frequencies present and suppress signal transmission into the system at these frequencies. Finally, the development of a low-cost real-time vibration analyzer for precision motion systems is presented. A case study is provided at the end of the chapter to illustrate the effectiveness of a remote vibration monitoring and control system for precision motion systems.

28.1 Introduction

Industrialization, propelled by advances in science and technology in the last millennium, has led to the development of mass-production equipment to satisfy man's relentless pursuit for products such as

automobiles, air-conditioners, audio and video products, and so on. Today, apart from the consumer's demand for more functionality in new product lines, a miniaturization phenomenon is also clearly evident where the physical size of the product can be smaller than its predecessor, even when it has expanded performance. In addition, the ever shortening time-to-market of products and productivity cost factors in today's highly competitive world together pose tough and challenging requirements on the manufacturing and automation systems that produce them. Thus, while high accuracy and precision in production systems are necessary to produce highly delicate parts and products, a high production speed must still be maintained even though speed and precision adversely affect each other. It is not difficult to appreciate this dilemma since a high production speed can lead to excessive mechanical vibration (Fertis, 1995; Uicker et al., 2003), which means inevitably a loss in precision (Tan et al., 2001). This chapter will seek to address the vibration issues in precision motion systems.

Different and numerous sources of vibration can be present in an industrial operating environment (Adams, 2000; Kelly, 2000). Vibration may be generated by rotating or reciprocating machineries such as: engines, motors, and compressors; impact processes such as drilling and PCB printing; the flow of fluid; and many others (Raichel, 2000). The vibration level can reach an excessive level when abnormal operating conditions occur due to unbalanced inertia, bearing failures in rotating systems such as turbines, motors, generators, pumps, drives, and turbofans, component failure and operation outside prescribed load ratings, and poor kinematical design (resulting in a nonrigid and nonisolating support structure). Vibration, whether naturally occurring or induced under abnormal conditions, is undesirable as it usually leads to dynamic stresses that, in turn, causes fatigue and deterioration of the machinery. Other adverse consequences include unnecessary energy losses, deterioration in performance, and an unduly high level of noise produced. These effects can be even more severe for high-precision motion systems with stringent requirements on precision and accuracy, since vibration will lead directly to poor repeatability properties, impeding any effort for systematic error compensation. Thus, it is even more essential that the vibration level in such systems be suppressed as far as possible with an efficient mechanical design and that functionality be included in the control to monitor and possibly adaptively reduce excessive vibration when it occurs.

This chapter provides several possible approaches to this objective. The first approach will focus on a proper mechanical design, based on the determinacy of the machine structure, to reduce the mechanical vibration to a minimum. While the system design approach is certainly a first and key step to minimizing vibration in mechanical systems, a parallel monitoring and suppression mechanism is necessary to cope with additional and usually unpredictable sources of vibration seeping in during the course of operations. An approach, utilizing an adaptive notch filter (narrow bandstop filter) in the control system, will be presented as a means of continuously identifying resonant frequencies present and suppress signal transmission into the system at these frequencies.

Finally, the development of a low-cost real-time vibration analyzer will be presented. This analyzer can be implemented independently of the control system, and as such can be applied to existing equipment without much retrofitting being necessary. A vibration signature is derived from the vibration signal acquired using an accelerometer that is attached to the machine under normal operating conditions. A pattern recognition template is used to compare real-time vibration signals against the normal-condition signature and an alarm can be activated when the difference deviates beyond an acceptable threshold. Actions of rectification can then be invoked before damage is done to the machine. A case study will be provided at the end of the chapter to illustrate the effectiveness of a remote vibration monitoring and control system for precision motion systems.

28.2 Mechanical Design to Minimize Vibration

In the development of high-speed and high-precision motion systems, the notion of determinism is a key consideration (Evan, 1989), which implies that a physical system complies with the law of cause and effect, and this behavior allows the physical system to be modeled mathematically.

The governing equations describing the model can then be used to predict the behavior of the system and thus allow for the compensation for possible errors to meet the demand of a tight error budget. A mechatronic approach, in which the structural design and the control design are to be seamlessly integrated (Rankers, 1997), is one of the possible approaches for machine design. This approach has been adopted efficiently by many scientists and engineers, and the benefits are clearly evident in the end products, such as the wafer scanner and stepper.

In this section, the key issues to address in a sound mechanical design to keep mechanical vibration to a minimum will be highlighted. The issue of mechanical design represents a very large area in precision motion systems. In this section, only key points will be highlighted in general, to enable designers to design “rigid” structures during the initial phase, even before the physical modeling stage. Design, being an iterative process, always requires the designer to revisit the drawing board frequently, until an optimum design is achieved. The section will give qualitative ideas with abundant figures to illustrate key ideas, rather than using a purely quantitative approach. The reason for this is that, during the initial phase of a design, intensive quantification is normally not necessary for decision making. Iteration and optimization, which are normally mathematically intensive, should be addressed during the next stage of the design process.

28.2.1 Stability and Static Determinacy of Machine Structures

A structure can be a supporting framework that houses all the subassemblies that make up a machine, or it can be a collection of many smaller structures, or even a single component. The reaction forces of the high-speed moving parts will excite the structural dynamics resulting in mechanical vibrations. These vibrations can be attenuated by reducing either the excitation or the response of the structure to that excitation (Beards, 1983). The first factor can be overcome by relocating the source within the structure or by isolating it from the structure so that the generated vibration is not transmitted to the structure via the supports. As for the second factor, changing the mass, the stiffness, or the damping can alter the structural response. In order to understand the dynamic responses of the structure, the real structure can be transformed into a physical model, which is usually a simplified model representative of the real structure. For example, a real machine can be modeled as a number of coupled spring–mass systems. A derived physical model of the real system can be translated to a mathematical model which can be solved via software or by hand, thereby allowing engineers from different disciplines to communicate and refine their portion of the design.

Every designer working on the structure for a machine needs to answer a very important question. Is the designed structure rigid and stable? A structure is rigid if its shape cannot be changed without deforming the members in the structure (Fleming, 1997), and a structure is stable if rigid-body translation or rotation cannot occur. A good way to tell whether a structure is stable or not is the degree of indeterminacy. A structure is considered *statically determinate* if all the support reactions and internal forces in the members can be determined solely by the equations of static equilibrium. Otherwise, the structure is considered *statically indeterminate*. Statically indeterminate structures arise owing to the presence of extra supports, members, reaction forces, or reaction moments. For a structure to be statically determinate, it must first be constructed correctly and then supported correctly.

28.2.2 Two-Dimensional Structures

Most machine structures, in practice, are three-dimensional. However, it is useful to look at a two-dimensional problem first, before extending the problem to a three-dimensional one. Generally, machine structures are stationary. Therefore, the sum of the forces and moments acting on it must be zero, which is in accordance with Newton’s Second Law. In mathematical form,

$$\sum \mathbf{F}_x = 0 \quad (28.1)$$

$$\sum F_y = 0 \quad (28.2)$$

$$\sum M_z = 0 \quad (28.3)$$

where F_x and F_y are the forces in the x -axis and y -axis, respectively, while M_z is the moment about the z -axis, where the z -axis is pointing out of the page. For a plane structure, we will make use of the sign conventions as depicted in Figure 28.1.

Since the static determinacy of a structure is a two fold issue, it is possible to proceed without considering the support first. Each structural configuration can be tested to verify if the plane structure satisfies the equation:

$$2j = m + 3 \quad (28.4)$$

where j denotes the number of joints and m denotes the number of members. There are three possible cases, as follows:

1. If $2j = m + 3$, then the structure is statically determinate.
2. If $2j > m + 3$, then the structure is unstable.
3. If $2j < m + 3$, then the structure is statically indeterminate.

The three conditions are depicted in Figure 28.2.

When a structure is unstable due to member deficiency, it appears that the structure becomes a four-bar mechanism with one degree of freedom (DoF), as shown in Figure 28.2c. This DoF is undesirable, since it is the structure that is being designed and not the mechanism. If, however, there are too many members present, the structure becomes statically indeterminate. Under such a condition, it will be difficult to assemble the fifth bar of the structure shown in Figure 28.2d, if the

FIGURE 28.1 Sign convention for plane structure.

FIGURE 28.2 Plane structure: (a) and (b) statically determinate structure; (c) unstable structure; (d) statically indeterminate structure.

FIGURE 28.3 (a) Unstable structure; (b) extra member.

dimension of the fifth bar is not exact. Assembly is probably possible using brute force, but internal stresses will be built into the structure even without any external loading. When a structure is statically determinate, it will be stress-free when it is not loaded externally other than by its own weight. In the event of thermal expansion of its member, owing to an increase in temperature, statically determinate structures allow expansion of their members, without inducing any stress resulting from an overconstrained condition due to the redundant members.

The triangle is the basic shape for a plane structure as shown in Figure 28.2a. Statically determinate plane structure can be expanded from this basic structure, simply by linking two new members to two different existing joints for every new joint added, as shown in Figure 28.2b. However, the axis of the two new members must not form a line; in other words, the three joints must not be on the same line, as shown in Figure 28.3a. It is also noteworthy that the ground constitutes one member as well, and all joints are pin-joints, as shown in Figure 28.3b.

The second part of structure design lies in its supports. In this aspect, the whole structure can be treated as a rigid body. A plane structure has three DoF; that is, the plane structure is capable of motion in the x and y directions, and rotation about the z -axis. Therefore, three members are needed providing three reactive forces to exactly constrain the plane structure in the plane.

FIGURE 28.4 (a), (b), and (c) Stable and exactly constraint supports; (d) unstable support.

Figure 28.4a–c show some possible support for plane structure, while Figure 28.4d shows an unstable support scenario.

It should be highlighted that the condition of having two support members at the same location can be replaced by a single pin-joint, as shown in Figure 28.5. It is apparent that, in both cases, they constitute two reaction forces and do not constrain the angular motion about the z-axis present in the plane structure.

The correct number of members in a structure, as well as the correct number of supports, must be in place for a stable and statically determinate structure. At this juncture, the issue of where the loads are to be applied on the structure must be addressed. To this end, it is necessary to examine the members that make up the structure. The stiffness of a bar member is affected by the way the load is applied with respect to its axial axis, its cross-sectional geometry (e.g., the diameter, for a round bar) and the modulus of elasticity, E , of its material. In most cases, the bar is either loaded in tension, compression, or bending, as shown in Table 28.1.

It is apparent from examining Table 28.1 that the stiffness of a bar is much better in axial loading than in bending loading. For a value of $d = 0.05$ m and $L = 1.2$ m, the ratio of k_t/k_b is 192. That is, a bar is 192 times stiffer when loaded axially than in bending. Therefore, when designing a rigid and stiff structure, the members must be loaded in tension or compression, never in bending. At times, redesigning the way an external load is applied on a structure can greatly improve the stiffness of the structure. Various configurations are shown in Table 28.2. As a general rule to observe, the loading point should be located at the joints.

FIGURE 28.5 Equivalent of a two-member support.

28.2.3 Three-Dimensional Structures

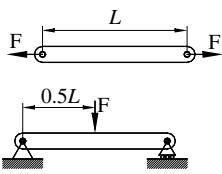

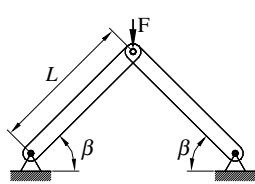

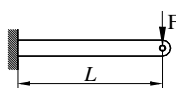

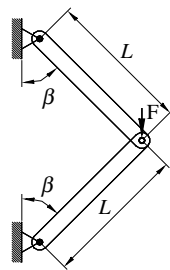

Next, space structures or three-dimensional structures will be considered. These are structures that are of interest in most applications. In a very general sense, space structures can be perceived as a combination of many plane structures, arranged in a manner that all the planes are not coplanar. Therefore, for a space structure to be rigid, every plane structure that makes up the space structure

TABLE 28.1 Comparison of Stiffness for Axial Loading versus Bending Loading

	Configurations	Loading Condition	Stiffness (N/m)	Normalized Stiffness
(a)		Tension	$k_t = 0.25\pi Ed^2/L$	1
(b)		Compression	$k_c = 0.25\pi Ed^2/L$	1
(c)		Bending	$k_b = 0.75\pi Ed^4/L^3$	$3(d/L)^2$

Units: E (N/m²), d (m), L (m), and $L \gg d$.

TABLE 28.2 Comparison of Stiffness for Various Loading Configurations

Configurations	Stiffness (N/m)	Normalized Stiffness	Compare
(a) 	$k_t = 0.25\pi Ed^2/L$	1	1
(c) 	$k_b = 0.75\pi Ed^4/L^3$	$3(d/L)^2$	1/192
(d) 	$k_\Lambda = 0.5\pi Ed^2 \sin^2 \beta/L$	$\sin^2 \beta$	1/2
(e) 	$k_{cl} = 0.047\pi Ed^4/L^3$	$0.1875(d/L)^2$	1/3072
(f)	$k_{>} = 0.25\pi Ed^2/L$	1	1

$\beta = 45^\circ, d = 0.05 \text{ m}, L = 1.2 \text{ m}.$

must be rigid in its own right. This is one reason to have a good understanding of plane structural rigidity.

Since machine structures are stationary, the sum of the forces and moments acting on the machine must be zero, which is in accordance with Newton's Second Law. Mathematically, this implies

$$\sum \mathbf{F} = 0 \tag{28.5}$$

$$\sum \mathbf{M} = 0 \tag{28.6}$$

where **F** and **M** are three-dimensional force and moment vectors, respectively. The sign conventions as depicted in Figure 28.1 will be used.

As before, each structural configuration can be tested to verify if the plane structure satisfies the equation:

$$3j = m + 6 \tag{28.7}$$

where j denotes the number of joints and m denotes the number of members. There are three possible cases, as follows:

1. If $3j = m + 6$, then the structure is statically determinate.
2. If $3j > m + 6$, then the structure is unstable.
3. If $3j < m + 6$, then the structure is statically indeterminate.

In the plane structure, the triangle is the basic shape, and is rigid and statically determinate. In a space structure, the basic form for being rigid and statically determinant is the tetrahedron, which is depicted in Figure 28.6. Adding a new noncoplanar joint to the three existing joints of a triangular plane structure derives the tetrahedron structure. This new joint is connected to the existing joints with three new members. By following this procedure, a rigid and statically determinate space structure can be derived.

Other space structures are shown in Figure 28.7 and Figure 28.8. It is also noteworthy that the members are connected with ball joints.

Thus far, the approach to obtain the tetrahedron space structure from the triangle plane structure, the pyramid from the tetrahedron, and the box from the tetrahedron has been illustrated. The next aspect of the design is to combine some of these structures. The structures can be treated as being coupled together as rigid bodies, and a rigid body in space has six DoF, i.e., the structure is capable of translations in the x , y , and z directions, and rotation about the x , y , and z axes. Therefore, six members are needed, providing six reactive forces to exactly constrain the structure in space. Figure 28.9 shows a typical gantry configuration, which is used extensively in many coordinate-measuring machines (CMM). However, one of the members is bearing a bending load, which has been shown earlier to be very detrimental to the stiffness of the structure. There are alternative structure configurations as shown in Figure 28.10 and Figure 28.11, although some redesign may be needed if such a configuration is to be utilized.

FIGURE 28.6 Basic space structure — the tetrahedron structure.

FIGURE 28.7 Pyramid structure derived from a tetrahedron structure.

FIGURE 28.8 Box structure derived from a tetrahedron structure.

If the ground is perceived as another rigid body to which the space structure is to be coupled, then the design of the supports for a space structure is similar to those of coupling two space structures together; that is, six reactive forces are needed to exactly constrain the space structure. Some ways to arrange the six supporting members constraining a space structure are suggested in Figure 28.12.

Examples of physical supports offering one, two, or three reactive forces are shown in Figure 28.13.

This method of design, known as kinematical design, requires the use of point contact at the interfaces. Unfortunately, this method has some disadvantages:

- Load carrying limitation.
- Stiffness may be too low for application.
- Low damping.

There are, however, ways to overcome the disadvantages, which are via the semikinematical approach. This approach is a modification of the kinematical approach, and it aims to overcome the limitations of a pure kinematical design. The direct way is to replace all point contact with a small area, as shown in Figure 28.14; doing so decreases the contact stress, but increases the stiffness and load carrying capacity. However, the area contact should be kept reasonably small.

This section has only illustrated some fundamental concepts in designing rigid and statically determinate machine structures. Interested readers may refer to Blanding (1999) for more details on designing a machine using the exact constraints principles.

SUMMARY

The approach taken to reduce the mechanical vibration in precision motion systems is to focus on a proper mechanical design, based on the determinacy of machine structures in this chapter. The aim of this approach is to design systems with stable and statistically determinate structures. Two-dimensional structures and three-dimensional structures are considered.

28.3 Adaptive Notch Filter

The task of eliminating or suppressing undesirable narrowband frequencies can be efficiently accomplished using a notch filter (also known as a narrowband-stop filter), if the frequencies are known. The filter highly attenuates a particular frequency component and leaves the rest of the spectrum relatively unaffected. An ideal notch filter has a unity gain at all frequencies except in the so-called null frequency band, where the gain is zero. A single-notch filter is effective in removing single-frequency or narrowband interference; a multiple-notch filter is useful for the removal of multiple narrowbands, which is necessary in applications requiring the cancellation of harmonics. Digital notch filters are widely used to retrieve sinusoids from noisy signals, eliminate sinusoidal disturbances, and track and enhance time-varying narrowband signals with wideband noise. They have found extensive use in the areas of radar, signal processing, communications, biomedical engineering, and control and instrumentation systems.

To create a null band in the frequency response of a digital filter at a normalized frequency, β_0 , a pair of complex-conjugate zeros can be introduced on the unit circle at phase angles $\pm \beta_0$, respectively. The zeros are defined as

$$z_{1,2} = e^{\pm j\beta_0} = \cos \beta_0 \pm j \sin \beta_0 \tag{28.8}$$

where the normalized null frequency, β_0 , is defined as

$$\beta_0 = 2\pi \frac{f_0}{f_s} \tag{28.9}$$

FIGURE 28.11 Coupling of a triangular plane structure to a tetrahedron space structure with six members.

FIGURE 28.12 Examples for applying six constraints to a rigid body: (a) three sets of twin reactive forces; (b) 3–2–1 reactive forces.

FIGURE 28.13 Examples of support with (a) one reactive force; (b) two reactive forces; and (c) three reactive forces.

Note that f_s is the sampling frequency in Hz (or rad/sec) and f_0 is the notch frequency in Hz (or rad/sec). This yields a finite impulse response (FIR) filter given by the following transfer function:

$$H(z) = 1 - 2 \cos \beta_0 z^{-1} + z^{-2} \quad (28.10)$$

A FIR notch filter has a relatively large notch bandwidth, which means that the frequency components in the neighborhood of the desired null frequency are also severely attenuated as a consequence. The frequency response can be improved by introducing a pair of complex-conjugate poles. The poles are placed inside the circle with a radius of α at phase angles $\pm \beta_0$. The poles are defined as

$$p_{1,2} = \alpha e^{\pm j\beta_0} = \alpha(\cos \beta_0 \pm j \sin \beta_0) \quad (28.11)$$

where $\alpha \leq 1$ for filter stability, and $(1 - \alpha)$ is the distance between the poles and the zeros.

The poles introduce a resonance in the vicinity of the null frequency, thus reducing the bandwidth of the notch. The transfer function of the filter is given by

$$H(z) = \frac{(z - z_1)(z - z_2)}{(z - p_1)(z - p_2)} \quad (28.12)$$

Substituting the expression for z_i and p_i , and dividing throughout by z^2 , the resulting filter has

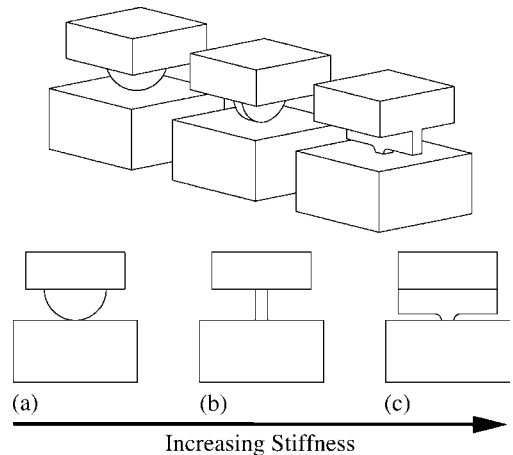

FIGURE 28.14 Kinematical vs. semikinematical design: (a) ideal condition — point contact; (b) line contact; (c) area contact.

the following transfer function:

$$H(z) = \frac{a_0 + a_1 z^{-1} + a_2 z^{-2}}{1 + b_1 z^{-1} + b_2 z^{-2}} \quad (28.13)$$

$$H(z) = \frac{1 - 2 \cos \beta_0 z^{-1} + z^{-2}}{1 - 2\alpha \cos \beta_0 z^{-1} + \alpha^2 z^{-2}} \quad (28.14)$$

Digitally, the filtered signal, y , is thus obtained from the raw signal, u , via the recursive formula in the discrete time domain as follows:

$$y(n) = a_0 u(n) + a_1 u(n-1) + a_2 u(n-2) - b_1 y(n-1) - b_2 y(n-2) \quad (28.15)$$

where the coefficients a_i and b_i are the same as those in Equation 28.13 because z^{-1} corresponds to the time-shift (delay through sampling period) operator.

The bandwidth and the Q-factor of the notch filter are, respectively

$$BW = \frac{2\sqrt{2}(1 - \alpha^2)}{[16 - 2\alpha(1 + \alpha)^2]^{1/2}} \quad (28.16)$$

$$Q = w_0 \frac{[16 - 2\alpha(1 + \alpha)^2]^{1/2}}{2\sqrt{2}(1 - \alpha^2)} \quad (28.17)$$

The filter transfer function, $H(z)$, has its zeros on the unit circle. This implies a zero transmission gain at the normalized null frequency, β_0 . It is interesting to note that the filter structure, Equation 28.14, allows independent tuning of the null frequency and the 3-dB attenuation bandwidth by adjusting β_0 and α , respectively. The performance of the notch filter depends on the choice of the constant, α , which controls the bandwidth, BW, according to Equation 28.16. The bandwidth, which is a function of the distance of the poles and zeros $(1 - \alpha)$, narrows when α approaches unity. Clearly, when α is close to 1, the corresponding transfer function behaves virtually like an ideal notch filter.

Complete narrowband disturbance suppression requires an exact adjustment of the filter parameters to align the notches with the resonant frequencies. If the true frequency of the narrowband interference that is to be rejected is stable and known *a priori*, a notch filter with fixed null frequency and fixed bandwidth can be used. However, if no information is available *a priori*, or when the resonant frequencies drift with time, the fixed notch may not coincide exactly with the desired null frequency, particularly if the bandwidth is too narrow (i.e., $\alpha \approx 1$). In this case, a tunable or adaptive notch filter is highly recommended. In Ahlstrom and Tompkins (1985) and Glover (1987), it is proposed to adapt the null bandwidth of the filter to accommodate the drift in frequency. In Bertran and Montoro (1998), it is suggested that an active compensator be used to suppress the vibration signals. Kwan and Martin (1989) adapt the null frequency, β_0 , while keeping the pole radii, α , constant. In other words, the parameters a_i and b_i of Equation 28.13 are adjusted such that the notch will center at the unwanted frequency while retaining the null bandwidth of the notch filter.

28.3.1 Fast Fourier Transform

The discrete Fourier transform (DFT) is a tool that links the discrete-time domain to the discrete-frequency domain (see Chapter 10, Chapter 21, and Appendix 2A). It is a popular off-line approach, widely used to obtain the information about the frequency distribution required for the filter design. However, the direct computation of the DFT is prohibitively expensive in terms of required computation effort. Fortunately, the fast Fourier transform (FFT) is mathematically equivalent to the DFT, but it is a more efficient alternative for implementation purposes (with a computational speed that is exponentially faster) and can be used when the number of samples, n , is a power of two (which is not a serious constraint). For vibration signals where the concerned frequencies drift with time, the FFT can be continuously applied to the latest n samples to update the signal spectrum. Based on the updated spectrum, the filter characteristics can be continuously adjusted for notch alignment. The block diagram

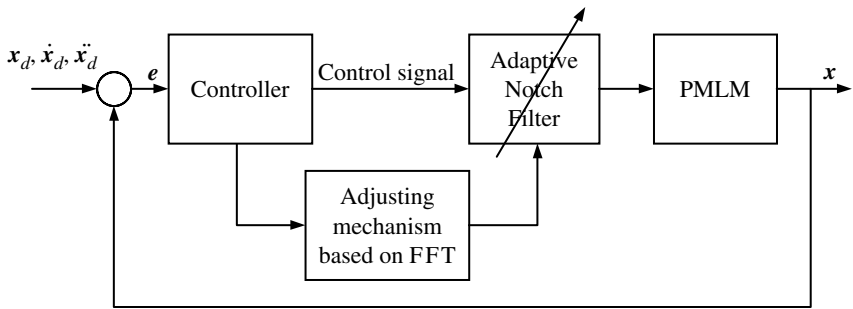

FIGURE 28.15 Block diagram of the adaptive notch filter with adjusting mechanism. (Source: Tan, K.K., Tang, K.Z., de Silva, C.S., Lee, T.H., and Chin, S.J., *J. Intell. Fuzzy Syst.*, 2001, IOS Press. With permission.)

of the adaptive notch filter that has been developed in the present work, with its adjusting mechanism, is shown in Figure 28.15.

28.3.2 Simulation and Experiments

A simulation study is carried out to explore the application of the adaptive notch filter in suppressing undesirable frequency transmission in the control system for a precision positioning system that uses permanent magnet linear motors (PMLM). In the simulation, a sinusoidal trajectory profile is to be closely followed and an undesirable vibration signal is simulated that drifts from a frequency of 500 Hz in the first cycle to a frequency of 1 to 5 Hz in the second cycle of the trajectory. Figure 28.16 shows

FIGURE 28.16 Simulation results without a notch filter: (a) error (μm); (b) desired trajectory (μm); (c) control signal (V). (Source: Tan, K.K., Tang, K.Z., de Silva, C.S., Lee, T.H., and Chin, S.J., *J. Intell. Fuzzy Syst.*, 2001, IOS Press. With permission.)

FIGURE 28.17 Simulation results using a fixed notch filter: (a) error (μm); (b) desired trajectory (μm); (c) control signal (V). (Source: Tan, K.K., Tang, K.Z., de Silva, C.S., Lee, T.H., and Chin, S.J., *J. Intell. Fuzzy Syst.*, 2001, IOS Press. With permission.)

FIGURE 28.18 Simulation results using an adaptive notch filter: (a) error (μm); (b) desired trajectory (μm); (c) control signal (V). (Source: Tan, K.K., Tang, K.Z., de Silva, C.S., Lee, T.H., and Chin, S.J., *J. Intell. Fuzzy Syst.*, 2001, IOS Press. With permission.)

the tracking performance of the precision machine without a notch filter. Figure 28.17 shows the performance when a fixed notch filter is used, and Figure 28.18 shows the performance with an adaptive notch filter. It is clearly evident that a time-invariant narrowband vibration signal can be effectively eliminated using just a fixed notch filter. However, when the vibration frequencies drift, an adaptive notch filter is able to detect the drift and align the notch to remove the undesirable frequencies, with only a short transient period.

The notch filter is subsequently implemented in the control system of a linear drive tubular linear motor (LD3810) equipped with a Renishaw optical encoder having an effective resolution of $1\text{ }\mu\text{m}$. The hardware setup for this experimental study is shown in Figure 28.19 whereas Figure 28.20 shows the linear motor in more detail.

The components of the linear motor consist of the thrust rod, the thrust block, the motor cable, and the optical encoder. The thrust rod is made of a thin-walled stainless steel tube housing high-energy permanent magnets. To enable the smooth translation of the thrust block along the length of the thrust rod, the thrust block is made from an aluminum housing that contains cylindrical coils arranged in a three-phase star pattern. An electromagnetic field is produced by energizing these coils. The interactions between the permanent magnetic field of the thrust rod and the changing magnetic field of the thrust block provide the induced force for the translation of the block. Usually, a sinusoidal or trapezoidal motor commutation is utilized to smoothen the translation of the block. The popular proportional–integral–derivative (PID) control is used in this experimental study. The dSPACE DS1102 (*dSPACE User's Guide*, 1996) digital signal processing (DSP) board is used as the data acquisition and control card. It is a single-board system, which is specifically designed for the development of high-speed multivariable digital controllers and real-time simulations in various fields. The DS1102 is based on the Texas Instruments TMS320C31 third-generation floating-point DSP, which builds the main processing unit, providing fast instruction cycle time for numeric intensive algorithms. It contains 128K words memory that is fast enough to allow zero wait-state operation. Besides these, the DS1102 DSP board supports a total memory space of 16M 32-bit words, including program, data, and I/O space. All off-chip memory and I/O can be accessed by the host, even while the host is running, thus allowing easy system setup and monitoring. The TMS320C31 is object-code compatible to the TMS320C30. The DSP is fully supplemented by a set of on-board peripherals, frequently used in digital control systems. Analog-to-digital and digital-to-analog converters, a DSP-microcontroller-based digital-input/output (I/O) subsystem, and incremental sensor interfaces make the DS1102 an ideal single-board solution for a broad range of digital control tasks.

The DS1102 DSP board is well supported by popular software design and simulation tools, including MATLAB and SIMULINK, which offer a rich set of standard and modular design functions for both classical and modern control algorithms. The SIMULINK model developed for the system (Figure 28.15), with the notch filter, is shown in Figure 28.21. This model is then downloaded to the DS1102 DSP board for real-time implementation using one of the options available from the pull-down menu.

It is now in order to present the experimental results utilizing the notch filter in the system. Figure 28.22 shows the performance of the PMLM when no filter is used. Figure 28.23 shows the improvement in the control performance when the notch filter is incorporated into the control system.

SUMMARY

An approach utilizing an adaptive notch filter in the control system is elaborated upon in this section. The notch filter is able to adaptively identify resonant frequencies present in the motion system and suppress vibration signal transmission into the system at these frequencies. The FFT is used to obtain the frequency distribution of the vibration signals. Experimental and simulation results are provided to illustrate the effectiveness of the adaptive notch filter.

28.4 Real-Time Vibration Analyzer

The development of an alternative, low-cost approach towards real-time monitoring and analysis of machine vibration (Vierck, 1979; de Silva, 2000) is described in this section. The main idea behind this approach is to construct a vibration signature based on pattern recognition of “acceptable” or “healthy” vibration patterns. The vibration analyzer can operate in three modes: learning, monitoring, or diagnostic. The learning mode, to be initiated first, will yield a set of vibration signatures based on which the monitoring and diagnostic modes will operate. In the monitoring mode, with the machine

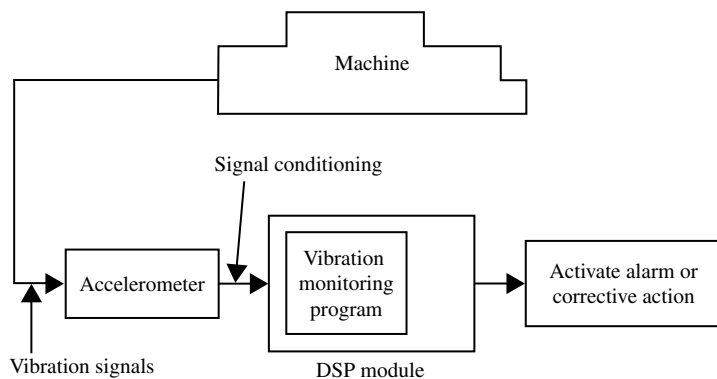

FIGURE 28.24 Schematic diagram of the real-time vibration analyzer. (Source: Tan, K.K., Tang, K.Z., de Silva, C.S., Lee, T.H., and Chin, S.J., *J. Intell. Fuzzy Syst.*, 2001, IOS Press. With permission.)

under normal closed-loop control, the analyzer only uses a naturally occurring vibration signal to deduce the condition of the machine. No test excitation is deliberately added to the input signal of the machine. More than one criterion may be used in the evaluation of the condition of the machine, in which case a fusion approach will generate a combined output (machine condition) based on the multiple inputs. In the diagnostic mode, explicit input signals are applied to the machine and the output signal (vibration) is logged for analysis with respect to the associated vibration signature. In what follows, the details of the various components and functions of the analyzer will be described systematically.

The block diagram of the real-time vibration analyzer system that has been developed is shown in Figure 28.24. It consists of an accelerometer, which is mounted on the machine to be monitored. The accelerometer measures a multifrequency vibration signal and transmits it to an intelligent DSP module after performing appropriate signal conditioning. This module can be a standalone device (Figure 28.25), or one integrated to a personal computer (PC) host. The vibration analysis algorithm is downloaded to this DSP module. With this algorithm, it can be established as to whether the condition of the machine is within a predetermined acceptable threshold. If the condition is determined to be poor, the DSP module will trigger an alarm to the operator who would enable a corrective action, or automatically activate a corrective action (e.g., change the operating conditions of the machine, modify the parameters of the controller or shutdown the machine).

The construction of the real-time vibration analyzer is inexpensive and requires only commercially available, low-cost components. The installation can be hassle free, as the accelerometer is able to gather vibration signals independent of the machine's own control system. Thus, there is no need to disrupt the operation of the machine. In the prototype reported here, a DSP emulator board TMS320C24x model (TMSS320C24x DSP Controllers Evaluation Module Technical References, 1997), from Texas Instruments, is used as the standalone DSP module (Figure 28.25). This C24x series emulator board is built around the F240 DSP controller, operating at

FIGURE 28.25 Hardware setup for the standalone DSP module. (Source: Tan, K.K., Tang, K.Z., de Silva, C.S., Lee, T.H., and Chin, S.J., *J. Intell. Fuzzy Syst.*, 2001, IOS Press. With permission.)

20MIPS with an instruction cycle time of 50 ns. It is optimized for digital motor control and conversion applications. Other key components supported on this DSP module are analog-to-digital converters (ADCs), dual access RAM (DARAM), on-chip flash memory, and an RS-232 compatible serial port. This DSP module and the accelerometer unit (with signal conditioning) constitute the only hardware requirements of the real-time vibration analyzer.

The vibration-analysis algorithm, which is described in the sequel, will be downloaded to the flash ROM on the DSP module after satisfactory evaluation and tests on the PC. The algorithm is programmed using a Visual C++-based compatible environment, that is, a Code Composer integrated environment (IDE). The C-based source code is then compiled into assembly code, using the built-in compiler available in the IDE.

28.4.1 Learning Mode

In the learning mode, with the machine operating under normal conditions, the vibration signals are acquired by the accelerometer and stored in the DSP module. A suitable vibration signature (Ramirez, 1985) is then extracted from the vibration signals. There are many types of vibration signatures that are adequate for the purpose of machine monitoring. For example, one form of vibration signature may be based on the amplitude of the vibration; another form may use a time-series analysis of the vibration; yet another form may employ the spectrum of the vibration, which can be efficiently obtained using the FFT algorithm. Regardless of the type, these vibration signatures are dependent on the nature of the input signals driving the machine. For example, a square wave input will produce a vibration spectrum that can be quite different from that resulting from an input of a chirp signal (i.e., a repeating sine wave of increasing frequency) or a pure sinusoid. Thus, a particular input signal will produce a unique spectrum based on which a unique vibration signature can be derived. Multiple vibration signatures corresponding to the natural vibrations of the machine (useful for the monitoring mode) or corresponding to different input signals (useful for the diagnostic mode) can thus be captured for subsequent diagnosis and monitoring of the machine.

28.4.2 Monitoring Mode

In the monitoring mode, the vibration signals are sampled periodically from the machine to monitor the condition of the machine. No deliberate or additional input signal is required, so the machine operation is not disrupted. The updated spectra are analyzed against the relevant vibration signatures. The analysis and comparison may be done in terms of the shift in the frequency or the amplitude of the spectrum, or a combination of the two. For example, one evaluation criterion (EV) may be based on the mean-square (ms) value of the error between the current real-time vibration spectrum and the vibration signature:

$$EV_1 = \frac{\sum_{q=1}^N (S_q - S_q^*)^2}{M} \quad (28.18)$$

where S_q is the discretized current real-time vibration spectrum, the superscript $*$ represents the vibration signature of the “healthy” machine, subscript q is the index for the data points, N is the total number of frequency points, and M is the total number of data points. Another EV may be formulated based on the difference in the amplitude of the current time series vibration pattern and its corresponding vibration signature:

$$EV_2 = \frac{\max(T_q) - \max(T_q^*)}{M} \quad (28.19)$$

where $\max(T_q)$ represents the highest amplitude of the current time series vibration pattern T_q , and $\max(T_q^*)$ is the highest amplitude of its corresponding vibration signature.

More than one evaluation criterion may be used in the determination of machine condition. In this case, a fusion technique is necessary. The key idea of fusion is to associate the machine with a *HEALTH* attribute, which is computed from multiple evaluation criteria. These criteria are expected to influence, to a varying degree, the *HEALTH* of the machine. The *HEALTH* attribute is thus an appropriate function, \Im , of the various criteria (EV_i s); that is

$$\text{HEALTH} = \Im(EV_1, EV_2, \dots, EV_n) \quad (28.20)$$

where n refers to the number of criteria being evaluated.

A fuzzy weighted approach may be used to realize the \Im function as follows. The *HEALTH* attribute is treated as a fuzzy variable (i.e., $\text{HEALTH} \in [0, 1]$). $\text{HEALTH} = 0$ will represent absolute machine failure, while $\text{HEALTH} = 1$ represents a perfectly normal machine condition. This attribute may be computed from a fuzzy operation on a combination of the evaluation criteria (EV_i s) obtained *via* an analysis of the vibration signals against their signatures. The final decision on the condition of the machine will be derived from the *HEALTH* attribute. Zadeh (1973) provides a comprehensive review on fuzzy logic.

A Takagi and Sugeno (1985) type of fuzzy inference is used in this chapter. Consider the following p rules governing the computation of an attribute:

$$\text{IF } EV_1^i \text{ IS } F_1^i \otimes \dots \otimes EV_n^i \text{ IS } F_n^i, \text{ THEN } u^i = \alpha^i \quad (28.21)$$

$$\sum_{i=1}^p \alpha^i = 1 \quad (28.22)$$

where $u^i \in [0, 1]$ is a crisp variable output representing the extent to which the i th evaluation rule affects the final outcome. Thus, α^i represents the weight of the i th rule, F_j^i represents the fuzzy sets in which the input linguistic variables (EV_i s) are evaluated, and \otimes is a fuzzy operator that combines the antecedents into premises.

The value of the attribute is then evaluated as a weighted average of the u_i s:

$$\text{HEALTH} = \frac{\sum_{i=1}^p w^i u^i}{\sum_{i=1}^p w^i} \quad (28.23)$$

where the weight w^i implies the overall truth value of the premise of rule, i , for the input. It is computed as

$$w^i = \prod_{j=1}^n \mu_{F_j^i}(EV_j^i) \quad (28.24)$$

where $\mu_{F_j^i}(EV_j^i)$ is the membership function for the fuzzy set, F_j^i , related to the input linguistic variable, EV_j^i , (for the i th rule). For example, in this application, EV_j may be the maximum error, MAX_ERR , and F_j^i may be the fuzzy set *HIGH*. The membership function is represented as $\mu_{\text{HIGH}}(\text{MAX_ERR})$. It may have the characteristic shown in Figure 28.26. The decision as to whether any corrective action might be

FIGURE 28.26 Membership function for the fuzzy input MAX_ERR . (Source: Tan, K.K., Tang, K.Z., de Silva, C.S., Lee, T.H., and Chin, S.J., *J. Intell. Fuzzy Syst.*, 2001, IOS Press. With permission.)

necessary can then be based on a simple *IF–THEN–ELSE* formulation as follows:

$$\begin{aligned} & \text{IF HEALTH} \leq \gamma, \text{ THEN STRATEGY} = \text{TRIGGER ALARM} \\ & \text{ELSE STRATEGY} = \text{CONTINUE TO MONITOR} \end{aligned}$$

Here, γ is interpreted as a threshold value. Suitable values for γ may be in the range $0.6 \leq \gamma \leq 0.9$. Here, *STRATEGY* is stated to trigger an alarm to the operator who will enable a corrective action, or automatically activate a corrective action (e.g., change the operating conditions of the machine, modify the parameters of the controller, or shutdown the machine).

Under this framework, it is relatively easy to include additional criteria for analysis and decision making to the system. The procedure will involve setting up the membership functions for the criterion, formulating the additional fuzzy rules required, and adjusting the scaling parameters (the α terms in Equation 28.21) to reflect the relative weight of the new criterion as compared with the existing ones. In this manner, in the monitoring mode, foreboding trends can often be spotted long before the vibration condition reaches a level that is seriously detrimental to the machine.

28.4.3 Diagnostic Mode

In the diagnostic mode, the current vibration signal corresponding to each input signal (with standardized amplitude and frequency) is analyzed against the associated signature obtained earlier in the learning mode, depending on the type of machine (also see Chapter 25). Similar to the monitoring mode, there can be multiple evaluation criteria used in the diagnostic mode, so that the fusion technique described earlier is also applicable. The input signals applied to the machine must be designed carefully so as to yield as much information of the machine condition as possible in the operational regime of interest. Two important considerations are the choices of amplitude and frequency.

Machines may have constraints in relation to the amount of travel that is possible. Too large an amplitude for the input signal may be not be viable for the machine owing to the limit of travel, or may even damage the machine. Also, the frequency range of the input should be chosen so that it has most of its energy in the frequency bands that are important for the system. Where input signals cannot be applied to the system in the open loop, the setpoint signal will serve as the input for the closed-loop system since it may not be possible to directly access the system under closed-loop control. Careful considerations of the mentioned issues will ensure that significant information can be obtained from the machine.

The input signals considered here are square wave input (Figure 28.27), chirp input (Figure 28.29), and sine wave input (Figure 28.31), standardized in amplitude to 1 V and in frequency to 5 Hz. The corresponding vibration signatures are shown in Figure 28.28, Figure 28.30, and Figure 28.32, respectively.

28.4.4 Experiments

A shaker table (Figure 28.33) is used as the test platform for the experiments presented here (also see Chapter 15). The shaker table can be used to simulate machine vibrations and evaluate the performance, for example, of active inertial dampers. The shaker table is driven by a high-torque direct-drive motor (which has a maximum torque of 1.11 N m, a maximum design load of 11 kg and generates a maximum force of 175 N). The maximum linear travel of the table is ± 2 cm.

The learning mode is first initiated to obtain the vibration signals with the shaker table operating under normal conditions. It is assumed in the experiments that the normal condition corresponding to the input is a square wave signal (with a standardized amplitude of 1 V and frequency of 5 Hz). For the purpose of implementing the diagnostic mode, the vibration signals are also obtained for the input signals of the sinusoidal and chirp type, with standardized amplitudes of 1 V and

FIGURE 28.27 Square wave input, with a standardized amplitude of 1 V and frequency of 5 Hz. (Source: Tan, K.K., Tang, K.Z., de Silva, C.S., Lee, T.H., and Chin, S.J., *J. Intell. Fuzzy Syst.*, 2001, IOS Press. With permission.)

frequencies of 5 Hz (see Figure 28.27 to Figure 28.32 for the inputs and their corresponding vibration signatures).

28.4.4.1 Input Variables — the Evaluation Criteria

Different types of EV can be used as input variables for the determination of the machine condition. For the present vibration-analysis application, the input variables chosen for the computation of the *HEALTH* attribute are given below.

28.4.4.1.1 Monitoring Mode

$$EV_1 = \frac{\sum_{q=1}^N (S_{sq,q} - S_{sq,q}^*)^2}{M} \quad (28.25)$$

$$EV_2 = \frac{(\max(T_{sq,q}) - \max(T_{sq,q}^*))^2}{M} \quad (28.26)$$

$$EV_3 = \frac{\sum_{q=1}^M (T_{sq,q} - T_{sq,q}^*)^2}{M} \quad (28.27)$$

where $S_{sq,q}$ represents the vibration spectrum for a square wave input (driving the machine) at the q th frequency point and $T_{sq,q}$ represents the time-domain signal of a square wave input at the q th time instant. N refers to the total number of points in the FFT spectrum and M is the number

FIGURE 28.28 Vibration signature of the square wave input, with a standardized amplitude of 1 V and frequency of 5 Hz. (Source: Tan, K.K., Tang, K.Z., de Silva, C.S., Lee, T.H., and Chin, S.J., *J. Intell. Fuzzy Syst.*, 2001, IOS Press. With permission.)

FIGURE 28.29 Chirp wave input, with a standardized amplitude of 1 V and initial frequency of 5 Hz. (Source: Tan, K.K., Tang, K.Z., de Silva, C.S., Lee, T.H., and Chin, S.J., *J. Intell. Fuzzy Syst.*, 2001, IOS Press. With permission.)

of time-series data points over an operational cycle. Hence, EV_1 refers to the ms deviation between the vibration spectrum and its signature; EV_2 refers to the square of the difference between the amplitude of the vibration signal over one operational cycle compared with its signature; EV_3 refers to the ms deviation between the vibration signal and its signature (time domain) over one operational cycle. The superscript $*$ represents the signature of the healthy machine.

28.4.4.1.2 Diagnostic Mode

$$EV_4 = \frac{\sum_{q=1}^N (S_{sq,q} - S_{sq,q}^*)^2}{M} \quad (28.28)$$

$$EV_5 = \frac{\sum_{q=1}^N (S_{cp,q} - S_{cp,q}^*)^2}{M} \quad (28.29)$$

$$EV_6 = \frac{\sum_{q=1}^N (S_{sn,q} - S_{sn,q}^*)^2}{M} \quad (28.30)$$

Here, cp denotes a chirp input signal and sn denotes a sine input signal.

For the monitoring mode, the input attributes are related only to the square input owing to the assumption that the input signal, under normal operating conditions, is the square wave signal (with a standardized amplitude of 1 V and frequency of 5 Hz).

FIGURE 28.30 Vibration signature of the chirp wave input, with a standardized amplitude of 1 V and starting frequency of 5 Hz. (Source: Tan, K.K., Tang, K.Z., de Silva, C.S., Lee, T.H., and Chin, S.J., *J. Intell. Fuzzy Syst.*, 2001, IOS Press. With permission.)

28.4.4.2 Evaluation Rules

The three rules for the computation of the *HEALTH* attribute are given below.

28.4.4.2.1 Monitoring Mode

- IF EV_1 IS LOW, THEN $u = \alpha_1$
- IF EV_2 IS SHORT, THEN $u = \alpha_2$
- IF EV_3 IS LOW, THEN $u = \alpha_3$

The values of the scaling parameters, that is, α terms in Equation 28.21, reflect the relative importance of the fuzzy rules in the determination of the *HEALTH* of the machine. The scaling values of α_1 , α_2 , and α_3 are set at 0.7, 0.2, and 0.1, respectively. The respective membership functions are

$$\mu_i(EV_i) = e^{-n(EV_i)^\beta} \quad (28.31)$$

where n and β are scaling factors for normalization of EV_i . Here, they are selected to be $n = 10$ and $\beta = 0.5$.

28.4.4.2.2 Diagnostic Mode

The three evaluation rules for the computation of the *HEALTH* attribute in the diagnostic mode are

- IF EV_4 IS LOW, THEN $u = \alpha_4$
- IF EV_5 IS LOW, THEN $u = \alpha_5$
- IF EV_6 IS LOW, THEN $u = \alpha_6$

FIGURE 28.31 Sine wave input, with a standardized amplitude of 1 V and frequency of 5 Hz. (Source: Tan, K.K., Tang, K.Z., de Silva, C.S., Lee, T.H., and Chin, S.J., *J. Intell. Fuzzy Syst.*, 2001, IOS Press. With permission.)

The scaling values of α_4 , α_5 , and α_6 are set at 0.4, 0.2, and 0.4, respectively. Similar membership functions as for the monitoring mode are used here. The machine condition attribute *HEALTH* is then computed as in Equation 28.23.

28.4.4.3 Tests

28.4.4.3.1 Monitoring Mode

In the monitoring mode, the normal input signal (i.e., the square wave with standardized amplitude of 1 V and frequency of 5 Hz) is applied to the shaker-table system. At $t = 5$ sec, a sinusoidal signal (with amplitude 0.4 V and frequency $f = 5$ Hz) is also applied to the system to simulate a fault arising in the machine. The time-domain signal of the machine (corresponding to the square input) is shown in Figure 28.34. The spectra of the machine before and after $t = 5$ sec are shown in Figure 28.35. The vibration-analysis algorithm is able to detect the fault in the machine. Before the introduction of the fault, the *HEALTH* attribute of the shaker table is found to be 0.98. After the introduction of the fault, the *HEALTH* attribute falls to 0.63, which is below the threshold value, set at 0.7. As a result, the alarm is triggered.

FIGURE 28.32 Vibration signature of the sine wave input, with a standardized amplitude of 1 V and frequency of 5 Hz. (Source: Tan, K.K., Tang, K.Z., de Silva, C.S., Lee, T.H., and Chin, S.J., *J. Intell. Fuzzy Syst.*, 2001, IOS Press. With permission.)

FIGURE 28.33 Test platform: the shaker table. (Source: Tan, K.K., Tang, K.Z., de Silva, C.S., Lee, T.H., and Chin, S.J., *J. Intell. Fuzzy Syst.*, 2001, IOS Press. With permission.)

28.4.4.3.2 Diagnostic Mode

In the diagnostic mode, three input signals (i.e., sine, square, and chirp wave with standardized amplitude and frequency) are selected to be applied to the shaker table system in turn. To simulate a fault arising at $t = 5$ sec, the input gain is increased by a factor of 1.4 times at $t = 5$ sec. The time-domain

FIGURE 28.34 Time-domain vibration signal corresponding to the square input, with a standardized amplitude of 1 V and frequency of 5 Hz (at $t = 5$ sec, a fault is simulated). (Source: Tan, K.K., Tang, K.Z., de Silva, C.S., Lee, T.H., and Chin, S.J., *J. Intell. Fuzzy Syst.*, 2001, IOS Press. With permission.)

FIGURE 28.35 (a) Vibration signature corresponding to the square input, with a standardized amplitude of 1 V and frequency of 5 Hz; (b) spectrum of the machine corresponding to the square input after fault occurs. vibration signal of the machine (corresponding to the chirp signal, with a standardized amplitude of 1 V and starting frequency of 5 Hz) is shown in Figure 28.36. The spectra (corresponding to the chirp signal) of the machine before and after $t = 5$ sec are shown in Figure 28.37. The time-domain vibration signal of the machine (corresponding to the sinusoidal wave input, with a standardized amplitude of 1 V and

frequency of 5 Hz) is shown in Figure 28.38. The spectra (corresponding to the sinusoidal input) of the machine before and after $t = 5$ sec are shown in Figure 28.39.

The vibration-analysis algorithm is able to detect the fault in the machine. Before the introduction of the fault, the *HEALTH* attribute of the shaker table is found to be about 0.97. After the introduction of the fault, the *HEALTH* attribute falls to 0.58, which is below the threshold value, set at 0.7. The alarm is triggered as a result.

SUMMARY

In this section, the development of a low-cost approach towards real-time monitoring and analysis of machine vibration is described. A real-time analyzer, based on a fuzzy fusion technique, is used to monitor continuously and compare the actual vibration pattern against a vibration signature. This intelligent knowledge-based real-time analyzer is able to detect excessive vibration conditions much sooner than a resulting fault could be detected by an operator. Subsequently, appropriate actions can be taken. This approach may be implemented independently of the control system and as such can be applied to existing equipment without modification of the normal mode of operation. Experimental and simulation results are provided to illustrate the effectiveness of this real-time vibration analyzer.

28.5 Practical Insights and Case Study

There are currently many companies in the industry that deal with machinery vibrations. Broadly, these companies can be classified into those that produce vibration-related testing products (e.g., FFT analyzers [Steinberg, 2000], vibration data collectors, and end-of-line production test equipment), and those that provide solutions in resolving noise- and vibration-related problems for different industries (e.g., automotive, aerospace, manufacturing, and engineering companies). For instance, if one of the machines in operation on the shop-floor is experiencing unexplained machinery noise or a high level of product failure, vibration analysis (Farrar et al., 2001) may provide some answers.

The case study explores the feasibility of remote vibration monitoring and control of a number of machines or mechanical systems located at different sites. For the sake of generality, "machines" is used as a general term to represent vibrating machines, mechanical systems, and other systems that exhibit vibration behavior. There are strong motivations for such setups. Since the middle of the 1960s, the concept of the distributed system has been widely adopted in the process industries, such

as the chemical industry, manufacturing industry, food processing industry, primary industry, and many others. These distributed systems are also characterized by smart devices. As the costs of manufacturing, that is, labor costs, the cost of raw materials, fixed costs, rental costs, and other production costs, are a major concern for the location of plants, many processes are currently widely distributed geometrically. The layout of an entire plant can be rather extensive, spreading across continents in certain cases.

The extensive distribution of an entire plant requires close coordination and synchronization of the distributed operations, as well as an efficient remote monitoring and control facility in place. The utilization of the Internet for this monitoring and control purpose perfectly complements the trend of distributed intelligence in the field controllers and devices on the shop-floor. As a result, superior control decisions can be made with these readily available resources and information, that is, historical data, knowledge databases, and so on. Internet working has become essential for plant automation. A case study which implements remote vibration monitoring and control of various machines will be illustrated in this section.

This vibration monitoring and control system possesses the structure as shown in Figure 28.40. It is able to monitor continuously the real-time health conditions of multiple machines at different sites, connected via the Internet. The system operates in two modes: the learning mode and the monitoring mode, as mentioned earlier. In the learning mode, vibration signatures, representative of the health of the machines to be monitored, are stored in the supervisory controller. Accelerometers mounted on the machine directly provide measurements of the vibration signals. In the monitoring mode, real-time vibration signals are streamed from the front-end controllers to the supervisory controller. Based on these real-time vibration signals from the various machines, the supervisory controller is able to generate decisions on the health condition of the machines, taking into consideration various criteria based on a fuzzy fusion technique, as mentioned earlier. Alarms will be activated when the health condition of the machines falls below an acceptable threshold level. Subsequently, rectification actions, to provide a warning or automatic corrective action (e.g., changing the operating conditions of the machine,

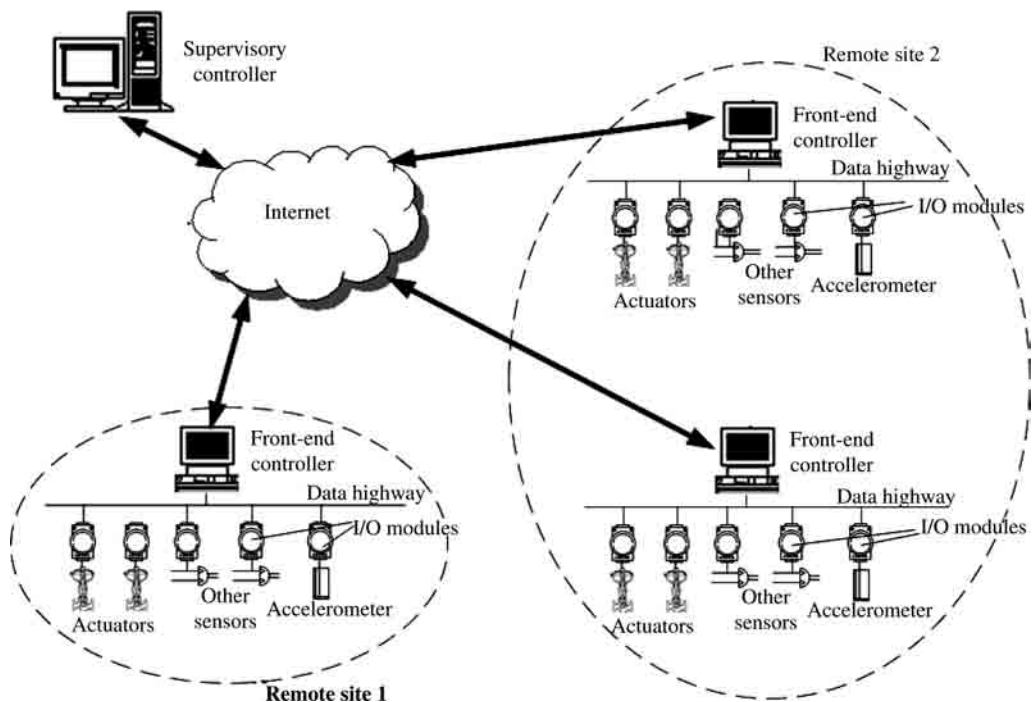

FIGURE 28.40 Remote vibration monitoring and control system.

modifying the parameters of the controller, or shutting down the machine), may be invoked before extensive damage is done to the machines.

Referring to the architecture of the vibration monitoring and control system as shown in [Figure 28.40](#), a data transfer and communication protocol needs to be adopted for such an application. There are several ways of connecting the supervisory controller and the remote machines. One of the possible ways is to apply DataSocket technology; yet another is to use low-level protocols such as TCP/IP and User Datagram Protocol. As can be seen, this vibration monitoring and control system may be applied to existing setups at the shop-floor level, without much modification necessary. The front-end field devices (i.e., actuators, sensors, and other I/O modules) are linked up *via* the field-level data highway. Two popular types of field-level data highway are fieldbus and twisted pair. Access security is a main issue of such remote applications. There is a need to prevent unauthorized users from accessing and modifying the system so as to maintain the integrity and proper functioning of the system. This can be achieved by

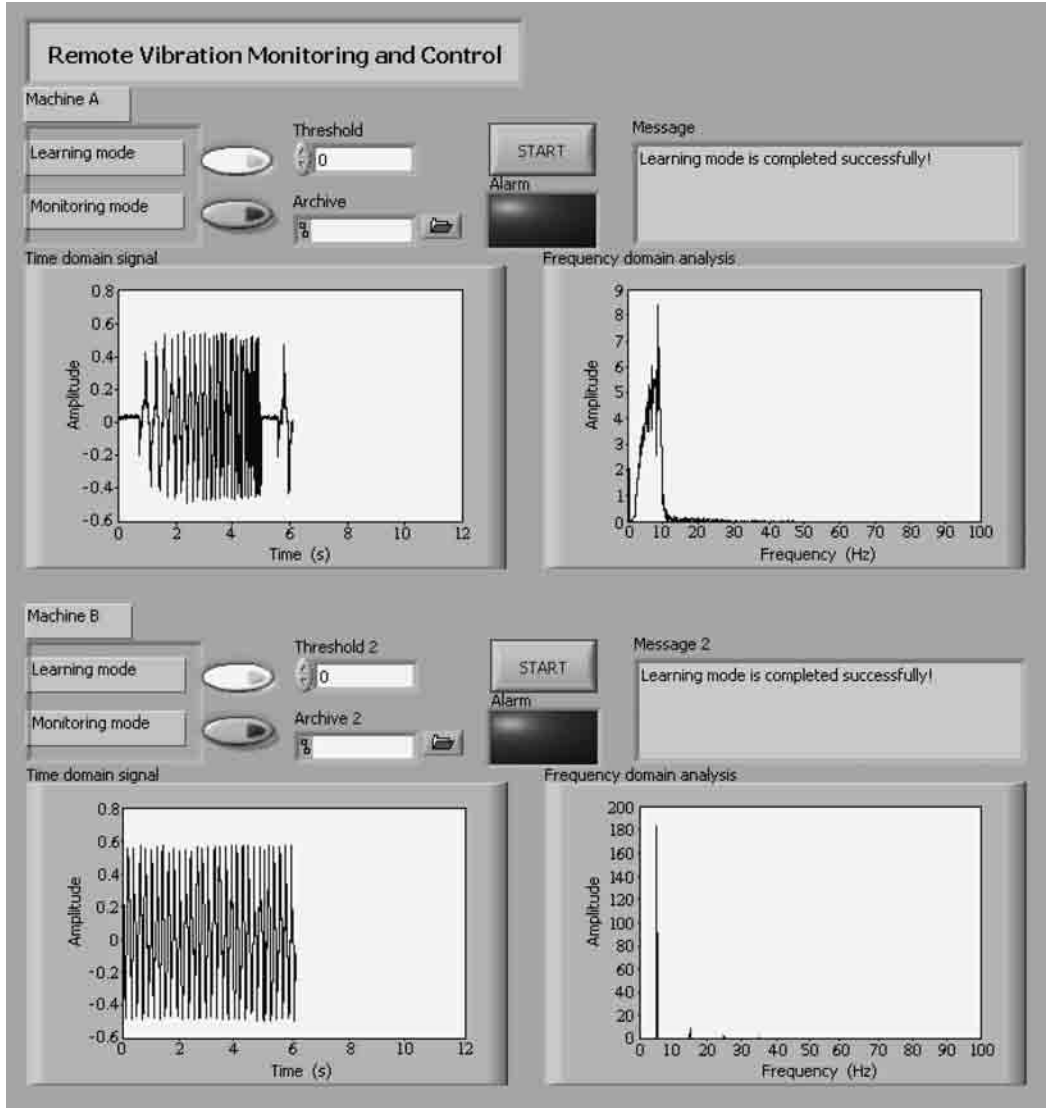

FIGURE 28.41 Learning mode — snapshot of the control panel at the supervisory controller end.

imposing some access authentication scheme. One commonly used basic access authentication scheme is the challenge–response authentication mechanism whereby the operator or user must provide some user logon information (e.g., user identification and a password) before accessing the supervisory controller terminal.

The control panel at the supervisory controller end (Figure 28.40) is as shown in Figure 28.41. At the supervisory controller end, the operator is able to monitor and control the health condition of various machines at different remote sites. As shown here, two machines (i.e., machine A and machine B) are being monitored. The learning mode is first initiated to obtain the vibration signatures of the two machines in the normal operational condition. The vibration signature of machine A resembles a chirp-like signal input whereas that of machine B resembles a sinusoidal-like signal input. At the end of the learning mode, a message is shown in the message box. Figure 28.42 shows a snapshot of the control panel in the monitoring mode. Here, the two machines are in good health, as the health indices

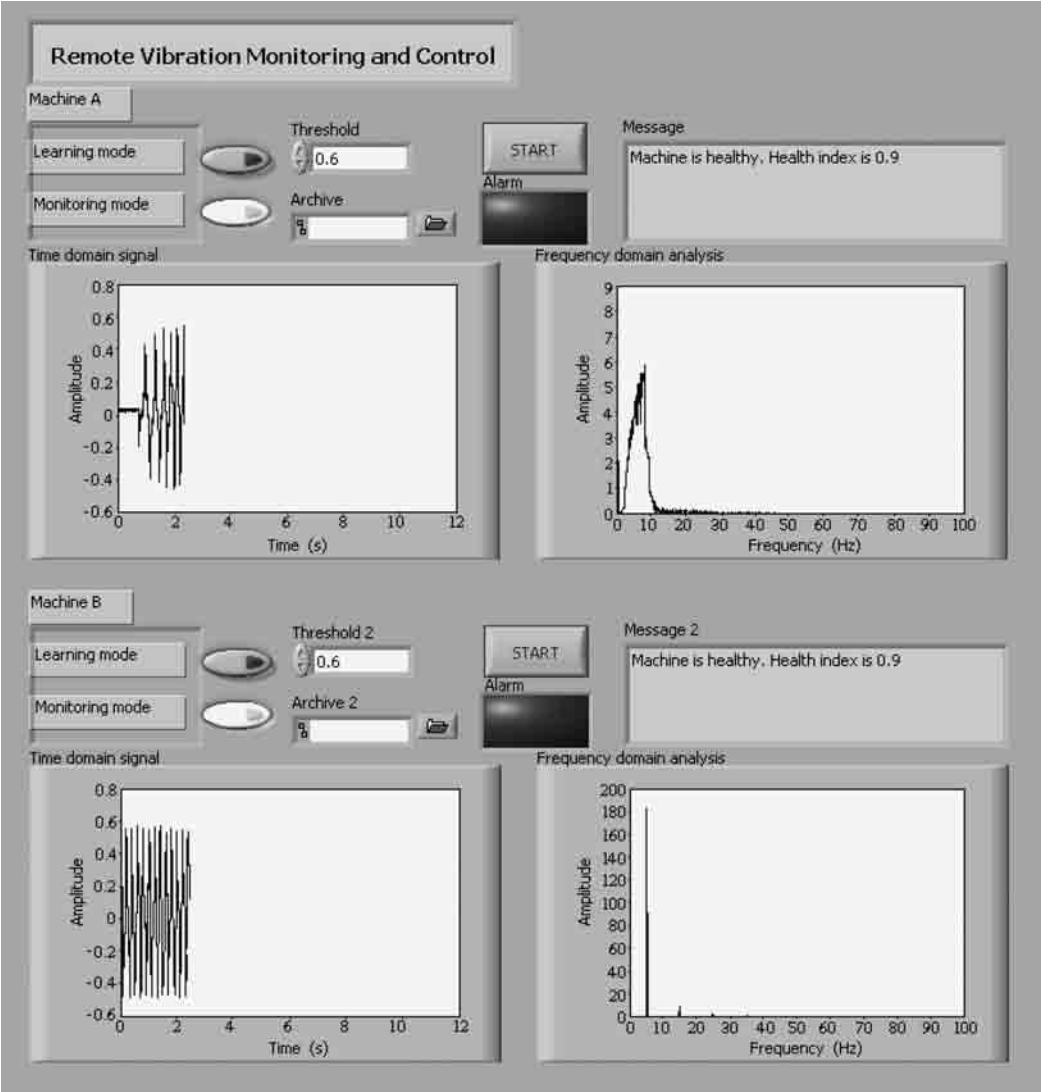

FIGURE 28.42 Monitoring mode — snapshot of the control panel at the supervisory controller end before any fault is invoked on machine A and machine B.

(i.e., current values are at 0.9) of the two machines are above the threshold value of 0.6. To simulate a fault arising in machine A, the input signal to machine A is changed to a sinusoidal input. This causes a simultaneous change in the vibration pattern of Machine A. A snapshot of the control panel at the supervisory controller end is as shown in Figure 28.43 after the fault is invoked to machine A. As can be clearly seen, the vibration pattern of machine A has changed. The message box displays that the health index of machine A (current value is at 0.49) has fallen below the threshold value of 0.6. To signal the deterioration of the health condition of machine A, the alarm LED is lit up. The health condition of machine B remains in the satisfactory region. To simulate a fault arising in machine B, the amplitude of the input signal to Machine B is increased slightly, by 20%. Consequently, this will also cause simultaneous change in the vibration pattern of machine B. A snapshot of the control panel at the supervisory controller end, after the fault is invoked to machine B, is as shown in [Figure 28.44](#).

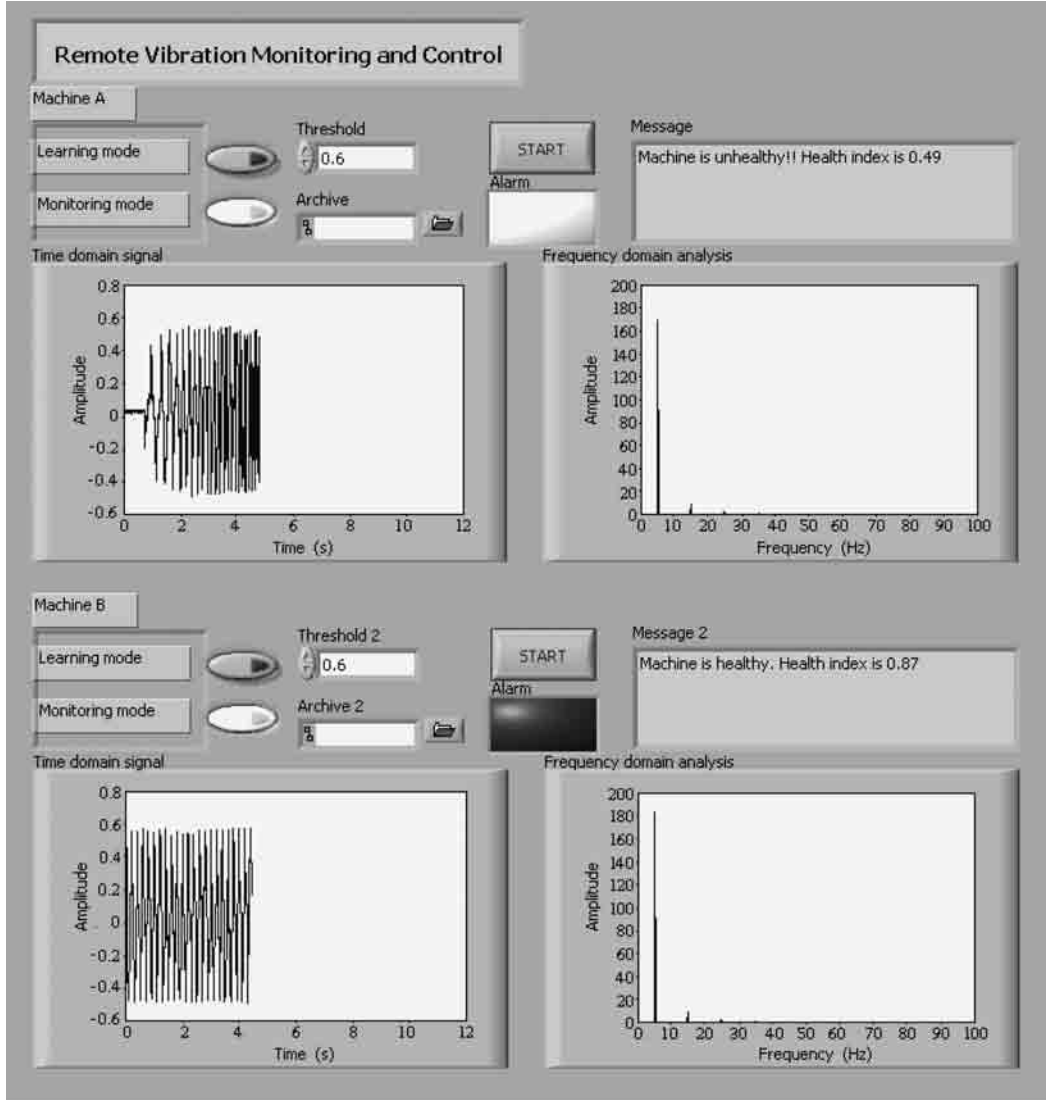

FIGURE 28.43 Monitoring mode — snapshot of the control panel at the supervisory controller end when a fault is invoked on machine A (at $t = 3$ sec).

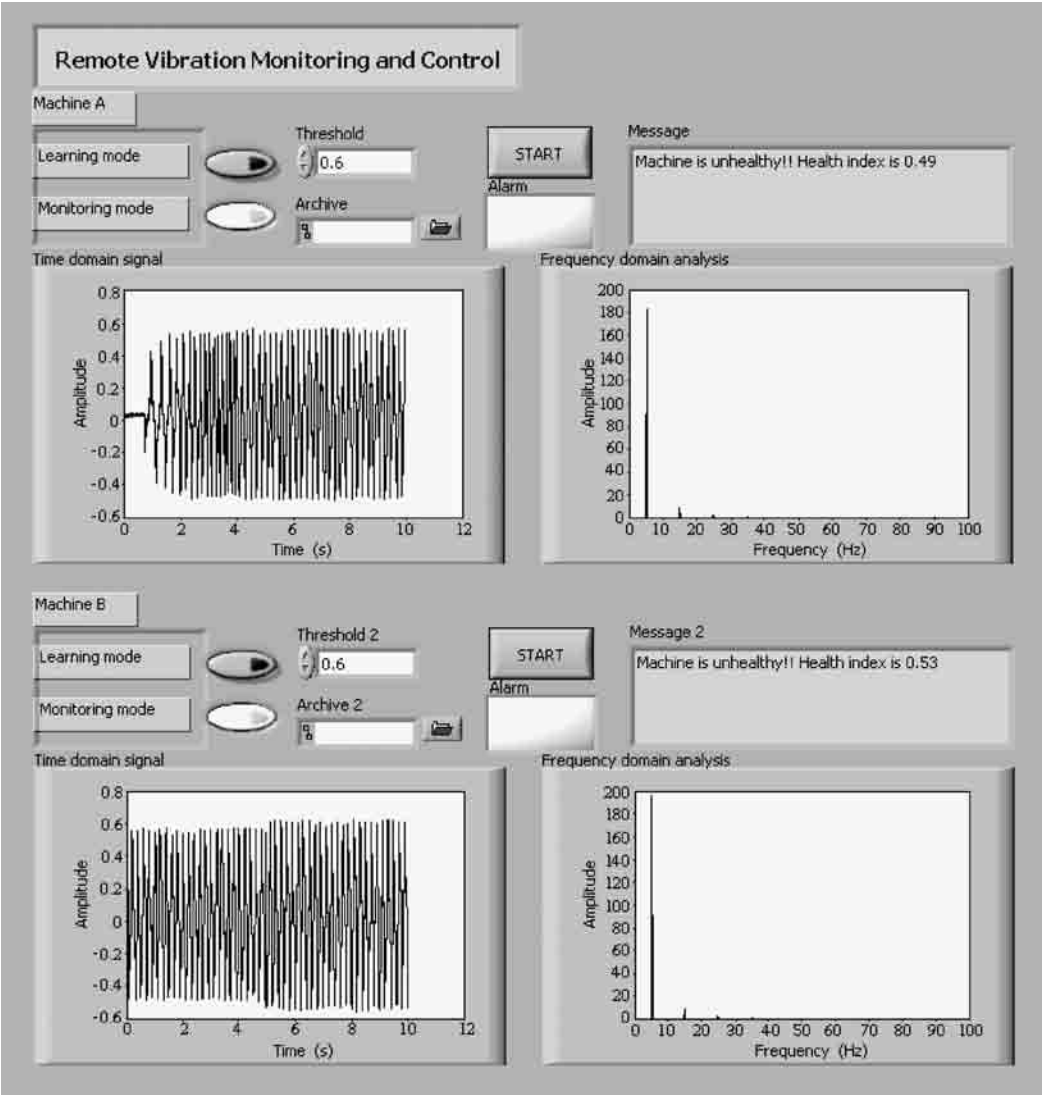

FIGURE 28.44 Monitoring mode — snapshot of the control panel at the supervisory controller end when a fault is invoked on machine B (at $t = 5$ sec).

The vibration pattern of machine B has changed. The message box displays the health index of machine B (current value is at 0.53) has fallen below the threshold value of 0.6. In the same way, the deterioration of the health condition of machine B is highlighted by activating the alarm LED.

SUMMARY

This section gives the reader practical insights into vibration monitoring and control applications in the industry. A case study is provided to explore the feasibility of remote vibration monitoring and control of a number of machines or mechanical systems located at different sites.

28.6 Conclusions

Approaches to address undue vibration arising in mechanical systems have been presented in the chapter. The first approach presented is concerned with a proper mechanical design with a view to reduce the sources of vibration. The second approach is the possibility of including functionalities in the control system to continuously monitor and possibly suppress vibration by terminating transmission at the resonant frequencies. The third approach uses a low-cost monitoring device, which can trigger alarm when excessive vibration is detected to enable corrective actions. Precision motion systems, where the effects due to vibration will directly affect performance, will usually adopt a number of such strategies to keep vibration level to a minimum and acceptable level.

Summary

This chapter presents seismic vibration control of civil engineering structures. It is divided into two main sections. The first part of the chapter deals with vibration control by seismic base isolation, whereas the second part covers methods of response control that use passive energy dissipation, active control, semiactive control, and hybrid control, respectively. Each part starts with a brief description of the historical development of these methods, followed by basic principles and important issues in their implementation. Thereafter, devices used for structural response control, their design methods, and recommended experimental procedures for verification of their properties and analytical modeling are discussed. Various methods generally used for analysis of such structures are then discussed in detail followed by a brief description of the implementation of these methods for various types of structures. In addition, performance of existing structures during past earthquakes is also included, to highlight the effectiveness of these methods during real earthquakes. Further information on the general topic of this chapter is found in [Chapter 22](#), [Chapter 30](#), and [Chapter 31](#).

29.1 Introduction

Seismic isolation and vibration-control systems are relatively new and sophisticated concepts that require more extensive design and detailed analysis than do most conventional seismic designs of structures. In general, these systems will be most applicable to structures whose designers seek superior earthquake performance. Seismic base isolation and passive energy-dissipation systems are viable design strategies that have already been used for seismic protection of a number of structures. Other special seismic protective system techniques such as active control, semiactive control, hybrid combinations of active and passive devices, and tuned mass and liquid dampers may also provide practical solutions in the

near future. An innovative challenge is highly expected in this field for the seismic safety enhancement of civil structures.

29.1.1 From Ductility Design to Base Isolation and Control Design

The conventional method of seismic design mainly deals with increasing capacity. The approach is based on designing a strong and ductile structure (see Figure 29.1), which can take care of the inertial forces generated by the earthquake shaking. The approach results in increasing the size of structural members and connections, and providing additional bracing members and shear walls, or other stiffening members. The increase in stiffness then attracts more seismic forces and in turn requires further strengthening, which becomes uneconomical. Therefore, the conventional practice permits safe design of a structure on the premise that inelastic action in a ductility-based designed structure will dissipate significant energy and enable it to survive a severe earthquake without collapse. The conventional designs may permit some structural damage because of inelastic deformation in the members and also in nonstructural elements. Contents of structure can get damaged due to large interstory drift and high-floor accelerations.

FIGURE 29.1 Schematic of a structure with ductile members.

It is difficult to control structural damage and it may be dangerous in unexpected strong seismic events. It has been observed that, in the event of major seismic events, structures based on the conventional design methods suffered damage, experienced high-floor accelerations, and resulted in disruption of essential services such as transportation, communication, and so on. Thus, for the class of structures like nuclear power plants, museums, hospital buildings, buildings with artifacts, important bridges, and such structures located in high-seismicity regions, this ductility-based design is not suitable. The need to minimize earthquake damage in critical and important structures prompted civil engineers to search for other methods of earthquake-resistant designs, which can not only protect structures from earthquake motions but also keep them functional during and after strong earthquakes. To this end, base isolation and structural control methods are found to be a solution.

Base isolation has the capability to reduce the seismic response of a structure by isolating it from the ground shaking (Figure 29.2a). An isolation system reduces the transmission of ground vibration, thus enabling the structure to experience less shaking from the ground. Therefore, structural damage and occupants' inconvenience can be minimized using this technique. However, at the expense of safety and the convenience of structure, the bearings undergo significant drift during large earthquakes that may disrupt the function of the bearings themselves and supply lines of services such as water and gas.

Another way of reducing seismic response is by using the structural control method. It has the capability of modifying the structural properties, such as stiffness, mass, and damping, and providing passive or active counterforces. Figure 29.2b shows the schematic diagram of the structural control method in a civil structure. It shows some examples of devices generally used for applying control forces.

The seismic safety enhancement of structures using the structural control method can be categorized as active and passive systems. There are also hybrid systems that represent combinations of active and passive, and semiactive systems to represent active controller that employs controllable passive devices.

FIGURE 29.2 Schematic of a civil structure with (a) isolation bearings and (b) the structural control method.

Owing to changes in code provisions or upgradation of seismic zones, many structures come into the category of “unsafe” and require retrofiting. Response control strategies are found to be easier than other options, economical, and are often the only alternative for such cases.

29.1.2 The Importance of Reducing Seismic Input and Response

As mentioned above, by using the conventional method of seismic design, the design may permit some structural damage because of inelastic deformation in the members, and also in nonstructural elements, during large earthquakes. The ductility enables the structure as a whole to absorb the seismic energy. Once the structural response goes deeply into the plastic range during a large earthquake, structures may not be operational or repairable.

If the seismic input to the structure and structural response can be reduced, then the structural damage can be minimized. For higher reliability of structures even under very severe earthquake motion, structural control techniques that effectively reduce seismic force to structures are developed. The fast development of technology, particularly in the fields of electronics and computer science, has provoked the researchers in some centers worldwide to intensify development of a new concept with the new philosophy of seismic design. Generally, this concept is known as a design of intelligent structures or smart structures.

Owing to the experience of severe damage due to the Kobe earthquake, public demand for seismic performances of civil infrastructures became relatively clear in Japan. Civil infrastructures are constructed with the tax paid by the public, so a collapse or near collapse with unrepairable damage cannot be accepted, even under a very rare earthquake loading. Infrastructures are also expected to serve as public tools to help rehabilitate the affected society. For this purpose, infrastructures have to be repaired in a relatively short time, even though their functions are temporarily terminated due to severe earthquake loading.

FIGURE 29.3 Public demand for seismic performance of infrastructure.

The public demand for seismic performance objectives of infrastructures shows that structural damage has to be limited even against very rare earthquake loading (Figure 29.3). The figure shows that civil infrastructures must be fully operational during and after frequent, weak earthquakes. They also expected to be operational even after very rare, strong earthquakes. To achieve the objectives, new technologies are to be developed that can result in the desired performance.

29.2 Seismic Base Isolation

29.2.1 Historical Development of Base Isolation

Seismic base isolation is not a very new idea. More than a century ago, John Milne, a professor of engineering in Japan, built a small house of wood and placed it on ball bearings to demonstrate that a structure could be isolated from earthquake shaking (Housner et al., 1997). In 1891, after the Narobi earthquake ($M = 8.0$), Kawai, a Japanese person, proposed a base-isolated structure with timber logs placed in several layers in the longitudinal and transverse direction (Izumi, 1988; see Figure 29.4). In 1906, Jacob Bechtold of Germany applied for a U.S. patent in which he proposed to place building on rigid plate, supported on spherical bodies of hard material (Buckle and Mayes, 1990). In 1909, a medical doctor from England, Calentarients, applied for patents for his invention comprising isolation system for earthquake-proof building (see Figure 29.5). He proposed separating a building from its foundation with a layer of sand or talc (Kelly, 1986). The Imperial Hotel in Tokyo, constructed in 1921, was intended to float on an underlying layer of mud. The building was founded on an 8-ft thick layer of firm soil under which exists a 60- to 70-ft thick layer of soft mud. The building was

FIGURE 29.4 Base isolation by timber logs. (Source: JSSI, *Introduction of Base Isolated Structures*, Japan Society of Seismic Isolation, Ohmsa, Tokyo, 1995. With permission.)

FIGURE 29.5 Calentarients' idea of seismic base isolation. (Source: JSSI, *Introduction of Base Isolated Structures*, Japan Society of Seismic Isolation, Ohmsa, Tokyo, 1995. With permission.)

highly decorative with many appendages. The soft mud acted as isolation system and the building survived the devastating 1923 Tokyo earthquake (Kelly, 1986; Buckle and Mayes, 1990).

Attempts were made in the 1930s to protect the upper floors of multistory buildings by designing very flexible first-story columns. In a later modification of the flexible first-story columns approach, it was proposed that the first-story columns should be designed to yield during an earthquake to produce an energy-absorbing action. However, to produce enough damping, several inches of displacement is required, and a yielded column has greatly reduced buckling load, proving the concept to be impractical. It was then proposed that, if the soft first story is constructed underground, then energy dissipaters can be installed at the top of this story (which approximates ground level) that prevent the superstructure from moving too far, and dissipate the energy of ground motion before it enters the building. The superstructure, from the first floor up, can be an economically braced, nonductile concrete frame requiring no internal shear walls (Arnold, 2001). To overcome the inherent dangers of soft supports at the base, many types of roller-bearing systems have been proposed. The rollers and the spherical bearings are very low in damping and have no inherent resistance to lateral load, and therefore some other mechanism that provides wind restraint and energy-absorbing capacity is needed. A long duration between two successive earthquakes can result in the cold welding of bearings and plates, thus causing the system to become rigid after a time. Therefore, the application of rolling supports was restricted to the isolation of special components of low or moderate weight (Caspe, 1984).

Parallel to the development of the soft first-story approach, the flexibility of natural rubber was also seen as another solution for increasing the flexibility of the system. In 1968, large blocks of hard rubber, 54 in number, were used to isolate the three-story Heinrich Pestalozzi School in Skopje, Republic of Macedonia. The building is constructed of reinforced concrete shear walls. This is the first building for which rubber bearings were used as base isolation against strong earthquakes. These rubber blocks are unreinforced and bulge sideways under the weight of this concrete structure (see Figure 29.6). Owing to having the same stiffness of the isolation system in all the directions, the building bounces and rocks backwards and forwards (Jurukovski and Rakicevic, 1995). These types of bearings are unsuitable for the earthquake protection of structures. The subsequent development of laminated rubber bearings has made base isolation a practical reality (Figure 29.7). Later, a large number of isolation devices were developed, and now base isolation has reached the stage of gaining acceptance and replacing the conventional construction, at least for important structures.

FIGURE 29.7 Rubber bearings with steel shims.

29.2.2 Basic Principle

Seismic base isolation is basically a lengthening of the fundamental time period of the structure with the help of a specially designed system that is placed between its superstructure and substructure (see Figure 29.8). Besides other advantages, the concept gained widespread acceptance due to the fact that most of the earthquake motions around the world have dominating frequencies in the range of 1.0 to 10 Hz, and the majority of conventionally designed structures also has their fundamental frequency of vibration lying in this range. Owing to this unwanted matching of the frequencies, these structures are subjected to high forces during earthquakes. The application of seismic base isolation shifts the fundamental time period away from the dominating frequencies of earthquake motions and thus detunes the frequencies. In other words, base isolation consists in filtering out high-frequency waves from the ground motion, thereby preventing the transmission of high energy in the structure. The effect of base isolation on reduction in force is shown schematically in Figure 29.9. Under favorable conditions, seismic base isolation can reduce drift to 0.2 to 0.5 of that which would occur if the building were fixed base (Figure 29.10). Reduction in acceleration has more influence on the force–deflection characteristics of the isolation system and may not be as significant as the reduction of drift (FEMA 356, 2000). However, the additional flexibility required for this period shift give rise to excessive relative displacement at the isolation level. Additional damping is introduced in the isolation system to limit this displacement response to within feasible limits. Still, it is necessary to provide an adequate seismic gap that can accommodate displacements at the isolation level. Most of the isolators have inherent damping, although sometimes supplemental energy dissipation devices may also be required at the isolation level. Various types of energy dissipation devices like metallic dampers and hydraulic dampers have been developed and can be used for this purpose (Skinner et al., 1993). The isolation damping also suppresses the resonance

FIGURE 29.8 Application of seismic isolation for different structures.

FIGURE 29.9 Conceptual diagram for seismic isolation.

resulting due to higher period contents of the earthquake motion. Although damping is useful in reducing the required seismic gap, excess damping may result in an increase in acceleration that may affect the performance of nonstructural elements and contents. Thus, an isolation system should essentially be able to (1) support a structure, (2) provide horizontal flexibility, and (3) dissipate energy. These three functions can be incorporated in a single device or can be provided by means of different components. In addition, it may be necessary to provide buffers, which can limit the isolator displacements during extreme earthquakes.

FIGURE 29.10 Behavior of (a) fixed-base and (b) base-isolated building.

29.2.3 Issues in Seismic Base Isolation

A number of issues for seismic isolation design have been identified based on experiences of their behavior. Some of the issues that should be considered before choosing the base-isolation approach for a project are touched in the following sections.

29.2.3.1 Performance Criteria

The performance criteria for the structure needs to be established in order to evaluate alternative seismic resisting systems; for example, it must be established whether the structure is required to be functional during and after major earthquakes, or if it is to be preserved for its historical importance. Whether seismic base isolation is a suitable design strategy for a particular project will depend primarily on the performance required. To achieve the *fully operational* or *operational* performance level, one can consider seismic base isolation as a possible design strategy, but if *life safe* is the required structural performance level, it may not be practical to choose seismic base isolation.

29.2.3.2 Type of Structure

Significant benefits obtained from isolation exist in structures for which the fundamental period of vibration without base isolation is short, that is, less than 1 sec. Certain structures may not be suitable for base isolation because of their shape; for example, this is true for slender high-rise buildings that have a natural period long enough to attract low earthquake forces without isolation. Therefore, seismic isolation is mostly used for low-rise buildings. Historical buildings, which generally are stiff masonry structures, can be appropriate structures for seismic base isolation. Bridges are the structures for which application of seismic isolation is very convenient. The provision of bearings at the tops of piers adds flexibility to stiffer piers and in turn avoids yielding of piers. It is easy to examine these bearings after a seismic event and replace them if needed.

29.2.3.3 Site Characteristics

In base-isolation design, the basic objective is to filter out the high frequencies of the ground motion by lengthening the time period of vibration to approximately 2 sec. Thus, conventional base isolation is not suitable for structures on soft soils where the ground motions are dominated by low frequencies. Therefore, a detailed investigation of the site must be carried out before possible isolation can be considered. Another important aspect is near-fault ground motions. Waves from such motions usually have long-period velocity pulses, which impart lot of momentum to the structure. This is particularly damaging to base-isolated structures because it may cause large horizontal base displacements. The displacement can result in instability of the structure, or it

can result in impact with moat walls, which can affect the sensitive equipment housed in the building. An isolator with bilinear force–displacement behavior and a large ratio of yield-force to supported weight can substantially reduce the displacement. The provision of high damping in an isolation system can also work. However, the degree of isolation during relatively frequent earthquakes without near-fault pulses is much reduced due to these provisions (Skinner and McVerry, 1996).

29.2.3.4 Retrofit Issues

In selecting a suitable retrofit system and properties of seismic isolation system, consideration should be given to the characteristics of the existing building, such as foundation capacity and strength of the superstructure. For retrofit of buildings, successful implementation of a seismic isolation system requires that the sequences of temporary bracing, shoring, cutting of existing columns and walls, and installation of isolators be well planned. Base isolation for the retrofit of bridges is simpler as they usually have thermal bearings, which can easily be replaced by seismic isolation bearings. The retrofitting of monuments or buildings of historical importance requires special efforts to cope with the need of minimum alterations. Provisions must be made to protect them from any seismic event during the retrofitting. Also it must be identified whether workable spaces and access to the work area is available.

29.2.3.5 Design of Building Services

Depending on the base-isolation system, base-isolated structures under earthquake motions can exhibit significant base slab displacements due to the low horizontal stiffness of the isolation elements. This may create problems on the supply lines transitioning between the parts of structure below and above isolation level. Therefore, special attention is to be given to installations of building services such as water supply, sewerage, gas, air-conditioning, and so on in order to prevent any damage to these supply lines, which might cause secondary effects. In the case of isolation of two or more structural units founded on a common foundation and connected by expansion joints, special care is needed regarding the proportions of the expansion joint in order to prevent the pounding of buildings during earthquakes.

29.2.3.6 Expected Life of Isolator

The isolation system should remain operational for the expected lifetime of the isolated structure. It should not require frequent maintenance during this period. Although the functioning of an isolator may be required few times during the lifetime of structure, it must perform well at such times. If life of the isolator is less than the life of structure, then it may be necessary to provide a mechanism for the inspection and replacement of the isolation system. Another related aspect is the protection of isolation elements against fire, and measures should be taken for this. Furthermore, as an isolation system is provided mostly at the base, its resistance to chemical and biological reactions is also important (Jurukovski and Rakicevic, 1995).

29.2.4 Seismic Isolation Devices

The successful seismic isolation of a particular structure is strongly dependent on the appropriate choice of the isolation system. In addition to providing adequate horizontal flexibility and appropriate damping, the isolation system should essentially have the capability of self-centering after deformation, high vertical stiffness to avoid rocking, and enough initial stiffness to avoid frequent vibration from wind and minor seismic events. Different types of isolators have been developed and proposed to achieve these properties, and some of them are discussed below.

29.2.4.1 Laminated Rubber Bearings

Rubber bearings offer the simplest method of seismic base isolation and are relatively easy to manufacture. The bearings are made by vulcanization bonding of sheets of rubber to thin steel reinforcing plates. Initially, the main function of the laminated rubber bearings was to provide flexibility for thermal displacements in bridges. Later, similar bearings found application in the isolation of buildings from vibration due to underground railways, and these bearings have performed well over a substantial period of time (Kelly, 1990). The bearings are very stiff in the vertical direction and flexible in the horizontal direction. High vertical stiffness of these bearings is achieved through the laminated construction of the bearing using steel plates. The cross section of a typical rubber bearing is shown in Figure 29.11. The most common elastomers used in elastomeric bearings are natural rubber, neoprene rubber, butyl rubber, and nitrile rubber. The mechanical (tear strength, high strain fatigue resistance, creep resistance) and low-temperature properties of natural rubber are superior to those of most synthetic elastomers used for seismic isolation bearings. Therefore, natural rubber is the most frequently recommended material for use in elastomeric bearings, followed by neoprene. Butyl rubbers are suitable for low-temperature applications and nitrile rubber has limited application in offshore oil structures (Taylor et al., 1992).

The damping ratio (i.e., the fraction of critical damping) achieved from natural rubber is low, in the order of 0.02 to 0.04, and therefore it is unusual to use it without some other element that is able to provide increased damping. In order to achieve better performance in a single unit, rubber used in the bearing is a compound formed with some filler agents. This compounding results in desired properties, such as (1) high damping and (2) high horizontal stiffness at low values of shear strain. The damping ratio (i.e., the fraction of critical damping) achieved is in the order of 0.10 to 0.20. These *high-damping rubber bearings*, originally developed in England, found several applications in Japan and United States. A number of fillers are employed, such as metal oxides, clay, and cellulose, but the filler that is most commonly used in seismic isolation bearings is carbon black (Taylor et al., 1992). Force–displacement behavior of these bearings depends upon the type of compounding. Figure 29.12 shows the results of cyclic loading test conducted on a four-layer high-damping rubber bearing specimen (Tanzo et al., 1992). In the experiment, the tests were carried out up to 200% (96 mm) shear strain. Vertical load for the tests was kept as 40 tonf (64 kg/cm²).

The application of steel shims in laminated rubber bearings provides necessary vertical stiffness, but at the same time makes these isolators heavy and expensive. Recently, Kelly (2001) proposed a seismic isolation system for developing countries, in which steel plates are replaced by fiber mesh. The *fiber-reinforced isolator* is expected to be significantly lighter and could lead to a much less labor-intensive manufacturing process.

FIGURE 29.12 Load–displacement loops for high-damping rubber bearing. (Source: Tanzo, W. et al. Res. Rpt. 92-ST-01, Kyoto Univ., 1992. With permission.)

29.2.4.2 Lead Rubber Bearing

This isolation system consists of a cylinder of lead enclosed in a rubber bearing. The system is also known as the NZ bearing system, and its components are shown in Figure 29.13. The lead plug produces a substantial increase in damping, from about 3% of critical damping in the natural rubber to 10 to 15%, and also increases the resistance to frequently occurring loads such as minor earthquakes or wind. The reason for choosing lead is that it is a crystalline material, and under normal conditions it changes its crystal structure under deformation but almost instantly regains its original crystal structure when the deformation ceases. Thus, repeated yielding due to cyclic loading does not cause fatigue. Lead yields in shear at the relatively low stress of about 8 to 10 N/mm², and therefore produces stable hysteretic behavior and dissipates significant energy in strong ground motion. Load–displacement behavior of a lead rubber bearing is shown in Figure 29.14 (JSSI, 1995). The hysteretic behavior of lead rubber bearings can be treated as bilinear, with initial stiffness in the range of 9 to 16 times the postyield stiffness. These bearings provide an economical and effective solution, incorporating period shifting, increased damping, and high stiffness at low strains, and providing vertical support in a single device (Skinner et al., 1993). It has found several applications in new constructions as well as for retrofitting of buildings and bridges in different parts of the world.

29.2.4.3 Friction-Based Systems

In this class of isolators, the superstructure is allowed to slide during major seismic events. The structure slides whenever the lateral force exceeds the friction force at the sliding interface. The horizontal friction force at the sliding surface offers resistance to motion and dissipates energy. Pure sliding systems have no inherent natural period and therefore are insensitive to variations in the frequency content of ground excitation. The acceleration at the base of the structure is limited to the coefficient of friction at the sliding interface. Thus, by keeping this coefficient of friction low, the acceleration felt by the structure can be reduced. Systems based on a Teflon (PTFE) and stainless steel interface have the potential to provide high levels of protection against floor acceleration because of the low friction of the materials. However, the friction coefficient cannot be reduced arbitrarily, as the sliding displacement may exceed the acceptable value. Another feature of this isolation system is that the frictional force is proportional to the vertical load coming on the bearing, and therefore the center of mass and the center of resistance of the sliding support coincide. As a result, the torsional effects produced by the asymmetry of building are diminished.

The main drawback of the system is the absence of restoring force due to which a large residual displacement from the original position of the structure may be left after a major earthquake event. There are other practical problems that can affect the efficiency of sliding isolation, such as cold welding, freezing, and deterioration of the sliding surfaces. Changes may occur in the friction coefficient due to ageing, environmental attack, temperature variation, or wear during use (Skinner et al., 1993).

As the sliding depends upon the coefficient of

friction, the system may require regular inspection to maintain its coefficient of friction. The unsatisfactory predictability of friction coefficient and the absence of any centering force suggest that Teflon bearings should be used as seismic isolators only in combination with some other centering devices like steel dampers or rubber bearings (Priestley et al., 1996). Based on this concept another system called the *resilient friction bearing* (R-FBI) system was developed (Mostaghel and Khodaverdian, 1987). The system consists of several concentric layers of Teflon-coated friction plates that are in friction contact with each other and a central core of rubber. The rubber provides the resilient force while the friction forces dissipate the energy.

An effective mechanism to provide recentering force by gravity has been utilized in a *friction pendulum system* (FPS). In this system, the sliding surface takes a concave spherical shape so that the sliding and recentering mechanisms are integrated in one unit. As the name indicates, there are two mechanisms that are employed to achieve isolation, namely, sliding friction and pendulum motion. The internal components consist of a stainless steel concave surface upon which slides a stainless steel articulated slider surfaced with a high-load capacity and a low friction bearing material composite (see Figure 29.15). The radius of curvature determines the sliding or isolation period of the system. The period of the structure supported on the FPS is independent of the structure mass and therefore the period does not change if the structure weight changes or is different than assumed. This results in better control over the response of the systems, like liquid storage tanks in which weight varies in time because of variable liquid storage level. However, since the restoring force is linearly proportional to the sliding displacement, in case of high-intensity earthquakes or a low coefficient of friction, the additional sliding introduces additional energy in the structure. To overcome this problem, Pranesh and Sinha (2002) proposed the *variable frequency pendulum isolator*, in which the geometry of the concave surface is designed such that its frequency decreases with the increase in sliding displacement and asymptotically approaches zero at very large displacement.

FIGURE 29.15 Schematic diagram of friction pendulum system.

29.2.4.4 Other Systems

A base-isolation system, which has found many applications in Japan, comprises of *low-damping rubber bearings* with *yielding metal devices*. The yielding of metals provides the necessary dissipation of energy. The commonly used dampers are shown in Figure 29.16 (Aoyagi et al., 1988; Takayama et al., 1988; Yasaka et al., 1988).

To standardize the designs of the sensitive structures of nuclear power plants for regions of different seismicity, an isolation system called the *EDF (Electricite de France) system* was developed. This is a laminated rubber bearing with friction plate at the top. An attractive feature of the EDF isolator is that, for the lower amplitude ground excitations, the lateral flexibility of the rubber provides the base isolation. At a high level of excitation, however, sliding will occur assuring maximum acceleration transmissibility of μg , where μ is the coefficient of friction between materials of sliding surface (Constantinou, 1994).

FIGURE 29.16 (a) Elasto-plastic steel damper; (b) lead damper; (c) steel rod damper.

FIGURE 29.17 Elements of a TASS system. (Source: Kawamura, S. et al. 1998. *Proc. IX World Conf. on Earthquake Engineering*, pp. 735–740. Tokyo, Japan. With permission.)

Taisei Corporation, Japan, developed the TASS (TAISEI Shake Suppression) system (Figure 29.17), which is composed of PTFE-elastomeric bearings and neoprene springs (Kawamura et al., 1988). PTFE-elastomeric bearings support the vertical load of the superstructure and reduce the horizontal seismic forces by sliding against severe earthquake motion. Horizontal springs provide weak lateral stiffness and restrain displacement. The TASS system never resonates to any type of excitation, stably supports superstructure, and limits the horizontal force transmitted to the superstructure to that equal to friction force.

In situations where circumstances may result in substantial tension forces on the bearings, it has generally been accepted that elastomeric, sliding, or roller isolators alone are not suitable. For this, a system that controls uplift was developed. The system consists of rubber bearings with a central hole to accommodate a tension device (Kelly and Chalhoub, 1990). Logiadis et al. (1996) proposed a *prestressed bearing* isolation system in which vertical prestressed tendons are located in pairs, symmetrical on both sides of each bearing to avoid tension in the rubber bearing.

Tarics (1996) developed a *composite isolator* to provide equal protection in minor, moderate, or major earthquakes (see Figure 29.18). The composite seismic isolator has two distinctly different stiffnesses, which are activated by the displacement demand. During minor or moderate earthquakes, the upper isolator provides flexibility. In the event of major earthquake, the higher stiffness of the lower isolator prevents excessive displacement. This isolator seems to be a promising alternative for near-fault ground motions. With similar objectives, Shimoda et al. (1992) proposed lead rubber bearings with a stepped lead plug. Several other systems, for example, the *sleeved pile system*, *GERB*, *alexisis-mon*, and so on, were developed by different researchers (Kelly, 1986; Buckle and Mayes, 1990) and the search for new isolation systems, which can give better performance under different conditions, is still continuing.

29.2.5 Design of Isolation Devices

As discussed above, several types of isolators have been proposed so far. Only a few bearings, namely, laminated rubber bearings, lead rubber bearing, FPS bearings, and Teflon–steel sliding bearings with a restoring device, have been developed to the stage of practical application. These isolators are in general observed to be effective in reducing seismic response; however, their effectiveness depends on the situation and design constraints. For example, rubber bearings are most suitable for high-frequency motions, while friction-type isolators may also be applied at the site where ground motion can have low-frequency content. Buildings with sophisticated electronic equipment and loose contents should preferably be isolated with rubber bearings to avoid transmission of high frequencies to the superstructure. In the case where, for some reason, it is not possible to provide large seismic gaps or for the conditions where light weight structure is to be isolated, the FPS-type isolators are more suitable. The main requirements for the design of a base-isolation system are (1) the ability to sustain gravity loads, (2) low horizontal stiffness that can lengthen the fundamental time period to the desired value, (3) large vertical stiffness to minimize amplification in vertical direction and complications due to rocking, (4) energy dissipation capacity to keep displacements at the isolation level within acceptable limits, and (5) sufficient initial stiffness to avoid unwanted vibrations due to wind loads and frequent minor seismic events. The design procedure of most widely used isolation systems, namely, high-damping rubber bearings, lead rubber bearings, and the FPS, is discussed in the following sections.

29.2.5.1 High-Damping Rubber Bearing

The design of high-damping laminated rubber bearings involves determining the plan size, the number of rubber layers, the thickness of each rubber layer, and steel shim. The steps involved in the design of high-damping rubber bearings are as follows:

1. Specify the design vertical load on the bearing (W), the design period for the isolated structure (T_1), and site conditions.

The load, W , is computed for the dead load and live load combination. The design period, T_1 , depends on site conditions. Its minimum value is usually taken as three times the fundamental time period of the structure when it is fixed base.

2. Find corresponding horizontal stiffness of the bearing, K_h , using

$$K_h = \frac{W}{g} (2\pi/T_1)^2 \quad (29.1)$$

3. Assign the values to quantities such as the maximum permissible shear strain (γ), Young's modulus (E), and the shear modulus (G) for the rubber compound.

Generally, γ is considered to be in the range of 100 to 150%. G can be taken from design specifications provided by the manufacturer. The value of G for this range of shear strains varies from 0.69 to 0.86 MPa, depending on the rubber composition (Kelly, 1997).

4. Specify the effective equivalent damping in the isolation system and allowable pressure on the bearing (p) for vertical loads.

The allowable pressure (p) for bearings with metal reinforcement can be taken as about 6.9 N/mm² (Kelly, 1997). Damping can be taken as 15 to 20%, subject to verification.

5. Using a response spectrum or code formulae, find the maximum horizontal displacement, that is, the design displacement (D). This depends on the spectral coefficient (i.e., the site condition), design period, and damping.
6. The plan area of the rubber (A) in bearing is primarily controlled by the design vertical load (W) and allowable pressure (p), and is determined by the expression

$$A = W/p \quad (29.2)$$

7. The total thickness of rubber, t_r , in the bearing is determined from the following equation:

$$t_r = GA/K_h \quad (29.3)$$

Total thickness, t_r , should not be less than D/γ .

8. Evaluate the shape factor (S) for the desired value of ratio of vertical stiffness (K_v) and horizontal stiffness (K_h) using following expressions:

$$6S^2 = K_v/K_h \quad \text{for circular bearings} \quad (29.4a)$$

$$6.73S^2 = K_v/K_h \quad \text{for square bearings} \quad (29.4b)$$

The minimum recommended value for the stiffness ratio is 400. These expressions are fairly accurate for shape factors of ten or less. However, for higher values of S , the effect of compressibility should also be taken into account (Kelly, 1997).

9. Using a basic definition of shape factor as the ratio of the cross-sectional area of the bearing to the force-free area of a single layer of rubber, the thickness of each rubber layer can now be determined by

$$t = \phi/4S \quad \text{for circular bearings} \quad (29.5a)$$

$$t = b/4S \quad \text{for square bearings} \quad (29.5b)$$

where ϕ is the diameter for circular bearing and b is the side for square bearing. Knowing the values of t_r and t , the number of rubber layers (n) can be computed.

10. The thickness of steel shims provided for laminated construction should be in the range of one tenth to one eighth of an inch (Kelly, 1997).

The material properties for rubber compounds used for isolation devices can be related to the rubber hardness. Properties for the range of rubber hardness normally used in bearing are listed in Table 29.1 (Bridgestone, 1990).

The designed bearing should be checked for the following criteria also.

29.2.5.1.1 Stability against Buckling

Buckling load may become critical in situations where bearings with a high rubber thickness relative to the plan dimension are to be provided. For example, in the case of base isolation for low vertical loads,

TABLE 29.1 Relationship between Rubber Hardness and Other Properties

Rubber Hardness (IRHD ± 2)	Young's Modulus, E (MPa)	Shear Modulus, G (MPa)	Material Constant, k	Minimum Elongation at Break (%)
35	1.18	0.37	0.89	650
40	1.50	0.45	0.85	600
45	1.80	0.54	0.80	600
50	2.20	0.64	0.73	500
55	3.25	0.81	0.64	500
60	4.45	1.06	0.57	400

rubber bearings are generally slender. Average compressive stress in the bearing (W/A) should not exceed the critical stress (p_{cr}) given by Kelly (1997):

$$p_{cr} = \frac{\sqrt{2}\pi GS}{t_r} r \quad (29.6)$$

where r is radius of gyration ($b/2\sqrt{3}$ for a square bearing and $\phi/4$ for a circular bearing).

Maximum shear strain is described as follows. Under vertical loading only, as per AASHTO recommendations for service loads (i.e., for the dead and live load), a factor of safety of three should be adopted for maximum shear strain values. Thus, maximum shear strain (γ_s) should satisfy the following condition:

$$\gamma_s \text{ i.e. } 6S \frac{W}{E_c A} \leq \frac{\varepsilon_b}{3}$$

where ε_b is the minimum tensile strain at which rubber breaks and E_c is compression modulus for bearing and is given by $E_c = E(1 + kS^2)$. E and k , for a given value of rubber hardness, can be taken from Table 29.1.

Under earthquake loading, the following applies. In the case of ultimate load that includes effect of earthquake loads, AASHTO recommends a factor of safety of 1.33. Thus, maximum shear strain (γ_u) due to combined effect of compression (γ_c), torsion (γ_t), and lateral load (γ_{eq}) should not exceed $\varepsilon_b/1.33$; that is, $\gamma_c + \gamma_{eq} + \gamma_t \leq \varepsilon_b/1.33$. γ_{eq} is given by D/t_r , and γ_t can be evaluated by

$$\gamma_t = \frac{b^2}{2tt_r} \frac{12De}{(B^2 + L^2)} \quad (29.7)$$

Here, B and L are dimensions of a structure with rectangular plan and e is the eccentricity. $\gamma_c (= 6SW'/E_c A_r)$ is computed for vertical load (W'), which also includes the effect of earthquake load. In this case, the effective area (A_r) is reduced due to lateral displacement (D) and it is the overlapping area of top and bottom in displaced condition. A_r can be determined using the following expressions:

$$A_r = A \left(1 - \frac{D}{b} \right) \quad \text{for square bearings} \quad (29.8a)$$

$$A_r = \frac{1}{2} \left\{ \phi^2 \sin^{-1} \left(\frac{\sqrt{\phi^2 - D^2}}{\phi} \right) - D \sqrt{\phi^2 - D^2} \right\} \quad \text{for circular bearings} \quad (29.8b)$$

29.2.5.1.2 Stability against Roll Out

Maximum horizontal displacement should not exceed the roll-out displacement (δ) given by

$$\delta = \frac{W_E b}{W_E + K_h h} \quad (29.9)$$

where vertical load (W_E) also includes the effect of earthquake load, b is the side for square and the diameter for the circular bearing, and h is the overall height of the bearing (Figure 29.19).

The check should be made for bearings with bolted connections also, so as to avoid the development of tensile stresses.

29.2.5.2 Lead Rubber Bearings

The design of lead rubber bearings can be split into two parts, namely, (a) the design of the lead plug and (b) the design of the laminated rubber bearing.

29.2.5.2.1 Design of Lead Plug

In fact, the lead rubber bearing can be designed effectively by assuming its force–displacement behavior comprises two distinct stiffnesses, namely, the preyielding and postyielding stiffnesses, as shown in Figure 29.20. The characteristic strength, Q_d , for the desired energy dissipation (W_D) or the known effective damping (ξ_{eff}) can be computed using

$$Q_d = W_D/4(D - d_y) \\ = 2\pi K_{\text{eff}} D^2 \xi_{\text{eff}}/4(D - d_y) \quad (29.10)$$

Q_d and yield displacement (d_y) are the unknowns. So for a first trial, considering d_y is very small as compared with design displacement (D), we have, as a first approximation

$$Q_d = W_D/4D \quad (29.11)$$

Using this approximate value for Q_d , the postyield stiffness (K_p) can be evaluated by

$$K_{\text{eff}}D = Q_d + K_p D \quad (29.12)$$

This may lead to modified value of yield displacement, d_y , given by

$$d_y = Q_d/(K_e - K_p) \quad (29.13)$$

where, depending upon the physical parameters of the laminated rubber bearing, K_e can be assumed to be about ten times the value of K_p .

This value of d_y can be used in the next trial to compute revised values of Q_d , K_p , and d_y . Trials are to be repeated until d_y converges.

Now, the yield force can be evaluated by

$$F_y = K_e d_y \quad (29.14)$$

Thus, the area of lead plug (A_p) can be determined using $A_p = F_y/f_y$, in which f_y is the yield strength of the lead in shear and has a value of 10.5 MPa (Skinner et al., 1993). In design, owing to considerations for the confinement of the plug, a reduced value of 7 to 8 MPa is generally considered.

FIGURE 29.19 Stability against roll out. (Source: Kelly, J.M. *Earthquake Resistant Design with Rubber*, Springer, London, 1997. With permission.)

FIGURE 29.20 Design parameters for lead rubber bearing.

29.2.5.2.2 Design of Laminated Rubber Bearing

Postyield stiffness of the bearing (K_p) is typically higher than the corresponding stiffness of the bearing without the lead plug (K_h):

$$K_p = f_L K_h$$

where f_L is a factor that takes into account the effect of lead plug and is always larger than unity. Typically, f_L is 1.15 (FEMA 356, 2000).

Another expression for computing K_p is given by (Yang et al., 2003)

$$K_p = K_h \left[1 + 12 \frac{A_p}{A_0} \right] \quad (29.15)$$

where A_0 is the area of the bearing based on allowable normal stress under the vertical load.

The final value of K_p obtained during design of the lead plug is used in these expressions to find K_h . This contribution (K_h) towards combined stiffness (K_p) controls the design of the laminated rubber bearing. The steps from Step 3 onwards, described earlier in the design of high-damping rubber bearings, can be followed to design this laminated rubber bearing.

One additional check for the lead plug should be applied:

$$1.25 \leq \frac{h_p}{\phi_p} \leq 5.0$$

where h_p is effective height of the lead plug and ϕ_p is its diameter (Yang et al., 2003).

29.2.5.3 Design of Friction Pendulum System

The basic design variables in FPS are (1) the radius of curvature (R), (2) the material friction coefficient (μ), and (3) the plan dimension. The desired isolation period governs the radius of curvature, whereas the plan dimension is controlled by the design displacement. R for a known value of the design period of the isolated structure (T_1) can be computed using

$$R = g(T_1/2\pi)^2 \quad (29.16)$$

where g is acceleration due to gravity.

The coefficient of friction (μ), along with the displacement, controls the energy dissipation. The effective damping (β) for this system is given by expression

$$\beta = \frac{2}{\pi} \left(\frac{\mu}{\mu + D/R} \right) \quad (29.17)$$

The desired damping, depending upon the properties of the system, may vary from 10% to 20% of critical damping. As the design displacement (D) depends upon damping (β), it becomes a trial-and-error process and requires few iterations to get the values of β , μ , and D for desired response.

The effective stiffness of the isolation system at design displacement can be evaluated by

$$K_{\text{eff}} = \frac{W}{R} + \frac{\mu W}{D} \quad (29.18)$$

29.2.6 Verification of Properties of Isolation Systems

As they are the most critical part of the base-isolated structure, the quality of isolation bearings is of paramount importance. Looking into uncertainties in the manufacture, the deformation characteristics and damping values of the isolation system must be verified by tests. Therefore, the selected units of the isolation system have to undergo testing for examining quality control and determining their actual load–deformation behavior. Force–deformation characteristics of the isolation system obtained from tests are used for analyzing the base-isolated structures. These tests also serve as a means to verify the

ability of the isolation bearings to withstand long-term vertical loading and numerous cycles of shear displacement during design basis and maximum capable earthquake. The primary function of an isolation system is called on during major earthquakes only and, for most of its design life, it is subjected to nonseismic loads. Therefore its behavior for such loads should also be verified by tests.

29.2.6.1 Tests for Isolation Systems

System characterization tests, prototype tests, and quality control tests are the three levels of tests that are recommended for an isolation system. The first tests provide the fundamental characteristics of the isolation system; the second allow one to know the design parameters of the isolation system fabricated for the project; and the third verify the quality control and consistency achieved in manufacturing. These tests are briefly discussed in the following sections (Taylor et al., 1995).

29.2.6.1.1 System Characterization Tests

These tests are performed to evaluate the basic characteristics of the isolation systems, especially its dependence on temperature, frequency, bilateral loading, wear and fatigue, and so on. The tests are also intended to provide the ultimate and reserve capacity of a device for various loading conditions. These tests are conducted only once for a system of a given design, material, and construction. However, they should be repeated if there are major changes. These tests are formally not required by codes; however, in practice, they are conducted for a new isolation system and the test results provide some idea about the suitability of the isolation system for a particular project.

29.2.6.1.2 Prototype Tests

These tests are conducted to verify the design properties of an isolation system prior to its construction. Effective stiffness, energy dissipation capacity, stability of hysteretic behavior (in a check for system degradation), and stability at maximum seismic displacement are the properties generally verified through these tests. The stability of an isolation system is verified for maximum and minimum vertical load conditions. Tests are also carried out for nonseismic loads. In the case of isolation systems for buildings, the major nonseismic force is wind load, and for bridges it may be thermal displacements and braking or centrifugal forces. If the isolation system is frequency-dependent, then prototype tests should be performed dynamically for a range of frequency that represents full-scale prototype loading rates. Similarly, if the behavior of the isolation system is significantly different for unilateral and bilateral loadings, then the isolation system should be tested for different combinations of displacements in two orthogonal directions. Specimens in these tests are subjected to extreme conditions and therefore are not to be used for construction.

29.2.6.1.3 Quality Control Tests

These tests are carried out to verify the quality and consistency of the manufacturing process, and to measure the as-built properties of the isolation system prior to installation. The quality control tests are divided into *production tests* and *completed unit tests*. Production tests are carried out on materials or components that are used in the making of the isolation unit. In the case of elastomeric bearings, the elastomer is tested for hardness, tensile strength and elongation at break, bond strength, compression set, low-temperature properties, high-temperature aging, and ozone resistance. Elements used for a sliding system are supposed to be tested for surface roughness, trueness of surface, interface material properties, bearing pad attachment, and sliding interface attachment. All completed units are tested for (1) sustained compression, and (2) combined compression and shear. The purpose of the sustained compression test is to verify (1) the quality of the bond between the elastomer and the steel for laminated elastomeric bearings and (2) the bond between the bearing liner and the metal backing plate for sliding bearings. A combined compression and shear test is conducted to verify that actual values of effective stiffness and damping are in close agreement with design values. After quality control testing, laminated elastomeric bearings are visually inspected for rubber-to-steel bond, surface cracks, laminate placement, and permanent deformation, while sliding bearings should be inspected for bearing liner-to-metal bond,

scoring of the stainless steel plate, leakage, and permanent deformation. In the case that the bearings do not meet the requirements, they should be rejected.

29.2.6.2 Uniform Building Code Recommendations

Uniform Building Code (UBC, 1997) recommends that the deformation characteristics and damping values of the isolation system used in the design and analysis of seismic-isolated structures is based on the sequence of cyclic loading tests of a selected sample of the components (Figure 29.21). First, the specimen is tested under a cyclic load corresponding to the design wind load. Subsequently, it is tested, for a prescribed number of cycles, with cyclic displacements varying from one

FIGURE 29.21 Schematic diagram for cyclic loading test of bearing.

fifth of the design displacement to the total maximum design displacement. Vertical load (dead load plus 50% of the live load) for all the above tests is prescribed as the average load on all isolators of common type and size. If an isolator unit is also a vertical load-carrying element, the cyclic load tests should be performed for maximum and minimum vertical loads, which includes the effects of an earthquake overturning evaluated corresponding to the test displacement.

29.2.6.2.1 Units Dependent on Loading Rates

If there is greater than 10% difference in effective stiffness values at the design displacement (i) obtained by performing test on an isolator unit at a frequency equal to the inverse of the effective period T_1 of the isolated structure, and (ii) obtained by performing test on the same unit at any frequency in the range of 0.1 to 2.0 times the inverse of T_1 , then the force–deflection properties of the isolator unit are considered to be dependent on rate of loading. In such cases, the tests are prescribed to be performed at a frequency equal to the inverse of T_1 .

29.2.6.2.2 Units Dependent on Bilateral Load

If the bilateral and unilateral force–deflection properties have greater than a $\pm 10\%$ difference in effective stiffness at the design displacement, the force–deflection properties of an isolator unit are considered to be dependent on bilateral load. In such cases, the tests specified above shall be augmented to include bilateral load increments of the total design displacement 0.25 and 1.0, 0.50 and 1.0, 0.75 and 1.0, and 1.0 and 1.0.

29.2.6.2.3 System Adequacy

The performance of the test specimens is assessed as adequate if the following conditions are satisfied:

1. The load–displacement curves for all tests have a positive incremental load-carrying capacity.
2. The difference between the average values of effective stiffness of the two test specimens of a common type and size does not exceed the prescribed value of 10%.
3. The effective stiffness of each test specimen for each cycle of test is within $\pm 10\%$ of the average value of effective stiffness for the specimen.
4. There is no greater than a 20% change in the initial effective stiffness of each test specimen over the prescribed number of cycles.
5. There is no greater than a 20% decrease in the initial effective damping of each test specimen over the prescribed number of cycles.
6. All specimens of vertical load-carrying elements remain stable at the total maximum displacement for the prescribed vertical load.

29.2.7 Analysis of Base-Isolated Structures

Depending upon the code requirements, one can choose the static or dynamic analysis procedure for a particular project. Regarding the static analysis method, codes generally have some bindings, whereas time-history analysis can be used for all types of situations. In UBC (1997), minimum values of some design parameters to be used in dynamic analysis are defined in terms of percentage of values obtained by static analysis and thus most of the steps of static analysis are necessary for a designer, even if the dynamic analysis procedure is followed. These analysis methods require the modeling of the base-isolation system and the superstructure. In most of the cases, the linear model for the superstructure of a base-isolated building is enough. However, the isolation systems generally require nonlinear model.

29.2.7.1 Modeling of a Superstructure

The superstructure of a base-isolated *building* can be modeled as rigid blocks, a two-dimensional and a three-dimensional linear model, or nonlinear models. The rigid block assumption is the simplest one, which is used in the design of isolation system, for preliminary analysis and feasibility studies. Moreover, it can also be used as a tool to crosscheck the results obtained from other rigorous analysis methods. Assuming the superstructure as a single-degree-of-freedom (single-DoF) model and the isolation system as linear spring plus linear viscous damper, Kelly (1990) developed linear theory for a base-isolated structure (Figure 29.22). In general, an isolation system aims at providing significant protection not only to the building but also to nonstructural components and contents. Therefore, a three-dimensional linear model for the superstructure is generally sufficient for analyzing a base-isolated structure. However, for the situations when the response to extreme earthquakes must be investigated, nonlinear models for superstructure should be used.

In case of the analysis of seismically isolated *bridges*, it may be important to take into account the pier masses and their own modes of vibration. The pier can be modeled using a linear beam element with mass, and the deck can be modeled with linear beams with mass. However, for very squat piers, the shear flexibility should also be considered. In the case of a regular structure, the coupling effect of the deck can be neglected, and a bend can be considered independent of the others. However, if a stiff deck is supported on piers of different flexibility, the structure should be modeled as a linear multi-DoF system. To ascertain the response for extreme loading conditions, the piers should be modeled with nonlinear models; however, the deck can still be simulated with linear elements. In such cases, proper account should be made for change in the effective stiffness of piers due to cracks (Priestley et al., 1996). In the case of *equipment*, the modeling depends upon the level of protection; however, the rigid block assumption for equipment generally suffices. *Liquid storage containers* should be modeled with proper consideration to the sloshing affect of liquid during base motion.

29.2.7.2 Modeling of Isolation System

The isolation system can be modeled as a linear or nonlinear element. The linear model of an isolation system consists of effective stiffness and effective damping at the design displacement. These values are derived from force–displacement test data for the isolation system. However, except in preliminary designs, the isolation system is generally modeled as nonlinear. Commonly used isolation systems, namely, high-damping rubber bearings, lead rubber bearings, friction bearings, and FPSs, can be modeled by bilinear model (Figure 29.23). However, for more precise results, the isolation elements should be modeled by their actual force–displacement behavior, for example, in the modeling of

FIGURE 29.22 A two-DoF model of base-isolated building. (Source: Kelly, J.M. *Earthquake Spectra*, 6(2), 223–244, 1990. With permission.)

high-damping rubber bearings, which in extreme conditions follow a trilinear model with stiffening at larger strains. The model used for analysis should be verified with force–displacement characteristics obtained by prescribed tests, discussed in Section 29.2.6. Moreover, the isolation system should be modeled with considerations for the following requirements (UBC, 1997):

1. Account for the spatial distribution of isolator units.
2. Calculate translation, in both horizontal directions, and the torsion of the structure above the isolation interface, considering the most disadvantageous location of mass eccentricity.
3. Assess overturning or uplift forces on individual isolator units.
4. Account for the effects of vertical load, bilateral load, and/or the rate of loading if the force–deflection properties of the isolation system are dependent on one or more of these attributes.

FIGURE 29.23 Analytical models for isolators: (a) pure friction system; (b) friction pendulum system.

29.2.7.3 Static Analysis Procedure

This procedure may be sufficient for analyzing a base-isolated structure that satisfies certain code requirements related to the height of a building, soil conditions, geometry of a structure, effective period of base-isolated building, force–deflection, and restoring-force characteristics of the isolation system, and so on. The procedure involves the use of simple expressions for computing design displacements (D) and lateral forces. Using the response spectrum or code formula, the design displacement is computed for a target period of the isolation system, its effective damping, and site conditions. Since time period and effective damping itself depends on design displacement, it becomes an iterative procedure. Appropriate values of damping and the target time period can be assumed for the first iteration. Force–displacement data for the isolation system, obtained from tests, is used to determine effective stiffness (k_{eff}) and damping at design displacement.

The design lateral seismic force for the isolation system and structural elements at or below the isolation system is simply evaluated as

$$V_b = k_{\text{eff}} D \quad (29.19)$$

Total lateral force for the structure above the isolation system is given by

$$V_s = \frac{k_{\text{eff}} D}{R_1} \quad (29.20)$$

The factor R_1 is based on the type of lateral force resisting system used for the structure above the isolation level.

The value of V_s is not to be taken as less than the following (UBC, 1997):

1. The lateral seismic force required for a fixed-base structure of the same weight, W , and a period equal to the isolated period
2. The base shear corresponding to the design wind load
3. One and a half times the lateral seismic force required to fully activate the isolation system

The total lateral force shall be distributed over the height of the structure in accordance with the formula

$$F_x = \frac{W_x h_x}{\sum_{i=1}^n W_i h_i} V_s \quad (29.21)$$

where W_x is weight at level x and h_x is the distance of level x from the base. F_x , the lateral force at level x , is applied over the area of the building at that level in accordance with the mass distribution. The maximum

displacement of the isolation system is calculated in the most critical direction and for maximum capable earthquake. The total design and maximum displacement of the elements of the isolation system should include the additional displacement due to actual and accidental torsion, calculated by taking into account the spatial distribution of the lateral stiffness of the isolation system and the most disadvantageous location of mass eccentricity.

29.2.7.4 Dynamic Analysis Procedure

The method involves response spectrum or time-history analysis, and is essential when, owing to code requirements, it is not possible to use the static analysis procedure alone. However, for the situations when (1) the structure above isolation system may reach the nonlinear range for the design earthquake motion, (2) the soil is soft or site conditions require site specific evaluation, or (3) the isolation system does not meet certain prescribed code criteria, even the use of the response spectrum method is not sufficient and the time-history analysis procedure becomes essential.

29.2.7.4.1 Response Spectrum Method

This method of analysis is very convenient for the laminated rubber bearing-type isolation system. A design spectrum is constructed for the design basis and the maximum capable earthquake. Total design displacement of the isolation system and the lateral forces and displacements of the isolated structure are computed for the design basis earthquake. Maximum displacement of the isolation system should be obtained for the maximum capable earthquake. In this method of analysis, damping for fundamental mode in the direction of interest is generally restricted to the effective damping of the isolation system or 30% of the critical damping, whichever is less. Damping for higher modes is consistent with those appropriate for the response spectrum analysis of similar fixed-base structure. To take into account the effect of bidirectional excitation, the total maximum displacement includes simultaneous excitation of the model by 100% of the most critical direction of the ground, and not less than 30% of the ground in the orthogonal direction (UBC, 1997). The maximum displacement of the isolation system is calculated as the vector sum of the two orthogonal displacements. The total lateral force shall be distributed over the height of the structure in accordance with Equation 29.21.

29.2.7.4.2 Time-History Analysis

This method of analysis can be used for base-isolated structures under all types of situation. The method is necessary for conditions where (1) isolation systems have a sliding system, (2) the structure is founded on very soft soil, (3) the isolation system allows low displacement, or (4) the force–displacement behavior of the isolation system depends on (a) the rate of loading, (b) the vertical load, or (c) the bilateral load. Appropriate horizontal ground motion time histories are selected, and their magnitudes, fault distances, and source mechanism should be consistent with those that control the design basis (or the maximum capable) earthquake. Where appropriate recorded ground motion time-history pairs are not available, appropriate simulated ground motion time-history pairs may be used. Each pair of time histories is applied simultaneously to the model, considering the most disadvantageous location of mass eccentricity. The maximum displacement of the isolation system is calculated from the vectorial sum of the two orthogonal displacements at each time step.

29.2.7.5 Software for Analysis

The need for an isolation system that is stiff under low levels of frequently occurring loads but flexible under higher levels necessarily leads to a nonlinear system. The force–displacement behavior of most of the isolators can be modeled as bilinear. However, in the case of high-damping rubber bearings, in extreme conditions, a trilinear model with stiffening at large shear strains better represents the behavior. These nonlinear force–displacement relationships of the bearings need the use of specialized computer programs to analyze base-isolated structures. The program should be capable of analyzing base-isolated

buildings with isolator models made of combination of discrete nonlinear elements and superstructure models that are fully elastic or that permit some localized nonlinear behavior.

Several programs are available for this purpose. The computer code NPAD has plasticity-based nonlinear elements that can be used to model certain types of elastomeric bearings. The program simulates the superstructure using a three-DoF per floor model and can analyze base-isolated structures with linear superstructure (Tospelas et al., 1994). The justification behind the approach of considering superstructure as linear is that seismic base isolation is generally provided to reduce the force transmitted to the superstructure to the point where it can be assumed to remain elastic. The computer program SADSAP has the capability to analyze three-dimensional structures with localized nonlinearities. The nonlinear elements available in the software can be combined to simulate the behavior of various types of isolation systems. The program may also be useful in analyzing base-isolated buildings with nonlinear bracing elements provided for supplemental damping (Kelly, 1997). Some general-purpose programs such as the DRAIN series and ANSR have the capability of nonlinear analysis of two- and three-dimensional structures and have provisions that can be used to simulate seismic isolators, which exhibit bilinear behavior (Tospelas et al., 1994). Some commonly used finite element analysis software such as ABAQUS, ANSYS, and COSMOS also have the capability for analyzing complex superstructures on nonlinear isolators (Kelly, 1997). However, sliding bearings cannot be modeled precisely with these programs.

SAP2000 (2002) can be used to analyze these structures and also has the facility to model friction bearings. The 3D-BASIS group of programs is a group of special purpose programs developed for nonlinear dynamic analysis of three-dimensional base-isolated structures, and has been used for the analysis of many base-isolated structures (Constantinou, 1994). The programs assume that the superstructure is elastic and the isolation system is nonlinear. Models used for modeling the isolation elements can also capture precisely frictional behavior. It is not possible to account for stiffening of laminated rubber bearings at higher strain levels using the programs discussed above. The program LPM (lumped parameter model), originally developed for nonlinear three-dimensional analysis of masonry structures, has the capability to model this stiffening and at the same time can also incorporate a nonlinear element in the superstructure (Kelly, 1997).

29.2.8 Experimental Methods for Isolated Structures

Although analytical simulation has progressed tremendously through the use of powerful computers utilizing accumulated theoretical and experimental data on structures, it is not yet possible to analyze and predict the inelastic response of base-isolated structures with total confidence. The responses of base-isolated structures are very much dependent on the characteristics of the input earthquake motion, isolation system, and the supported structures. Experimental tests have been used to verify and calibrate mathematical models, as well as to provide data for the design of structures. However, extensive tests are needed to study the complex behavior of base-isolated structures under realistic conditions that are likely to occur during earthquakes. Different test methods such as quasistatic testing, shaking table testing, online hybrid testing, and substructured online testing have been proposed. A typical problem that appears when performing quasistatic tests on an isolated structure is the alteration of the restoring forces due to strain-rate effect existing for this material. This problem does not exist for shaking table tests performed at the real-size and real-time scale. Shaking table tests of base-isolated specimens have been used successfully for investigating the behavior. However, it requires a large-capacity table for testing a full-scale specimen. The involvement of high cost for large-size shaking tables and the limited capacity of available shaking tables necessitate the structure to be drastically scaled down. This scaling of a structure presents some limitations for the extrapolation of the results to the real scale.

As a promising option, the online hybrid test method seems to be well suited for obtaining the seismic response of isolated structures thanks to available quasistatic loading equipment and high-speed computers. However, this technique involves the fabrication of a complete structural prototype

FIGURE 29.24 Substructured hybrid testing for seismically isolated structures. (Source: Tanzo, W. et al. Res. Rpt. 92-ST-01, Kyoto Univ., 1992. With permission.)

for proper modeling. Thus, test models must be simplified, for example, into a single-DoF model, and/or specimens have to be reduced in scale.

By incorporating substructure concepts into the online hybrid test technique, a substructured online hybrid test method can be used, in which a complete system is considered to be divided into analytical substructures and experimental substructures (Tanzo et al., 1992). In the case of seismically isolated structures, inelastic deformations are designed to occur only in isolation system. The isolation system, which is generally difficult to model mathematically, is taken as experimental substructures (Figure 29.24). The remaining part of the structure is taken as analytical substructures in which presently available analytical models are used to describe their restoring-force characteristics. For the experimental substructure, restoring-force information is directly measured from a specimen loaded according to its current deformation state. The substructured online hybrid test procedure for the earthquake response of base-isolated structure is explained in Figure 29.25.

29.2.9 Implementation of Seismic Isolation

29.2.9.1 New Construction

29.2.9.1.1 Buildings

In the early stages of the development of seismic isolation, the main target of the earthquake-resistant design of the structure was the prevention of collapse. However, later, other additional considerations, such as the value of structure or its content, have exerted their importance on the seismic design of structures. For example, facilities of postearthquake importance such as fire stations, police stations, hospitals, communication centers, and so on, have a critical role and are required to remain operational immediately after a major seismic event. Similar reasoning applies to museums housing unique artifacts or buildings that are architecturally important. The required low level of structural and nonstructural damage may be achieved by using an isolation system, which limits structural deformations and ductility demands to low values. The isolation system can be provided at different levels. However, while deciding the isolation level, considerations should be given for (1) the seismic gap, (2) the continuity of supply lines, stairways, and elevators, and (3) details of cladding below the isolation level. In addition, provisions for (1) access to bearings for inspection and replacement, (2) backup system for vertical loads, and (3) full diaphragm for the uniform distribution of lateral load to individual bearings also need to be considered. Figure 29.26 shows typical positions for bearings in buildings (Mayes and Naeim, 2001).

The first building constructed using modern isolation bearings was a government facility, the William Clayton Building in Wellington, New Zealand, which was completed in 1981. After that, a number of seismically isolated buildings have been constructed there, and in most of them the isolation system used is lead rubber bearings. The most widespread use of seismic isolation systems is in Japan. The first seismically isolated structure to be completed in Japan was the Yachiyodai Residential Dwelling, a two-story building completed in 1982. Better performance of seismically isolated buildings during the

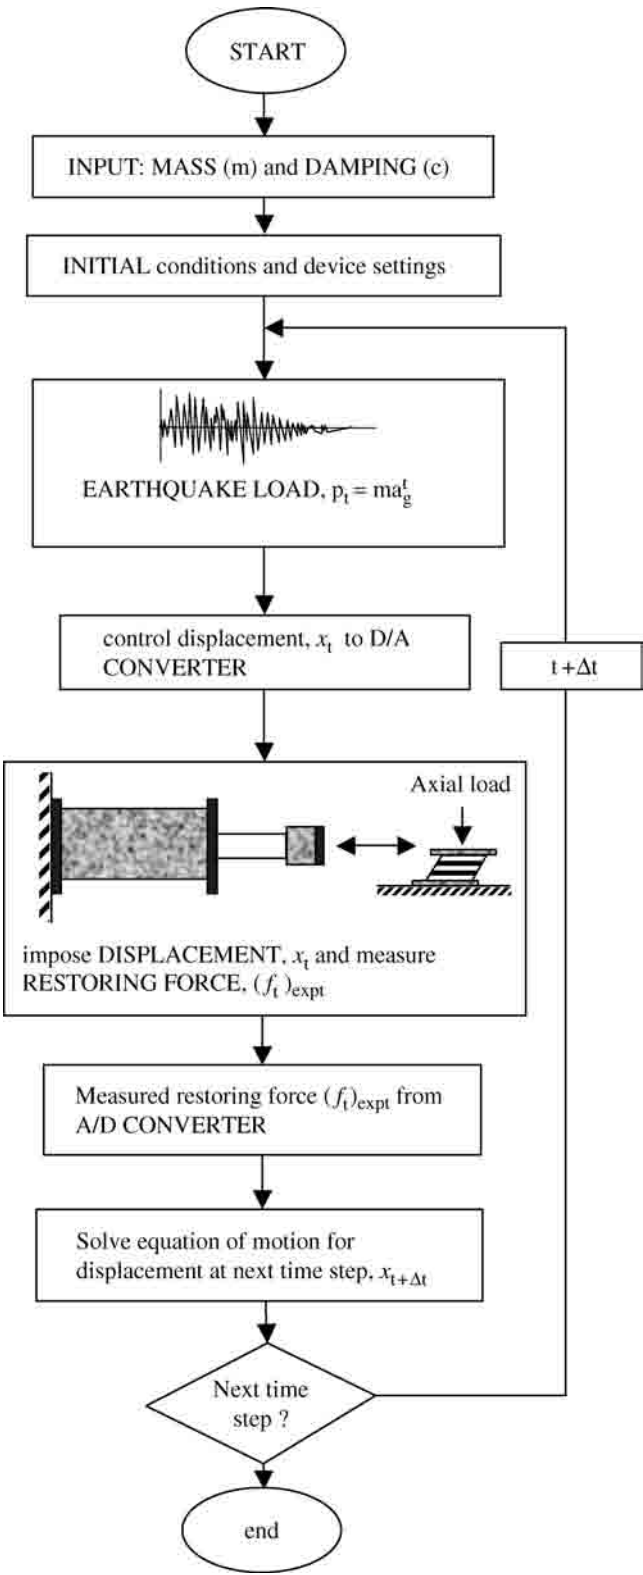

FIGURE 29.25 Procedure for substructured online test method for a base-isolated structure. (Source: Tanzo, W. et al. Res. Rpt. 92-ST-01, Kyoto Univ., 1992. With permission.)

Kobe earthquake of 1995 triggered the rapid increase in number of seismic isolation projects. Before the Kobe earthquake, the number of such buildings in Japan was 82; this suddenly increased to about 650 within 4 years of the earthquake. Besides rubber bearings, there have been some applications of frictional sliding systems also for seismic isolation of buildings (Nishitani, 2000). The first newly constructed base-isolated building in the United States was the Foothill Communities Law and Justice Center in California, which was completed in 1986. Until 1990 there were four isolated buildings. After the good performance of base-isolated buildings during the Northridge earthquake, the number increased and, at the end of 1998, there were approximately 40 isolated buildings completed or in construction in the United States (Clark et al., 2000). Some buildings in other countries, including Italy, France, Canada, Mexico, China, England, Russia, Armenia, Indonesia, Iran, Chile, and India, now use these systems. Until now, the emphasis on base-isolation applications has mostly been for structures with sensitive and expensive contents or high-risk structures like nuclear power plants and computer centers. However, there is an increasing interest in applying this technology to public housing and schools in developing countries (Fuller and Muhr, 1995). Most of the base-isolation projects have made use of laminated rubber bearings and lead rubber bearings. In Japan, laminated rubber bearings are often used with energy-dissipating devices, both with and without provision for recentering.

29.2.9.1.2 Bridges

In most cases, bridges are strategic structures and require a higher degree of protection to ensure their functionality after a seismic event. For many simple bridges, it has been found that seismic isolation of the superstructure gives improved seismic resistance, often at a reduced cost, while it is also effective for thermal expansion of the superstructure (Skinner et al., 1993). The aim of seismically isolating bridge superstructures is usually to protect the piers and their foundations, and sometimes to protect the abutments also. With this approach, bearings are placed between the superstructure and the top of the substructure (the piers and abutments). Under normal conditions, they behave like regular thermal bearings. However, in the event of a strong earthquake, they add flexibility to the structure by elongating its period and dissipating energy. In addition, most of the mass of a bridge is concentrated at the deck level, which is inherently strong and can be assumed to be rigid. This permits the superstructure to oscillate at a lower frequency than its piers, which results in the reduction or elimination of deformation of the substructure components beyond their elastic range, particularly at locations that are difficult to inspect or repair (e.g., the piles). Superstructure isolation systems are designed, as far as is practical, to provide moderate flexibility, high damping, torsional balance, and an appropriate distribution of seismic loads between the superstructure supports.

Isolated bridges in the United States are generally designed for the effects of a design-basis earthquake; however, the components of the isolation system are provided with increased displacement capacity and are tested for the effects of maximum capable earthquake. This design philosophy is based on observations of bridge failures in past earthquakes, which were primarily due to excessive bearing displacement and the loss of bearing support rather than the collapse of substructure. Providing for strong restoring force in this design philosophy prevents the accumulation of significant permanent displacements and allows for a relatively reliable estimation of peak bearing displacement and substructure force.

Isolation systems adopted by Italian engineers restrict the transmission of force to elements of the substructure to a predetermined level, which is independent of seismic action. Thus, the Italian engineers chose to limit the force transmitted to the substructure to a desired level, at the expense, however, of large variation in peak bearing displacements and the development of permanent displacements. In Japan, *men shin* (reduction of response) design is followed for the design of bridges. Although *men shin* design is closely related to the seismic isolation design, the natural period of a bridge is not forcibly elongated in this method, because there are various restrictions in increasing the natural period. Instead of elongating the period, the emphasis in the *men shin* design is on increasing the energy-dissipating capability and distribution of lateral forces to as many substructures as possible in order to decrease the lateral forces for the design of substructures (Iemura, 1994a, 1994b). It is common to restrain the transverse displacement of bridge isolators, and therefore many bridges in Japan are isolated in longitudinal direction only.

The application of seismic isolation for bridges started in the early 1970s. Bridges isolated in New Zealand before 1978 used metallic dampers for seismic isolation. Later, lead rubber bearings replaced the metallic dampers for their seismic isolation. Italian engineers also started the application of modern technology of seismic isolation for bridges in the mid-1970s and now have a long list of isolated bridges. The first seismically isolated bridge in Japan was the Hokuso line viaduct in Chiba Prefecture. The viaduct was completed in 1990 and used lead rubber bearings for its isolation system. The United States also obtained its first seismically isolated new bridge in 1990, when two bridges, namely, Sexton Creek Bridge in Illinois and Toll Plaza Road Bridge in Pennsylvania, were completed. Lead rubber bearings were used as the isolation system for both the bridges (Skinner et al., 1993).

29.2.9.2 Seismic Retrofit

Postearthquake analysis of recent earthquakes around the world shows that the damage was especially concentrated in the buildings and bridge structures that were not designed for earthquake loads or were designed by following the old seismic design guidelines. Moreover, a significant proportion of the damage was due to nonstructural elements and the contents housed in the buildings (Kelly, 1997). In order to prevent the recurrence of damage in such seismically deficient structures, it is vital to understand their vulnerability and retrofit them for expected future seismic events. In the case of important structures, retrofit techniques are required to provide a solution that can also lead to continued functioning during and after major earthquakes, protection of nonstructural components and contents, and, sometimes, to preserve their historic character.

29.2.9.2.1 Buildings

Conventional retrofitting has been the most common way of enhancing the performance of existing, seismically deficient structures. However, to maintain the usability of important structures after a big earthquake and to protect the valuable contents housed in the buildings, conventional methods can help a little. Simple strengthening or stiffening of a structure through reducing inelastic response displacement, however, may increase the response acceleration and the forces. Some of the other demerits of this approach are (i) the large amount of labor required to increase the strength and ductility of critical sections distributed throughout the complex structural system and (ii) damage may occur due to inelastic behavior of structural elements during a major seismic event (Iemura and Adachi, 2003). Besides this, conventional methods of retrofitting often require restricting the use of the building during the retrofit. Some buildings, housing important activities, cannot afford to have their routine usage stopped and therefore require retrofitting through an earthquake-resistance system that enables continued building use even during the retrofit operation.

Seismic isolation has proved to be very effective not only in enhancing the safety of existing seismically deficient buildings, but also to preserve the function and protect the contents. Unlike the conventional approach, this retrofit method aims to reduce the earthquake force to a level lower than the strength of the existing structure (Figure 29.27). Seismic isolation is the method that can mitigate both interstory drift and high-floor accelerations simultaneously, and it has been used in retrofitting of important buildings, buildings housing valuable contents, and structures of postearthquake importance.

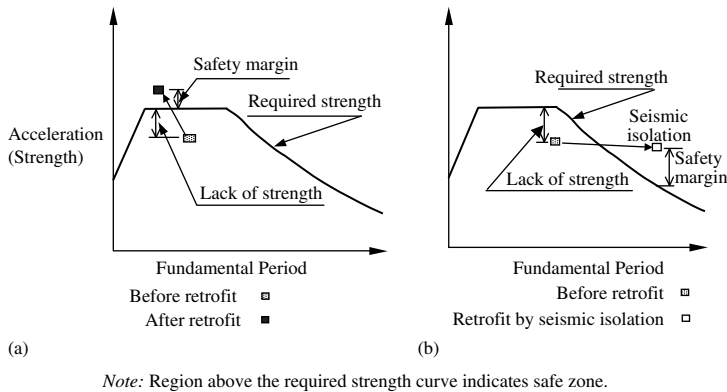

FIGURE 29.27 Concept of retrofitting methods: (a) conventional; (b) seismic isolation. (Source: Sugano, S., *Proc. XII World Conf. on Earthquake Engineering*, 2000. With permission.)

Moreover, as the modification or demolition of building features is minimized, the method has found application in many monuments of historical importance, protecting them from future earthquakes (Buckle, 1995). Recently, the old masonry Chapel of Rikkyo (St Paul's) University, Tokyo, constructed in 1920, was retrofitted with seismic isolation to preserve this historical asset to the university (Seki et al., 2000). Retrofitting using seismic isolation of the 72-year-old Clock Tower, a symbol of Kyoto University, Japan, is presently underway (Ogura et al., 2003).

The seismic isolation method is found to be more appropriate for the retrofitting of seismically vulnerable buildings that are required to function even during retrofit operation. To meet such a demand, the retrofitting method should affect minimum alterations to the existing structures and should produce a low level of noise and vibration. The technique has successfully been applied to a number of such buildings. In the retrofitting of Rankine Brown Building of Victoria University, Wellington, New Zealand, which houses the main library and administration of the university, one of the main requirements was the building's uninterrupted usage during the retrofit operation (Robinson, 2003). Meeting a similar challenge, the government office of Toshima Ward, in Tokyo, has been retrofitted with rubber and sliding isolators below the existing foundation and was used as usual by the officials and citizens even during the retrofit works. Similarly, a building of Nihon University in Tokyo, Japan, in which seismic isolation was applied at the top of the columns of basement floor, was available for research and education during the retrofit operation (Kawamura et al., 2000).

Although seismic isolation reduces earthquake forces, it does not eliminate them. Consequently, the strength and ductility of an existing structure must at least be sufficient to resist the reduced earthquake forces that remain even after isolation. Further, the requirement of space for the seismic gap and provisions for services, elevators, and so on to follow large displacements at isolation level are some issues that need prior attention. Although not applicable to all structures and all site conditions, seismic isolation still has great potential to reduce the risk in existing buildings and bridges that are not capable of resisting expected future earthquakes. This method, in the beginning, was used generally for preservation of cultural assets, but now has many applications in the retrofitting of other buildings also.

29.2.9.2.2 Bridges

A large number of old bridges were constructed with little or no consideration for seismic requirements. Some of them have been retrofitted, mostly by conventional methods. However, the remaining bridges are waiting for the enhancement of their strength to meet the latest code requirements. In existing bridges, bearings have generally been provided to accommodate longitudinal thermal movements between the superstructure and the supports. Therefore, little structural modification is required to use seismic isolation as a retrofit method. A common structural configuration, a continuous deck supported

on bearings at the tops of piers, attracts the option of seismic upgrading of existing bridge structures by seismic isolation and is often practical and relatively inexpensive. Seismic isolation has been used for the retrofitting of number of bridges in New Zealand. During the early period of its application in the United States, seismic isolation was mainly used for the retrofitting of bridges and the isolation system used was mainly lead rubber bearings (Skinner et al., 1993).

However, to replace an existing bearing with an isolation bearing, enough space is required between the deck and pier top. All the jacks used for replacing the bearings should be driven by the same hydraulic pump and raised at the same time to prevent stressing any cross members between girders. The dampers can be connected to the substructure using heavy-duty mechanical or chemical anchorages, with the other end bolted to the girders. Since an earthquake can shift a bridge in any direction, universal joints are recommended on each end of the damping device to prevent the shaft from being bent during movements other than axial ones. The damper should be set to the bridge in its midstroke position or a position that takes full advantage of the free movements (Hippley, 1997).

In situations where rigid connection of footing and piers has made the bearing capacity of existing piles inadequate for the new seismic requirements, seismic isolation bearings can be used at the base of columns. Sometimes, it may be costly to retrofit a seismically deficient pier and foundation by conventional methods due to submerged conditions that may require construction of cofferdams. In such cases, seismic isolation can reduce the demand on the seismically deficient piers by redistributing the force and transferring it to the abutments, which are significantly less expensive to retrofit. Seismic retrofits are intended to bring bridges up to reasonable earthquake standards; however, in some old bridges, the retrofit method is also required to have the least effect possible on the historic appearance and seismic isolation is the appropriate alternative for this requirement.

29.2.9.3 Other Implementations

Apart from in buildings and bridges, seismic isolation has found application in other structures. It has been used for a number of reactor units in France for which the site safe shutdown earthquake acceleration was $0.2g$. An isolation system of neoprene pads with topping of lead-bronze alloy limits the acceleration to a value of $0.2g$. A similar system was used for reactor units in Koeberg, South Africa, where the site safe shutdown earthquake acceleration was $0.3g$ (Tajiran, 1998). Seismic isolation has a lot of potential for the protection of sensitive equipment that can malfunction when the acceleration reaches beyond its allowable limit. Communication centers, hospitals, computer centers, and other facilities housing such sensitive equipment can use seismic isolation to remain functional even after a major seismic event. Proposed systems for the seismic isolation of sensitive equipment are to (1) base isolate the entire building or a portion of the building, (2) isolate essential flooring systems only (raised floors), and (3) isolate individual pieces of equipment by placing them on separate isolation bearing systems (see Figure 29.28). In Japan, there are many buildings that are using the raised floor system to protect computers and other sensitive equipment. Seismic isolation is found to be very useful for semiconductor facilities, in which cost of the delicate items is as high as 75% of the total investment (Amick et al., 1998). Liquid storage tanks are important components of chemical factories and are also used in increasing

number to store liquefied natural gas. The FPS was applied for seismic isolation of a large-size tank in Greece, and steel–rubber bearings were used for another tank in Korea, storing liquefied natural gas (Tajiran, 1998).

Seismic base isolation can also be used for the seismic protection of antique pieces. Iemura and coworkers designed a special seismic isolation system to protect a wooden carved statue of Moroku Bosatsu (Maitreya). It is an antique cultural artifact, considered to be the first wooden carved statue in Japan. The isolation system provides protection in all three directions (Figure 29.29). The details of the isolation system are provided in Table 29.2.

The overall size of the isolation system is shown in Figure 29.30. The shaking table test was also carried out to verify the effectiveness of the isolation system. Results of the experiment are presented in Table 29.3 and clearly show that the isolation system is very effective in reducing the accelerations.

FIGURE 29.30 Overall size of the three-dimensional base-isolation system.

29.2.10 Performance during Past Earthquakes

Analytical models and experimental tools have been developed by researchers to simulate the behavior of a structure under earthquake motion. However, none of these methods can validate the behavior of a structure as does a real earthquake. In fact, many of the concepts of earthquake-resistant design are

TABLE 29.3 Results of Shaking Table Tests of a Three-Dimensional Base Isolation System

the outcome of the analysis of observations made or recorded during past earthquakes. In the case of base isolation, as it is a relatively newer approach, it can help to assess the modeling techniques, existing analysis and design procedures, and methods followed in construction. Such analyses may help in evaluating the effectiveness of base isolation and also exposing weak aspects of designs. Strong motion-recording instrument networks have been installed on some of the base-isolated structures in different parts of the world in order to record the response of those structures during earthquakes. During the Northridge, Kobe, and Turkey earthquakes, a few base-isolated structures had their isolation system reaching nonlinear range, and the recorded performance of these structures can give a fair idea of the behavior of base-isolated structures during strong earthquake motions.

29.2.10.1 Performance of Buildings

The Northridge earthquake of January 1994 saw thousands of conventionally designed buildings and their contents suffer extensive damage and be closed for several days. However, two base-isolated buildings, namely, University of Southern California Hospital building and Fire Command and Control Facility, performed well during the earthquake. During the event, the seven-story base-isolated hospital building experienced a peak ground acceleration of 0.37g. The recorded peak acceleration at the roof was 0.21g. Analytical study showed that presence of the isolation system reduced the peak story shear at the base to about one third of that if the building had its base fixed (Nagarajaiah et al., 1996). “Workers in a large supply room within the hospital reported no disruption of supplies, or material falling off shelves, as a result of the earthquake. In contrast a pharmacy at the ground level in an adjacent medical building with fixed-base reported substantial disruption of the supplies” (EERI, 1996). The two-story base-isolated Fire Command and Control Facility could not perform as per expectation due to minor negligence in detailing the seismic gap. The building is base-isolated by high-damping rubber bearings and experienced peak ground acceleration of 0.19g. The recorded response shows the presence of sharp acceleration spikes that were due to pounding. However, the analytical study by Nagarajaiah et al. (2001) shows that, even with pounding, maximum base story shear of the base-isolated building was half that of the fixed-base case and without pounding it would have been one fourth.

In January 1995, the unexpected earthquake of magnitude 7.2 in Kobe shocked the engineering community. The 7 sec of strong shaking caused a heavy loss of life (over 5000 people died) and a catastrophic loss to infrastructure. The strong earthquake tested two existing base-isolated buildings in the region, namely, the six-story building of West Japan Postal Savings Computer Center (WJPSCC) and the three-story building of Technical Research Institute of Matsumura Gumi Corporation (TRIMGS). The six-story WJPSCC building that is base-isolated with elastomeric isolators, lead rubber bearings, and steel coil dampers experienced peak ground acceleration of 0.306g. A nearby six-story fixed-base building experienced peak ground acceleration of 0.27g. However, during the event, the maximum acceleration recorded at the roof of the fixed-base building was about nine times of that recorded at the roof of the WJPSCC building. Similarly, a

comparison of the roof acceleration of the three-story base-isolated TRIMGS building with that of a nearby three-story fixed-base building reveals that, due to base isolation, the peak accelerations at the roof were reduced by a factor of approximately 4.9 in the north–south direction and 2.5 in the east–west direction. It was later realized that the performance of this base-isolated building might be adversely affected due to freezing cold, when the rubber has a tendency to become stiffer (Izawa et al., 1996).

29.2.10.2 Performance of Bridges

In the year 1999, Turkey faced two major earthquakes, the first one on 17th August and the second on 12th November. At the time of the events, there were two base-isolated structures in the region, namely, Bolu Viaduct and Bolu Bridge. The structures were designed for a peak ground acceleration of 0.4g with isolation system comprising of a friction system and crescent moon-type hysteretic elements. During the earthquake of August 17, 1999, when the estimated ground acceleration at the Bolu viaduct site was 0.39g in the longitudinal direction and 0.31g in the transverse direction, the viaduct survived without any damage. The residual displacement was of the order of 1 mm only. However, the second event produced near-fault, or rather on-fault, pulse-type motion with a peak ground acceleration at the viaduct site in the order of 1.0g. The unexpected level of ground acceleration caused heavy damage to the viaduct. It was reported that the sliding bearings fell down from most of the piers before any cyclic movement. This performance again raised the issue of feasibility of base isolation for such near-fault pulse-type motions. During the same event, Bolu Bridge experienced the estimated peak ground motion of 0.65g, much higher than the design value. However, the only significant damage suffered by the bridge was the failure of some elements of the expansion joints because they were designed for a movement of 100 mm only (corresponding to the earthquake with a return period of 50 years). After the earthquake, the bridge showed a residual displacement in longitudinal direction of 45 mm and in transversal direction varying from 60 to 100 mm (Marioni).

The Eel River Bridge (U.S.), after being retrofitted with lead laminated rubber bearings, was hit by the magnitude 7.0 Cape Mendocino (Petrolia) earthquake in the year 1992. The peak ground acceleration recorded at a nearby recording station was 0.55g. The bridge suffered structural damage limited to the spalling of concrete at joints. Another base-isolated bridge, Sierra Point overpass (U.S.), was subjected to the 1989 Loma Prieta earthquake when peak ground acceleration at the base of bridge columns was 0.090g. The bridge, first constructed in 1956, was later retrofitted with lead rubber bearings in 1985. However, the abutments were not modified for the larger clearance required in isolation. This design weakness was exposed during the Loma Prieta earthquake and caused significant amplification in the steel superstructure of the bridge. However, no damage was sustained (Lee et al., 2001). Rangitaiki River Bridge at Te Teko, New Zealand, with lead rubber bearings on each pier and plain rubber bearings on abutments, suffered minor damage and a small permanent displacement during the 1987 Bay of Plenty earthquake. The peak acceleration, recorded at about 11 km from the bridge site was 0.33g. It was observed that owing to the inadequate fastening details for the isolators, one of the two bearings on abutment was dislocated (McKay et al., 1990). Bai-Ho bridge (Taiwan), a three-span, continuous nonprismatic prestressed concrete girder bridge, was subjected to the magnitude 6.0 Gia-I earthquake in year 1999. The bridge is seismically isolated in its longitudinal direction with lead rubber bearings; however, shear keys and specially designed steel rods are installed on both abutments to restrict the transverse movement of the superstructure. The peak acceleration recorded on the deck in longitudinal direction was slightly higher than that in the foundation while, owing to restraints, the peak acceleration in the transverse direction was 2.5 times than that of foundation (Lee et al., 2001). During the Kobe earthquake, the base-isolated Matsunohama Bridge had good recorded performance; however, the ground acceleration was not profound enough to test the effectiveness of the isolation system (Izawa et al., 1996).

In summary, analysis of the records obtained from a variety of base-isolated structures during real earthquakes presents some very interesting facts. In general, it was observed that, during strong earthquakes, numerous conventionally designed buildings suffered damage and remained closed for several days; however, the base-isolated buildings in the same region not only survived but continued to operate. On the other hand, in some cases, strong earthquakes exposed the lack of attention to minor construction details and the effectiveness of base isolation for near-fault earthquakes. Better performance of base-isolated structures during the Northridge and Kobe earthquakes have now persuaded the structural engineers and owners and triggered a rapid increase in the number of base-isolated buildings. In Japan alone, the number of buildings of this kind constructed during 1995 was almost the same as that of those constructed during the period from 1985 to 1994.

29.3 Seismic Vibration Control

29.3.1 Historical Development of Seismic Vibration Control

It is worth noting that a structural vibration control system for reducing seismic responses was developed several centuries ago in Japan, by an unknown engineer. This was applied to the construction of a Gojunoto (pagoda). The Gojunoto was five stories tall and was constructed of closely fitting mortised wooden beams and columns (Figure 29.31). During an earthquake, the vibrations of such a vertical cantilever structure would produce bending moments that could not be resisted by tension at the mortised joints. To overcome this weakness, a long wooden pole was suspended freely from the upper part of the pagoda so that it could undergo pendular vibrations if the pagoda was excited into motion by an earthquake. The weight of the pole exerted a compressive prestress on the pagoda, thus increasing the bending resistance. The bottom of the pole extended into a cylindrical hole in the ground that was of a larger diameter than the pole. Thus, when the pagoda was excited into vibrations by an earthquake, some of the vibrational energy would be transferred into oscillations of the pole and the impact of the pole on the sides of the hole would dissipate energy.

In 1969, Gupta and Chandrasekaran (1969) studied the effectiveness of a number of tuned mass dampers (TMDs) put in a single-DoF system to reduce seismic responses. The TMD system has both linear and elasto-plastic restoring-force characteristics and viscous-type damping. The study was shown in the Fourth World Conference on Earthquake Engineering (WCEE) in Santiago, Chile. In the Fifth WCEE in 1973, Skinner et al. (1973) presented their studies on energy absorption devices for earthquake-resistant structures. The devices were based on the plastic deformation of mild steel. In 1977, Ohno et al. (1977) introduced optimum tuning of the dynamic damper for civil structures under earthquake

FIGURE 29.31 Sketch of a wooden pagoda with suspended pole that is free to undergo pendular vibration. (Source: Tanabashi, R., *Proc. II World Conf. on Earthquake Engineering*, 1960. With permission.)

excitations. Skinner et al. (1977) showed their works on studying hysteretic dampers for increasing structural earthquake resistance, and Tyler (1978) demonstrated the usefulness of flexural yielding of steel plate energy-dissipation devices in New Zealand.

In the seventh WCEE in 1980, Sladek and Klingner (1980) reported their studies on tuned-mass dampers for seismic response reduction in civil structures, whereas Keightley (1980) presented his work on a dry friction damper for multistory structures. Figure 29.32 shows the schematic of a framed structure with additional friction dampers and the hysteretic loop of the damper.

In 1984, Pall (1984) numerically studied the performance of a framed building equipped with friction devices. The performance was found to be superior to that of a conventional building. Scholl (1984) introduced brace dampers. The stiffness and damping of the damper can be set to alter the stiffness and damping in a structure. It was typically installed at the cross points in braced-frame structure systems. Liu et al. (1984) investigated the effectiveness of an active mass-damper control system for controlling coupled lateral-torsional motions of tall buildings subjected to strong earthquakes.

A special themed session named “Seismic response control of structural systems” was held at the Ninth WCEE in 1988. Some studies on passive systems were reported such as: a hysteretic damper that is put between two adjacent structures (Kobori et al., 1988); a multiple passive TMD (Clark, 1988); viscoelastic materials (Bergman and Hanson, 1988); viscous damping walls (Arima et al., 1988); and magnetic damping (Shimosaka et al., 1988). Also, some studies on active control were reported, such as an experimental study on active mass dampers (Aizawa et al., 1988) and air injection for suppressing sloshing in a liquid tank (Hara and Saito, 1988; Sogabe et al., 1988). Since then, the active vibration control of buildings and other civil structures has attracted a worldwide growing interest as an innovative technology in earthquake engineering.

During the Tenth WCEE in 1992, more thorough studies on structural control were reported such as: predictive control of structures with reduced number of sensors and actuators (Lopez-Almansa et al., 1992); applicability of vibration control to nonlinear structure (Shimada et al., 1992); full-scale implementation of active control (Soong et al., 1992); effects of soil-structure interaction (SSI) on actively controlled structure (Wong and Luco, 1992); the time-delay problem (Hou and Iwan, 1992); and fuzzy logic control (Tani et al., 1992). In this conference, the decision to form an international association and to hold a world conference dedicated to structural control was made. The International Association for Structural Control (IASC) was formed in 1993. The efforts led to the successful First World Conference on Structural Control in 1994 in Pasadena, California (IASC, 1994).

It was followed by the Second World Conference on Structural Control in 1998, which was held in Kyoto, Japan (IASC, 1999). The Third World Conference on Structural Control was held in April 2002, in Como, Italy (IASC, 2003). The conferences showed increasing interest among researchers and an increase of innovations and applications of structural control technologies in civil structures.

29.3.2 Basic Principles

Structural vibration control basically involves the regulation of structural properties in order to achieve structural a desirable response to a given external load and modification of the excitation. The regulation of structural properties includes the modification of mass, damping, and stiffness of the structure so that

FIGURE 29.32 (a) Friction dampers in a framed structure; (b) hysteretic loop of the damper. (Source: Keightley, W.O. *Proc. VII World Conf. on Earthquake Engineering*, 1980. With permission.)

it can respond more favorably to the external excitation. Moreover, it is also possible to reduce the level of excitation transmitted to the structure. Structural control can be defined as a mechanical system that is installed in a structure to reduce structural vibrations during loadings such as strong earthquakes.

29.3.2.1 Passive Control System

The basic function of a passive control system is to absorb or consume a portion of the input energy, thereby reducing energy-dissipation demand on primary structural members and minimizing the possible structural damage. In the passive system, controlling forces develop at the locations of installation of the mechanism itself. The energy necessary for generation of these forces is provided through the motion of the mechanism during the dynamic excitation. The relative motion of the mechanism defines the amplitude and the direction of the controlling force. Passive control has four main advantages: (1) it is usually relatively inexpensive; (2) it consumes no external energy (energy may not be available during a major earthquake); (3) it is inherently stable; and (4) it works even during a major earthquake.

In the passive system area, structural response control can be divided into two groups. The first group uses supplemental damping to reduce structural responses by conversion of kinetic energy to heat. The second group uses supplemental oscillators to reduce the structural response by transferring energy among vibration modes. The first group includes devices that operate on principles such as frictional sliding, the yielding of metals, phase transformation in metals, deformation of viscoelastic solids or fluids, and fluid orificing. The second group includes dynamic vibration absorbers such as TMDs and tuned liquid dampers.

The major difference between viscous/viscoelastic devices and friction/yielding devices is the maximum force that each device will develop during an earthquake. The maximum earthquake forces developed in viscous/viscoelastic devices are determined by the maximum displacements and velocities across these devices. The maximum earthquake forces in a friction/yielding device equals the design friction force/design yield force plus strain hardening. Thus, the maximum earthquake forces are more easily controlled in the friction/yielding devices.

The effect of increasing damping in a structure can be appreciated by studying the earthquake response spectrum. The earthquake response spectrum of a quantity is a plot of the peak value of the response quantity as a function of the natural vibration period of the system. Each such plot is for single-DoF system having a fixed damping ratio, and several such plots for different values of damping ratio are included to cover the range of damping values. The most commonly used spectra in earthquake engineering are the absolute acceleration response spectrum, the velocity response spectrum, and the displacement response spectrum. For more information on how to develop earthquake response spectrum, readers are referred to Chopra (1995).

Figure 29.33 shows the response spectra of measured ground acceleration during the Kobe, Japan, earthquake on January 17, 1995. The ground acceleration north–south (NS) component was recorded at the Kobe Marine Meteorological Observatory in Chuo-ku. As is shown in the figure, increasing the damping ratio from 5 to 30% decreases the response spectra. Therefore, on a level of ordinary structure that has 5% of damping, the response can be reduced further by increasing the structural damping. In the area of passive systems, a variety of mechanical energy dissipaters to increase structural damping has been developed and tested in the laboratory and, in some cases, in actual structural applications, such as bracing systems, friction dampers, viscoelastic dampers, and other mechanical dampers.

The principle of the TMD dates back to the 1940s when Den Hartog (1947) reintroduced the dynamic absorber invented by Frahm in 1909. Figure 29.34 shows the principle of the TMD. A large system under alternating force $P_0 \sin \omega t$ is represented by a K – M system where K and M are the stiffness and the mass of the system, respectively. The vibration absorber consists of a comparatively small vibratory system with stiffness k and mass m . The natural frequency, $\sqrt{k/m}$, of the attached absorber is chosen to be equal to the frequency, ω , of the disturbing force. It has been shown (Den Hartog, 1947) that the main mass, M , does not vibrate at all and that the small system, k – m , vibrates in such a way that its spring force is at all instants equal and opposite to $P_0 \sin \omega t$. Thus, there is no net force acting on M and therefore that mass

FIGURE 29.33 Effect of damping on earthquake response spectra.

does not vibrate

$$\omega_M = \sqrt{\frac{K}{M}}, \quad \omega_m = \sqrt{\frac{k}{m}}, \quad \mu = \frac{m}{M} \quad (29.22)$$

It is useful to introduce the new notations, above. Assume that $\mu = 0.2$, and $\omega_M = \omega_m$. For this condition, the resonance curve of the system is illustrated in Figure 29.35. At $\omega = \omega_m$ or $\omega/\omega_m = 1$, the motion of the main mass ceases altogether (Chopra, 1995). Since the system has two DoF, two resonant frequencies exist and the response is unbounded at those frequencies.

If the exciting frequency, ω , is close to the natural frequency, ω_m , of the attached absorber, and the operating restrictions make it possible to vary either one, the vibration absorber can be used to reduce the response amplitude of the main system to near zero. It is worth noting that the larger the attached absorber mass, m , the smaller the absorber displacement, $(x_2 - x_1)$, relative to the displacement of main mass, M . However, a large absorber mass presents a practical problem. At the same time, the smaller is the mass, m , the narrower is the operating frequency range of the absorber (Chopra, 1995).

29.3.2.2 Active Control System

Active control systems are used to control the response of structures to internal or external excitation, such as machinery or traffic noise, wind, or earthquakes, where the safety or comfort level of the

FIGURE 29.34 Additional vibratory k – m system to a larger K – M system to reduce vibration of the larger system.

occupants is of concern. Active control makes use of a wide variety of actuators, which may employ hydraulic, pneumatic, electromagnetic, or motor-driven ball-screw actuation. An essential feature of active control is that external power is used to effect the control action. This makes the system vulnerable to power failure, which is always a possibility during a strong earthquake.

For the actuators properly to apply the desired forces, sensors are placed in the structure in order to measure structural response. The sensors convey response information to a central computer that then uses this information to calculate the desired actuator forces. The advantage of an active control system is that it attains excellent control results. However, there are many drawbacks to using the active control system. It is relatively expensive to design and to operate due to the large amount of power needed. It has the potential to destabilize the structural system. Furthermore, it tends to take up more space than passive control devices.

A fully active structural control system has the basic configuration as shown schematically in Figure 29.36. The structural control system in the figure basically consists of sensors, controllers, and actuators. Sensors are used to measure either external excitations or structural responses, or both. Controllers process the measured information and compute necessary control forces needed based on a given control algorithm. Actuators are used to produce the required forces and are usually powered by external energy sources.

According to the characteristics of the controlling effects, active control can be classified into two categories: open-loop control and closed-loop control. A control system in which the control input is applied without the knowledge of the plant output is called an open-loop control system. Figure 29.37 shows a block diagram of an open-loop control system, where the subsystems (controller and plant) are shown as rectangular blocks. Open-loop control will be successful only if the controller has a reasonably good prior knowledge of the behavior of the plant, which can be defined as the relationship between the control input and the plant output. Mathematically, the relationship between the output of a linear plant and the control input can be described by a transfer function. However, in actuality, the presence of plant behavior uncertainty is unavoidable. Therefore, it is clear that an open-loop control system is unlikely to be successful.

In the case that the controller adjusts the control input according to the actual observed output, the system is called a closed-loop system. In this system, the control input is a function of the plant's output. Since in a closed-loop system the controller is constantly in touch with the actual output, it is likely to succeed in achieving the desired output even in the presence of uncertainty in the linear plant's behavior (the transfer function). The mechanism by which the information about the actual output is conveyed to the controller is called feedback. On a block diagram, the path from the plant output to the controller is called a feedback loop. A block diagram of a possible closed-loop system is given in Figure 29.38.

FIGURE 29.35 Resonance curve for the system in Figure 29.34 that shows response amplitude vs. exciting frequency (the dashed curve indicates negative x_2 or phase opposite to excitation) for $\mu = 0.2$ and $\omega_M = \omega_m$. FIGURE 29.36 Schematic diagram of active control system.

FIGURE 29.37 An open-loop control system; the controller applies control input without knowing the plant output.

FIGURE 29.38 Example of a closed-loop control system with feedback; the controller applies a control input based on the plant output.

When the desired output is a constant, the resulting controller is called a regulator. If the desired output changes with time, the corresponding control system is called a tracking system. In any case, the principal task of a closed-loop controller is to minimize the “error” as quickly as possible.

29.3.2.3 Semiactive Control System

Semiactive control falls between passive and active on the control spectrum. A semiactive control system is similar to an active system in that the system uses sensors and controllers, and operates on external power. However, the source of external energy is used only for adjustment of the mechanical characteristics of the system (Rakicevic and Jurukovski, 2001). The inherent benefit of a semiactive control device is that the mechanism used does not require large amounts of external power. Many semiactive devices can be powered by batteries protecting them from sudden power loss during earthquakes. Semiactive control systems are basically derived from passive systems; they are modified in such a way that they enable adjustment or correction of their mechanical characteristics.

A typical strategy for a semiactive control system is that an “ideal” actively controlled device is first assumed and appropriate primary controller designs for this device are designed. Then, a secondary controller is used that clips the optimal control force so it is dissipative in a manner consistent with the physical nature of the device. This strategy has been widely used (e.g., Dyke et al., 1996a, 1996b, Jung et al., 2001).

Spencer and Sain (1997) found that many active control systems for civil engineering applications operate primarily to modify structural damping. They claimed that preliminary studies indicate that appropriately implemented semiactive systems perform significantly better than passive devices and have the potential to achieve the majority of the performance of fully active systems, thus allowing for the possibility of effective response reduction during a wide array of dynamic loading conditions. In other words, semiactive control devices offer the adaptability of active control devices without requiring the associated large power sources (Spencer and Sain, 1997).

Moreover, according to presently accepted definitions (Housner et al., 1997), a semiactive control device is one that cannot inject mechanical energy into the controlled structural system (including the structure and the control device), but has properties that can be controlled optimally to reduce the responses of the system. Therefore, in contrast to active control devices, semiactive control devices do not have the potential to destabilize (in the bounded input/bounded output sense) the structural system. Semiactive control devices are often viewed as controllable passive devices.

Semiactive control technologies have recently been widely investigated in terms of the reduction of the dynamic response of structures subjected to earthquake and wind excitations (Housner et al., 1997; Spencer et al., 1997; Patten, 1998; Kurata et al., 1999; He et al., 2001; Iemura et al., 2001; Jung et al., 2001). Various semiactive devices have been proposed that utilize forces generated by surface friction or viscous fluids to dissipate vibratory energy in a structural system.

29.3.2.4 Hybrid Control System

The common usage of the term “hybrid control” implies the combined use of active and passive control systems. For example, this may be a structure equipped with distributed viscoelastic damping

supplemented with an active mass damper on the top of the structure, or a base-isolated structure with actuators actively controlled to enhance performance. The method, which consists of using both passive and active devices, should utilize the merits of both passive and active methods and avoid the demerits of these methods. Thus, higher levels of performance should be achievable. Additionally, the resulting hybrid control system can be more reliable than a fully active system because, should the active control malfunction, the minimum seismic protection of the structure can be done by the passive control.

29.3.2.5 Categorization of Basic Principles

From the above group of structural control systems, there are basically five principles concerning earthquake-induced structural response control that are important to consider. They are listed below:

1. Cutting off the input energy from the earthquake ground motion; examples:
 - (a) Floating structures
 - (b) Frictional structures
2. Isolating the natural frequencies of the structures from the predominant seismic power components; examples:
 - (a) Base-isolated structures
 - (b) Long period structures
3. Providing nonlinear structural characteristics and establishing a nonstationary state nonresonant system; examples:
 - (a) Inelastic structures
 - (b) Varying stiffness and damping structures
4. Utilizing energy absorption mechanism; examples:
 - (a) Viscous damper
 - (b) Viscoelastic damper
 - (c) Inelastic behavior
5. Supplying control force to suppress the structural response; examples:
 - (a) Active mass damper
 - (b) Active tendon
 - (c) Joint damper

29.3.3 Important Issues in Vibration Control

29.3.3.1 Soil–Structure Interaction

Seismic vibration control of a civil structure deals with methods to suppress the response in a structure subjected to earthquake excitation. To control the structural dynamic response, the structural system model must be known. Modeling of a structure is relatively straightforward, using a finite number of DoF, because the dimensions of the structure are finite. However, in general, civil structures are supported on surrounding soil from which the tremor excites the structure. This makes the structure interact with the surrounding soil. Therefore, it is very important to include SSI for controlling the seismic response.

SSI will result in a structural response that may be quite different from the structural response computed for a fixed-base building. The frequency of vibration of the structure may be lower because of the interaction. The change in frequency may also affect the response of the overall structure or its substructures or components. Moreover, soils are notoriously nonlinear when subjected to strong ground motions at the level of engineering interest (Marshall, 2001). Damping of the final system increases because of the radiation of energy of the propagating waves away from the structure (Wolf, 1985).

29.3.3.2 Device–Structure Interaction and Time Delay

Other important effects come from the device–structure dynamic interaction. Dyke et al. (1995) studied the role of control–structure interaction in mitigating dynamic response. Their findings show that accounting for control–structure interaction and actuator dynamics in the design process can improve the performance and robustness of a control system.

Time delay between control command and actual control force also causes problems. A study by Hou and Iwan (1992) showed the problems of time delay in the vibration control of structures. Also, Agrawal and Yang (2000) claimed that applications of unsynchronized control forces due to time delay may result in a degradation of the control performance, and it may even render the controlled structure unstable. Therefore, they provide a state-of-the-art review for available methods of time-delay compensation.

29.3.3.3 Design Guidelines

Since structural control is a new concept in civil structures, design guidelines are now being developed to provide the design engineers with tools for the safe design or seismic rehabilitation of structures. For a passive control system, the American Society of Civil Engineers has prepared for the Federal Emergency Management Agency a “Prestandard and Commentary for the Seismic Rehabilitation of Buildings” (ASCE, 2000), in which requirements for the systematic rehabilitation of buildings using energy-dissipation systems is set forth. In the standard, analysis and design criteria for passive energy dissipation systems are provided.

In this prestandard, two sections deal with structural control technology. First, is “Passive Energy Dissipation Systems,” which contains (1) General Requirements, (2) Implementation of Energy Dissipation Devices, (2) Modeling of Energy Dissipation Devices, (3) Linear Procedures, (4) Nonlinear Procedures, (5) Detailed Systems Requirements, (G) Design Review, and (H) Required Test of Energy Dissipation Devices. Each subsection is explained in detail in the prestandard for the users.

However, in the second section, “Other Response Control Systems,” it is mentioned that analysis and design of response control other than in the passive systems above shall be reviewed by an independent engineering review panel. This is because the technology of active, semiactive, and hybrid control is not sufficiently mature and the necessary hardware is not sufficiently robust to warrant the preparation of general guidelines for the implementation of the technology.

29.3.4 Vibration-Control Devices

29.3.4.1 Passive Control Systems

29.3.4.1.1 *Metallic Yielding Dampers*

One of the effective mechanisms useful for the dissipation of energy input to a structure from an earthquake is through the inelastic deformation of metals. The idea of utilizing added metallic energy dissipaters within a structure to absorb a large portion of the seismic energy began with the conceptual and experimental work of Kelly et al. (1972) and Skinner et al. (1975). Devices considered by them included torsional beams, flexural beams, and U-strip energy dissipaters as shown schematically in [Figure 29.39](#).

During the following years, considerable progress has been made in the development of metallic dampers. For example, many new designs have been proposed, including the hourglass or X-shaped and triangular plate dampers as shown in [Figure 29.40](#).

The X-shaped steel plates form devices called ADAS (Added Damping and Stiffness; see Perry et al., 1993), because the devices essentially add stiffness as well as damping to the element where they are installed. For example, if they are installed between two adjacent floors, then it will increase the stiffness and damping between those two floors. Increasing the stiffness will generally attract more seismic forces. However, since the devices have much lower yielding forces than the elements where they are installed, then the postyield stiffness of the devices is dominant during a strong earthquake.

FIGURE 29.39 Schematic of metallic dampers: (a) torsional beam and (b) U-strip, and the directions of alternating forces. (Source: Skinner, R.I. et al. *Earthquake Eng. Struct. Dyn.*, 3, 287–296, 1975. With permission.)

FIGURE 29.40 Schematic of (a) X-shaped (Source: Tsai, K.-C. et al. *Earthquake Spectra*, 9, 505–528, 1993. With permission.) and (b) triangular plate dampers, and the directions of alternating forces. (Source: Perry, C.L. et al. *Earthquake Spectra*, 9, 559–579, 1993. With permission.)

The devices dissipate energy through the flexural yielding deformation of mild steel plates. Each device consists of a series of steel plates arranged in parallel, with boundary elements at the top and bottom to establish end fixity, which bend in double-curvature flexure when subjected to lateral loading. The direction of the lateral loadings is shown in Figure 29.41. The plates are cut in an hour-glass shape to match the moment diagram and thus maximize the uniformity of plastification over the height of the steel plates.

Cyclic loading tests to determine the reliability of the ADAS were performed by Bergman and Goel (1987). The tests demonstrated that the devices maintained stable hysteretic properties, dissipated significant energy with no pinching or slip zones, and continued to have these properties until plate fracture at high strain or high numbers of cycles. The schematic hysteretic loop of ADAS

FIGURE 29.41 ADAS element: (a) lateral view; (b) longitudinal view with lateral forces; and (c) moment diagram over the height of the steel plates.

devices tested by Bergman and Goel (1987) is shown in Figure 29.42. It is worth noting that the apparent stiffening of the device in the figure is due to finite deformation, not strain hardening of the material; therefore, the effects of finite deformation should be included in the assessment of a design.

Tsai et al. (1993) have performed cyclic loading tests on TADAS (Triangular-plate ADAS; see Figure 29.40b). The hysteretic loops of the tested TADAS are similar to those of ADAS, such as the apparent stiffening at large displacement, since the mechanism is the same. Although the slotted pin connection at the apex reduces the axial tension force, some friction at the pin location contributes to the stiffening of hysteretic loops (Soong and Dargush, 1997).

29.3.4.1.2 Friction Dampers

Another excellent mechanism for energy dissipation is friction. The mechanism has been used for many years in automotive brakes to dissipate kinetic energy of motion. In friction dampers, stick-slip phenomena must be minimized to avoid introducing high-frequency excitation.

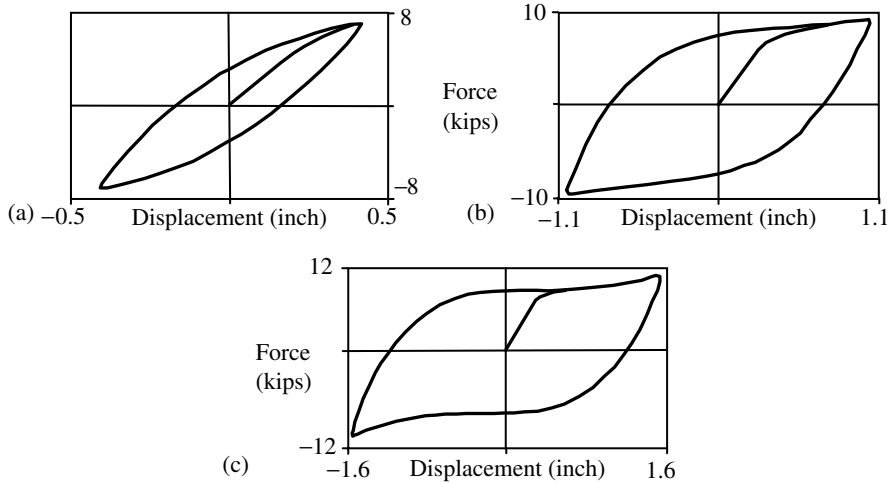

FIGURE 29.42 Schematic hysteresis loop of the ADAS device with maximum displacements of (a) 0.42 in. (10.7 mm); (b) 1.04 in. (26.4 mm); and (c) 1.56 in. (39.6 mm). (Source: Bergman, D. and Goel, S., Rpt. UMCE 87-10, Univ. Michigan, 1987. With permission.)

FIGURE 29.43 Pall friction damper: (a) set up in a structure; (b) schematic of the damper.

Furthermore, friction materials should have a consistent coefficient of friction over the intended life of the device (Housner et al., 1997).

The Pall device (Pall and Marsh, 1982) is one of the friction dampers that can be installed in a structure in an X-braced frame as illustrated in Figure 29.43. The mechanism of the damper is that, when there is axial tension force in the bracing system, as shown in the figure by outward arrows, then plates A and B are moving outward from each other. This movement is resisted by some friction force at the slip lap joint between plates A and B. This movement also causes plates C and D to move toward each other because of the existence of the links. This movement is also resisted by some frictional force between plates C and D. Without the existence of the links, the bracing may buckle because of axial compression force. The friction level between plates is designed so that the plates will not slip to each other during wind storms or moderate earthquakes. Under severe loading conditions, the devices slip in order to dissipate energy so that structural response can be reduced. The force–displacement relationship of Pall dampers has been studied extensively. A plot of its typical cyclic response is illustrated in Figure 29.44 (Filiatrault and Cherry, 1987).

FIGURE 29.44 Schematic of force–displacement hysteresis loop of the Pall friction damper. (Source: Filiatrault, A. and Cherry, S. *Earthquake Spectra*, 3, 57–78, 1987.)

29.3.4.1.3 Viscoelastic Dampers

The application of viscoelastic dampers to civil engineering structures seems to have begun in 1969, when approximately 10,000 viscoelastic dampers were installed in each of the twin towers of the late World Trade Center in New York to reduce wind-induced vibrations. An example of a viscoelastic damper is illustrated in Figure 29.45.

The damper consists of a viscoelastic material bonded to steel plates. The viscoelastic materials used in structural application are typically copolymers or glassy substances, which dissipate energy when subjected to shear deformation (Soong and Dargush, 1997). With induced structural vibration, the damper will absorb and dissipate the vibrational

FIGURE 29.45 Typical viscoelastic-damper configuration.

FIGURE 29.46 Typical schematic hysteresis loop of viscoelastic damper. (Source: Shen, K.L. and Soong, T.T. *J. Eng. Mech. ASCE*, 121, 694–701, 1995. With permission.)

energy by shearing deformation within the viscoelastic material. Heat will be generated in the viscoelastic material and released through the steel members of the damper.

A typical hysteresis loop produced by viscoelastic dampers is shown in Figure 29.46. By using viscoelastic dampers, although the structural response is elastic, hysteresis loops are formed because of the viscoelastic material. The area enclosed in the hysteresis loops is the energy dissipated by the viscoelastic dampers during one cycle of oscillation.

The behavior of viscoelastic materials under dynamic loading depends on vibrational frequency, strain, and ambient temperature. In general, the relationship between shear strain, $\gamma(t)$, and shear stress, $\tau(t)$, under harmonic shear strain with frequency, ω , can be expressed as (Zhang et al., 1989)

$$\tau(t) = G'(\omega)\gamma(t) + \frac{G''(\omega)}{\omega} \dot{\gamma}(t) \tag{29.23}$$

$G'(\omega)$ and $G''(\omega)$ are shear storage modulus and shear loss modulus of the viscoelastic material, respectively. The loss factor is defined by $\eta = G''(\omega)/G'(\omega)$. In general, as the vibrational frequency increases, the values of $G'(\omega)$ and $G''(\omega)$ become larger. However, if the ambient temperature increases, those values become smaller. Test results of a typical viscoelastic damper averaged over the first 20 cycles are shown in Table 29.4.

For a viscoelastic damper with shear area, A , and thickness, δ , the corresponding force–displacement relationship is

$$F(t) = k_d(\omega)X + c_d(\omega)\dot{X} \tag{29.24}$$

in which X and \dot{X} are the relative displacement and velocity of the damper, respectively, and

$$k_d(\omega) = \frac{AG'(\omega)}{\delta} \quad c_d(\omega) = \frac{AG''(\omega)}{\omega\delta} \tag{29.25}$$

TABLE 29.4 Typical Viscoelastic Damper Properties

Temperature (°C)	Frequency (Hz)	Strain (%)	k_d^a (lb/in.)	G' (psi)	G'' (psi)	η
24	1	5	2124	142	193	1.36

From the above equations, it is clear that a linear system with added viscoelastic dampers remains linear with the dampers contributing to increased viscous damping as well as stiffness. However, it needs to be pointed out that, for viscoelastic material at large strains, there is considerable self-heating due to the large amount of energy dissipated. The heat generated changes the mechanical properties of the material, and the overall behavior becomes nonlinear. This means that a linear analysis utilizing the above equations can only be for approximation of the response.

29.3.4.1.4 Viscous Fluid Dampers

The most convenient and common functional output equation for a damper comes from classical system theory, and is that of the so-called “linear” or “viscous” damping element

$$F(t) = c_d \dot{X}(t) \quad (29.26)$$

in which $F(t)$, c_d , and $\dot{X}(t)$ are the damping force, damping coefficient, and relative velocity across the damper, respectively.

In mechanical engineering, it is difficult to manufacture a useable fluid-filled component having a purely viscous output, because even moderate pressure hydraulic flows through a simple orifice follow a very different output equation, in which differential pressure varies with the fluid velocity squared. Therefore, the output of the basic hydraulic damping element is

$$F(t) = \text{sgn}(\dot{X}(t))c_d|\dot{X}(t)|^2 \quad (29.27)$$

As a result of long research in this area, which was started in the 1960s, the most useful dampers being used in buildings today are the so-called “low exponent” type, with an output equation of the form:

$$F(t) = \text{sgn}(\dot{X}(t))c_d|\dot{X}(t)|^\alpha \quad (29.28)$$

In most cases, α is an exponent having a specified value in the range of 0.3 to 1.0. Values of α that have proven to be the most popular are in the range of 0.4 to 0.5 for building designs with seismic input (Taylor, 2002).

The design elements of a fluid damper are relatively few. However, the detailing of these elements varies greatly. Typical elements for a fluid damper are shown in Figure 29.47. Typical experimentally measured force–displacement loops are shown in [Figure 29.48](#).

29.3.4.1.5 Tuned Mass Dampers

Much of the early development of dynamic vibration absorbers, as mentioned in Section 29.3.2.1, has been limited to the use of dynamic absorbers in mechanical engineering systems in which one operating frequency is in resonance with a machine’s fundamental frequency. However, building structures are subjected to earthquakes which possess many frequency components. The performance of a

FIGURE 29.47 Typical schematic of a fluid damper. (Source: Taylor, D.P. *Passive Structural Control Symp.*, 2002. With permission.)

dynamic vibration absorber, referred to as the TMD herein, in complex multi-DoF systems is expected to be different. Consider the resonance curve in Figure 29.49 of a system shown in Figure 29.34, but now with different parameters: $\mu = 0.05$, but still $\omega_M = \omega_m$ (see Equation 29.22 for the definition of these parameters). An additional parameter, the damping ratio of TMD, is shown in Equation 29.29. Where c is damping coefficient of a linear viscous damper installed between structural mass, M , and TMD mass, m ,

$$\zeta_{\text{TMD}} = \frac{c}{2m\omega_m} \quad (29.29)$$

When the damping ratio in the TMD equals zero, the response amplitude is infinite at the two resonant frequencies. When the damping ratio becomes infinite, the two masses are virtually stuck to each other; the result is a single-DoF system with mass, $1.05 (M)$ with the amplitude becoming infinite again at a resonant frequency (see Figure 29.49). Therefore, somewhere between these extremes, there must be a value of the TMD damping ratio for which the peak becomes a minimum. Therefore, the objective in adding the TMD herein is to bring the resonant peak of the amplitude to its lowest possible value so that smaller amplifications over a wider frequency bandwidth can be achieved.

There are many types of TMD for implementation and the following are some examples (Figure 29.50). An innovative challenge is highly expected in this field.

There is another type of TMD that uses liquid as the mass; this damper is called the tuned liquid damper (TLD). The TLD has been used in ships for controlling vibrations because of water waves. The TLD uses water or other liquid as the moving mass and the restoring force is generated by gravity. Energy absorption comes from boundaries between liquid and containers and turbulence in the liquid flow. The basic principle of the TLD in absorbing kinetic energy of the main structure is the same as the TMD. Figure 29.51 shows types of TLD. Favorable properties of TLD compared with TMD are as follows:

- Smooth movement in small vibration is possible because of no mechanical friction.
- It is reasonable in cost and maintenance because of no complex mechanism.
- It can be applied easily in two horizontal directions with a single TLD.
- It can be compact and portable if large numbers are used.

FIGURE 29.49 Resonance curve for the system in Figure 29.34 that shows response amplitude vs. exciting frequency for $\mu = 0.05$ and $\omega_M = \omega_m$.

FIGURE 29.48 Typical schematic of fluid damper hysteretic loops. (Source: Constantinou, M.C. and Symans, M.D. *Struct. Des. Tall Build.*, 2, 93–132, 1993. With permission.)

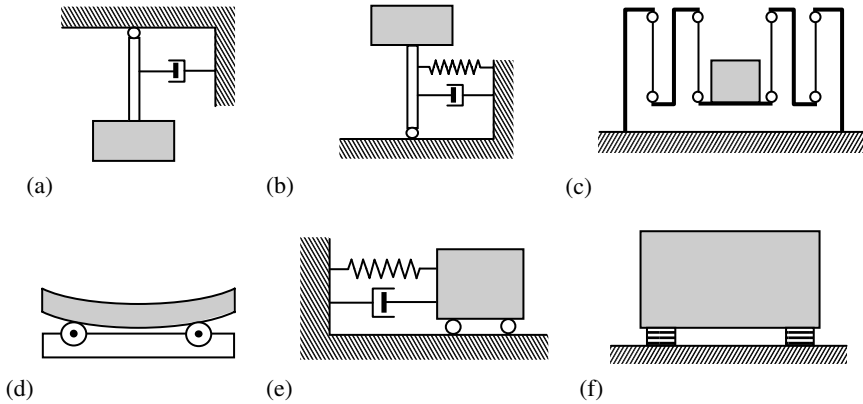

FIGURE 29.50 Examples of different types of TMD: (a) pendulum with damper; (b) inverted pendulum with spring and damper; (c) pendulum of which hangers are wound to save space; (d) swinging mass on rotational bearings; (e) sliding mass with spring and damper; (f) mass on rubber bearings. (Source: Iemura, H. *Passive and Active Vibration Control in Civil Engineering*, Springer, New York, 1994a,b. With permission.)

FIGURE 29.51 Types of TLD: (a) tuned sloshing damper with meshes and rods; (b) tuned liquid column damper with orifice. (Source: Iemura, H. *Passive and Active Vibration Control in Civil Engineering*, Springer, New York, 1994a,b. With permission.)

The TLD can be divided into two categories. First, is the sloshing damper as shown in Figure 29.51a. The vibration period is adjusted by the size of the container and the depth of the liquid. The damping capacity is increased by placing meshes or rods in the liquid. The second category is the tuned liquid column damper as shown in Figure 29.51b. The vibration period is adjusted by the shape of the column or the air pressure in the column. The damping capacity is increased by adjusting the orifice in the column, which generates a high turbulence.

29.3.4.2 Active Control System

29.3.4.2.1 Electromagnetic Actuator

An electromagnetic actuator is frequently employed where it is necessary to provide a mechanical force depending on an electric current. Figure 29.52 shows the elements of such a device. A magnetic structure supports a circuit of magnetic flux driven by the coil of N turns carrying current i , in ampere. Part of the magnetic circuit is a movable armature that slides smoothly on the support member. An air gap (or possibly a vacuum gap) of length d m is also in the magnetic circuit. Assume that d is small enough for the magnetic flux density to be essentially constant at B Wb/m² across the face of the armature. The cross-sectional area of the armature face is A m². A tractive force, F , in Newtons, developed on the face of the armature, is related to the area and field strength as

$$F = \frac{AB^2}{2\mu_0} \quad (29.30)$$

where μ_0 is the magnetic permeability of the air gap having a value of $4\pi \times 10^{-7}$ H/m (Henries/meter). The magnetic field intensity is proportional to the magnetomotive force $N \times i$ ampere turns. For an efficient magnetic structure, the magnetic flux density is

$$B = \frac{\mu_0}{d} N \times i \tag{29.31}$$

which, combined with Equation 29.30, gives a useful relationship:

$$F = \left[\frac{A \mu_0 N^2}{2} \right] \left(\frac{i^2}{d^2} \right) \text{ Newton} \tag{29.32}$$

Note that F is positive when i is either positive or negative. This means that the force, F , is always tractive if the current, I , is either positive or negative. The maximum value for magnetic flux density, B , which can be realized using modern magnetic materials in normal environments, is approximately 1 Wb/m² (Clark, 1996).

In most cases, it is necessary to apply force in both the positive and negative directions. In this case, the device is constructed with two air gaps having the corresponding traction forces opposed to one another, as shown in Figure 29.53.

It is interesting to observe how the net force, F , on the armature depends on z and Δi (differential current = $i_L - i_0 = i_R - i_0$; see Figure 29.53 for the parameters) when these are constants. The schematic plot of F vs. z , with Δi as a parameter, is shown in Figure 29.54. It is worth noting that the plot is nonlinear. It is also noted from the figure that, if z is positive, F is also positive. It means that the force developed on the armature due to a small displacement from the equilibrium position is in the direction to increase that small displacement. This characterizes a condition of static instability. Feedback control can be used to stabilize this inherently unstable device when such a device is used as an actuator.

29.3.4.2.2 Hydraulic Actuators

Hydraulic actuators can produce large forces even at large displacements, which is useful for seismic response-control applications. The actuator is usually driven using electrical signals. In other words, an electro-hydraulic device is used to convert the low-powered signals into high-powered hydraulic fluid flow. One example of such a device is an electro-hydraulic servo-valve. The schematic of such a device is shown in Figure 29.55.

FIGURE 29.52 Elements of an electromagnet. (Source: Clark, R.N. *Control System Dynamics*, Cambridge Univ. Press, U.K., 1996. With permission.)

FIGURE 29.53 Push-pull electromagnet. (Source: Clark, R.N. *Control System Dynamics*, Cambridge Univ. Press, U.K., 1996. With permission.)

FIGURE 29.54 Force vs. displacement of push-pull electromagnet with differential current as a parameter. (Source: Clark, R.N. *Control System Dynamics*, Cambridge Univ. Press, U.K., 1996. With permission.)

FIGURE 29.55 Schematic of servo-valve actuator. (Source: Clark, R.N. *Control System Dynamics*, Cambridge Univ. Press, U.K., 1996. With permission.)

The valve shown in the figure is a single-stage spool valve. The simple design shown in the figure exhibits the basic principles, inherent in most types of servo-valves, of conversion from electromagnetic to hydraulic energy; in other words, actuating force. By changing the electric signals going to the spool valve, the actuating force can be generated because the hydraulic pressure acting on the piston in one side is greater than the other side (see Figure 29.55). The actuating force can also be altered in real time, enabling real-time control of seismically excited structures.

29.3.4.3 Semiactive Control System

29.3.4.3.1 Variable-Orifice Hydraulic Dampers

A variable damping device used for the semiactive control method can be achieved by using a controllable, electro-mechanical, variable-orifice valve to alter the resistance to flow of a conventional hydraulic fluid damper. Figure 29.56 shows a schematic of such a device. The effectiveness of variable-orifice dampers in controlling seismically excited buildings has been demonstrated through both simulation and small scale experimental studies (Hrovat et al., 1983; Mizuno et al., 1992; Kurata et al., 1994; Patten et al., 1994; Sack et al., 1994; Liang et al., 1995; Niwa et al., 2000).

FIGURE 29.56 Schematic diagram of variable-orifice valve oil damper.

29.3.4.3.2 Controllable Fluid Dampers

Another class of semiactive devices use controllable fluids. The advantage of controllable fluid devices over controllable valve devices is that they contain no moving parts other than the piston. The essential characteristic of controllable fluids is their ability to change reversibly from a free-flowing, linear viscous fluid to a semisolid with a controllable yield strength in milliseconds, when exposed to an electric (for electro-rheological fluid) or magnetic (for magneto-rheological [MR] fluid) field (Housner et al., 1997).

MR fluids typically consist of micron-sized, magnetically polarizable particles dispersed in a carrier medium such as mineral or silicone oil. When a magnetic field is applied to the fluid, particle chains form and the fluid becomes a semisolid and exhibits viscoplastic characteristics. Transition to rheological equilibrium can be achieved in a few milliseconds. A schematic diagram of the controllable fluid damper is shown in Figure 29.57.

FIGURE 29.57 Schematic diagram of magnetorheological damper. (Source: Spencer, B.F. et al. *J. Eng. Mech.*, 123, 1997. With permission.)

29.3.4.3.3 Controllable Friction Dampers

Various controllable friction devices have been proposed to dissipate vibratory energy in a structural system. Akbay and Aktan (1990, 1991) and Kannan et al. (1995) proposed a variable-friction device in which the force at the frictional interface was adjusted by allowing slippage in controlled amounts. A similar device was also studied by Cherry (1994) and Dowdell and Cherry (1994a, 1994b).

A recent work by He et al. (2003) studied a semiactive electromagnetic friction damper (SAEMFD) for controlling seismic responses. Figure 29.58 shows a schematic diagram of the SAEMFD. The device consists of a friction pad

FIGURE 29.58 Schematic drawing of semiactive electro-magnetic friction damper. (Source: He, W.L. et al. *J. Struct. Eng.*, ASCE, 129, 941–950, 2003. With permission.)

sandwiched between two steel plates. These three layers are slot-bolted together so that sliding takes place between the steel plates and the friction pad. The friction force between steel plates and the friction pad depends on the coefficient of friction (μ) and the normal force $N(t)$. Two insulated solenoids are installed on the outer surfaces of the steel plates and the electric current in these solenoids is regulated such that an electromagnetic attractive force exists between the two solenoids. Hence, the normal force $N(t)$ between the steel plates is directly proportional to the square of the current in the solenoids.

29.3.4.4 Hybrid Control System

The hybrid control methods which consist of both passive and active devices have been proposed and implemented, utilizing the merits of both passive and active methods and avoiding the demerits of these methods. Thus, higher levels of performance may be achievable. Additionally, the resulting hybrid control system can be more reliable than a fully active system, although it is also often somewhat more complicated.

One example of a hybrid system is a TMD with actuators that is put between the TMD mass and its support so that the effectiveness of the TMD is increased by this technique. Figure 29.59 shows a schematic diagram of a passive TMD, an active AMD (active mass damper), and a hybrid ATMD (active TMD). Another example of hybrid control is a combination of base isolation with some form of active control to limit excessive displacement (Fujii et al., 1992; Kageyama, M. and Yasui, 1992; Feng et al., 1993; Reinhorn and Riley, 1994).

29.3.5 Control Algorithm

29.3.5.1 Active Control System

The most important part of active control is the algorithm, because the control forces are based on this. Research efforts in active structural control have been focused on a variety of control algorithms based

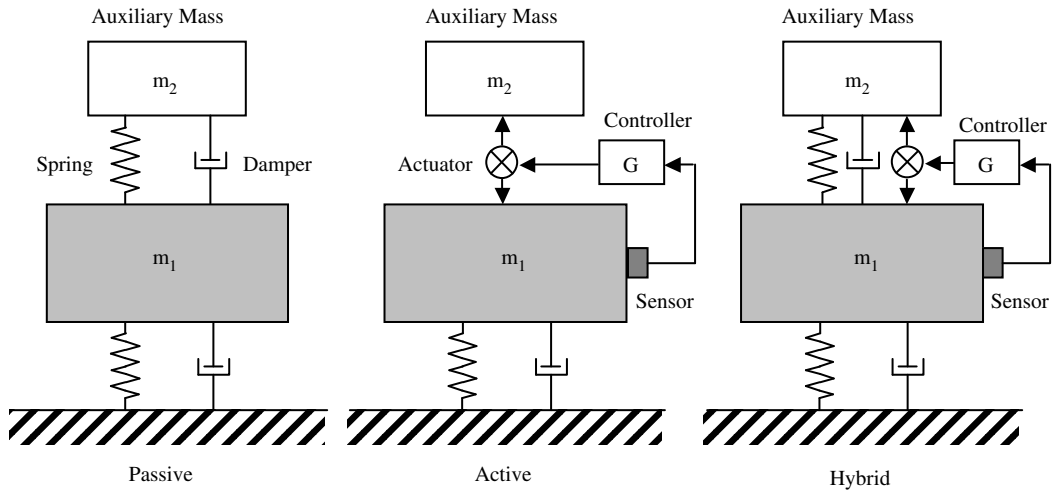

FIGURE 29.59 Schematic diagram of a passive, an active, and a hybrid mass damper system.

on several control design criteria. An example of a famous control algorithm is linear optimal control because all of the control design parameters can be determined for multiinput and multioutput systems. Also, the control allows us to formulate directly the performance objectives of a control system. The adjective optimal above means that a control system can be designed to meet the desired performance objectives with the smallest control energy, which is the energy associated with generating the control inputs. Such a control system that minimizes the cost associated with generating control inputs is called an optimal control system. The optimal control system directly addresses the desired performance objectives, while minimizing the control energy, by formulating an objective function that must be minimized in the design process.

If the transient energy of a system is the total energy of the system when it is undergoing the transient response, then the successful control system must have the capability to decay quickly the transient energy to zero. By including the transient energy and the control energy in the objective function, both parameters can be minimized. The objective function for the optimal control problem is a time integral of the sum of transient energy and control energy expressed as a function of time.

The general, optimal control formulation for regulators can be explained as follows. Consider a structure (Figure 29.60) under dynamic loading that is represented by Equation 29.33:

$$\mathbf{M}\ddot{\mathbf{x}}(t) + \mathbf{C}\dot{\mathbf{x}}(t) + \mathbf{K}\mathbf{x}(t) = \mathbf{D}\mathbf{u}(t) + \mathbf{E}\mathbf{f}(t) \quad (29.33)$$

where \mathbf{M} , \mathbf{C} , \mathbf{K} are, respectively, the $n \times n$ mass, damping, and stiffness matrices, and $\mathbf{x}(t)$ is the n -dimensional displacement vector, $\mathbf{f}(t)$ is an r -vector representing applied load or external excitation, and $\mathbf{u}(t)$ is the m -dimensional control force vector. The $n \times m$ matrix, \mathbf{D} , and $n \times r$ matrix, \mathbf{E} , are location matrices that define locations of the control force and the excitation, respectively.

The equation can be rewritten using the state-space representation in the form

$$\dot{\mathbf{z}}(t) = \mathbf{A}\mathbf{z}(t) + \mathbf{B}\mathbf{u}(t) + \mathbf{H}\mathbf{f}(t), \quad \mathbf{z}(0) = \mathbf{z}_0 \quad (29.34)$$

where

$$\mathbf{z}(t) = \begin{bmatrix} \mathbf{x}(t) \\ \dot{\mathbf{x}}(t) \end{bmatrix} \quad (29.35)$$

FIGURE 29.60 Typical civil structure with its dynamic properties.

is the $2n$ -dimensional state vector

$$A = \begin{bmatrix} \mathbf{0} & \mathbf{I} \\ -\mathbf{M}^{-1}\mathbf{K} & -\mathbf{M}^{-1}\mathbf{C} \end{bmatrix} \quad (29.36)$$

is the $2n \times 2n$ system matrix, and

$$B = \begin{bmatrix} \mathbf{0} \\ \mathbf{M}^{-1}\mathbf{D} \end{bmatrix} \text{ and } H = \begin{bmatrix} \mathbf{I} \\ \mathbf{M}^{-1}\mathbf{E} \end{bmatrix} \quad (29.37)$$

are $2n \times m$ and $2n \times r$ location matrices specifying, respectively, the locations of controllers and external excitation in the state space. In Equation 29.36, $\mathbf{0}$ and \mathbf{I} denote the null matrix and the identity matrix of appropriate dimensions, respectively.

For simplicity, assume that we have a linear time invariant plant, as shown in Equation 29.34 above, and suppose we would like to design a full-state feedback regulator for the plant such that the control input vector is given by

$$\mathbf{u}(t) = -\mathbf{G}\mathbf{x}(t) \quad (29.38)$$

where \mathbf{G} is a feedback gain matrix. The control law given by the above equation is linear. Since the plant is also linear, the closed-loop control system is linear. The control energy, CE, can be expressed as

$$CE = \mathbf{u}^T(t)\mathbf{R}\mathbf{u}(t) \quad (29.39)$$

where \mathbf{R} is a square, symmetric matrix called the control cost matrix. Such an expression for control energy is called a quadratic form, because the scalar function in Equation 29.39 contains quadratic functions of the elements of $\mathbf{u}(t)$. The transient energy, TE, can also be expressed in a quadratic form as

$$TE = \mathbf{x}^T(t)\mathbf{Q}\mathbf{x}(t) \quad (29.40)$$

where \mathbf{Q} is a square, symmetric matrix called the state weighting matrix. The objective function can then be written as follows:

$$J(t, t_f) = \int_t^{t_f} [\mathbf{x}^T(\tau)\mathbf{Q}\mathbf{x}(\tau) + \mathbf{u}^T\mathbf{R}\mathbf{u}(\tau)]d\tau \quad (29.41)$$

where t and t_f are the initial and final times, respectively; that is, the control begins at $\tau = t$ and ends at $\tau = t_f$, where τ is the variable of integration.

The optimal control problem consists of solving for the feedback gain matrix, \mathbf{G} , such that the scalar objective function, $J(t, t_f)$, given by Equation 29.41, is minimized. Hence, the optimal control problem solves a regulator gain matrix, \mathbf{G} , which minimizes $J(t, t_f)$, subject to the constraint given by Equation 29.34.

MATLAB[®] *Control System Toolbox* (MathWorks, 1998) provides a function “lqr” for the solution of the linear optimal control problem shown above (also see Appendix 32A). By using this command, the gain matrix, \mathbf{G} , can easily be obtained. For a numerical simulation, the matrix, \mathbf{G} , is used for obtaining optimal forces, $\mathbf{u}(t)$, as shown in Equation 29.38. The MATLAB[®] *Control System Toolbox* user manual is a good reference (MathWorks, 1998) for applying this command. For a real application in a structure, the optimal forces, $\mathbf{u}(t)$, must be converted to real forces by actuating devices. Actuating devices are covered in Section 29.3.4.

In the above explanation, the linear optimal controller has been derived with full-state feedback that minimizes a quadratic objective function. The controller robustness to process and measurement noise can only be indirectly ensured by iterative techniques. There are more advanced topics in modern control that directly address the problem of robustness by deriving controllers that maintain system response and error signals to within prescribed tolerances. One example is the H_∞ (pronounced *H-infinity*) optimal control design technique. The reader may refer to control design textbooks, such as that written by Tewari (2002).

29.3.5.2 Semiactive Control System

Because of the intrinsically nonlinear nature of semiactive control devices, development of control strategies that are practically implementable and can fully utilize the capabilities of these unique devices is an important and challenging task. Various nonlinear control strategies have been developed to take advantage of the particular characteristics of semiactive devices, including bang-bang control (Mukai et al., 1994; McClamroch and Gavin, 1995), clipped optimal control (Dyke et al., 1996a), bistate control (Patten et al., 1994), fuzzy control methods (Sun and Goto, 1994), and adaptive nonlinear control (Kamagata and Kōbori, 1994). Caughey (1993) proposed a variable stiffness system that employed a semiactive implementation of the Reid (1956) spring as a structural element. He et al. (2001) proposed a resetting semiactive stiffness damper used for controlling seismically excited cable-stayed bridges. Iemura and Pradono (2003) introduced a pseudonegative stiffness control algorithm used for producing artificially rigid–perfectly plastic force–deformation hysteretic loops by using controllable damper.

29.3.5.2.1 Common Control Schemes for Controllable Dampers

An example will be given here for common control schemes for a controllable damper. Examples of a controllable damper are variable-orifice damper and MR fluid dampers. Both types of dampers are covered in Section 29.3.4. The strategy of a clipped-optimal control algorithm (Dyke et al., 1996a, 1996b) for seismic protection using MR fluid dampers is as follows. First, an “ideal” active control device is assumed, and an appropriate *primary* controller for this active device is designed. Then a *secondary* bang-bang-type controller causes the smart damper to generate the desired active control force, so long as this force is dissipative. The primary controller can be one of active control algorithms shown above. For the general smart damping device, the secondary control strategy is given by

$$f_{sa,i} = \begin{cases} f_{a,i}, & f_{a,i} \times \dot{x}_{dev} < 0 \\ 0, & \text{otherwise} \end{cases} \quad (29.42)$$

where $f_{sa,i}$ is the control force of the i th MR fluid damper, $f_{a,i}$ is the desired control force for the i th device, and \dot{x}_{dev} is the velocity across the i th damper. Since the controllable damper is an energy-dissipative device that cannot add mechanical energy to the structural system, special care must be taken in the design of the primary controller so that the desired control force, $f_{a,i}$, is dissipative during the majority of the seismic event.

29.3.5.2.2 Special Control Schemes for Controllable Damper

The term “special” here refers to control schemes that have certain objectives for the hysteretic loops of the controllable dampers. The control schemes are not centralized, so that each damper is controlled separately in one structure or, in other words, one controller is for one damper. The advantage is that should one controller malfunction, this controller will not affect the other controller.

One example is given by He et al. (2001). A resetting semiactive stiffness damper (RSASD) is used to control the peak seismic response of a structure. The RSASD consists of a cylinder-piston system with an on–off valve in the bypass pipes connecting two sides of the cylinder. Basically, the damper is similar to a variable-orifice oil damper as shown in Figure 29.58; however, the orifice valve is replaced by an on–off valve. This damper serves as a stiffness element in which the stiffness is provided by the bulk modulus of the fluid in the cylinder when the valve is closed. When the valve is open, the piston is free to move, and the hydraulic damper provides only a small damping, without stiffness.

Such a stiffness damper can be operated in the resetting mode. During the operation in this mode, the valve is always closed. The energy is then stored in the hydraulic oil of the damper in the form of potential energy. At an appropriate time, the valve is pulsed to open and close quickly. At that moment, the piston is at the resetting position, and the energy stored in the hydraulic damper is released and converted into the head loss across the damper. Hence, by pulsing the valve at appropriate times, structural response can be reduced by drawing energy from the system (He et al., 2001).

Another example is that of Kurino et al. (2003). They presented a device developed for an actual application whose system employs a decentralized control algorithm that uses information only from built-in sensors.

The pseudonegative stiffness control algorithm (Iemura and Pradono, 2003) is also intended for controlling a variable damper based only on the displacement and velocity sensors located within the damper. The purpose is to control the variable damper’s hysteresis loop. An example of the application of this control algorithm to a bridge model is shown in Section 29.3.7.2.

29.3.6 Experimental Performance Verification

29.3.6.1 Shaking Table Tests of a Flexible Structural Model with TMD, AMD, and ATMD

For practical implementation of TMD, AMD, and ATMD for structures, it is important to find the efficiency of each control system for random excitations. The author has made an analytical and numerical studies on the efficiency of different control methods. To verify the results, a three-DoF structural frame model (Figure 29.61) with and without control devices is tested on a shaking table at Kyoto University, Japan (Iemura et al., 1992).

Natural periods for modes 1, 2, and 3 are 0.6578, 0.2580, and 0.1568 sec, respectively. The relevant participation factors for each mode are 1.2204, 0.3493, and -0.1341 , respectively. The moving mass and other mass of the TMD are 3.5 and 5.5 kg, respectively. The spring constant is 0.581 kg/cm . The damping ratio is 25.06%. These properties are used for the experiment. The masses of the TMD consist of the AC servo-motor, moving mass, driving guides, and velocity meter. At the time of the experiment of the TMD, the moving mass was fixed and the TMD

FIGURE 29.61 Three-DoF experimental model with TMD/ATMD.

was hung from the third floor. In order to work as the hybrid type ATMD, the moving mass was driven by the motor. For the pure active control experiment, the motor and the moving mass are set directly on the third floor.

It was clearly found that the second mode response is not reduced by the TMD but is effectively reduced by the AMD and ATMD. The TMD is effective only in the first mode frequency range, while active control force can cover a wide frequency range.

It was also found that the control force of the ATMD is much lower than that of AMD, especially in the first mode frequency range. The first mode response is reduced mainly by the TMD and the second mode response is reduced by the AMD. This verifies the energy efficiency of ATMD. This is the reason that the ATMD concept is now popularly used for practical application.

29.3.6.2 Substructure Hybrid Test

Before introducing additional dampers to a structure for seismic-response reduction, the precise frequency-dependent properties of the damper should be obtained from the damper. These properties will be used for numerical simulation on the effectiveness of the damper in reducing seismic responses. It is quite difficult to work out the appropriate model for a specified device because of the existence of strong nonlinearity. For a more reliable experimental test of structures with structural control devices, so-called “substructure hybrid experiment” techniques have been developed.

The term “substructure hybrid” implies a technique that combines the device loading experiment and numerical simulation of structural response. Why should it be separated? It is because civil structures are relatively large and expensive to construct in a laboratory. Therefore, only the inelastic part is tested experimentally. The elastic part, which is easier to model, is numerically simulated on a computer. Both results are combined in real time at every time step of the simulation. Up until now, various kinds of test methods have been proposed. Most of them can be classified into three categories from the viewpoint of the loading equipment.

29.3.6.2.1 Hybrid Tests Using Hydraulic Actuator

Hydraulic actuators are commonly used for loading experiments. They are advantageous for testing specimens that needs large excitation force and displacements (Tanzo et al., 1992; Igarashi et al., 1993; Igarashi, 1994; Williams and Blakeborough, 2001). Various algorithms and techniques have been proposed in order to conduct precise, real-time experiments such as the “operator splitting numerical integration scheme,” which is suitable for online controlled experiments (Nakashima, 1993). A compensation method based on extrapolation is proposed by Horiuchi and Konno (2001) for the response delay of the actuator. Similar feedforward-based compensation methods are widely used for the numerical algorithm’s development and real-time testing (Nakashima and Masaoka, 1999; Nakashima et al., 1999; Blakeborough et al., 2001).

29.3.6.2.2 Hybrid Tests Using Shaking Table

Substructure hybrid loading test systems have been developed for shaking table equipment. Since most shaking tables are driven by hydraulic actuators, algorithms as well as technologies for the hydraulic actuators system are directly applicable to the shaking table test systems. Iemura et al. (2002) introduced the inverted digital filter of the shaking table for compensating its dynamics, and conducted a real-time hybrid experiment using the electromagnetic mass damper installed in the nonlinear structure. The shaking table test is applicable to a test specimen such as the TMD.

29.3.6.2.3 Hybrid Tests Using Inertia-Force-Driven Loading System

This is a newly developed method for hybrid loading test (Toyooka, 2002; Iemura et al., 2003). The system consists of a large size mass, rubber and roller supports, and active mass driver. The schematic figure of the system is shown in [Figure 29.62](#) and the property of the system is in [Table 29.5](#). The active mass driver is attached to the mass. The test specimen is attached to the mass and the ground. The mass

Stroke limit	± 10 cm

(i.e., the concrete slab) can be excited with large displacement, velocity, and acceleration by making use of the shaker (Iemura et al., 2003). The Inertia-Force-Driven Loading (IFDL) system was developed to allow an economical and accurate loading environment for energy dissipation devices to characterize the dynamic properties and to comprehend the performances of these devices under the realistic loading conditions.

29.3.7 Implementations

29.3.7.1 Semiactive Control of Full-Scale Structures Using Variable Joint Damper System

29.3.7.1.1 Background of Study

In order to verify the effectiveness of the application of the semiactive control technique to the joint damper system (JDS), seismic response control tests using full-scale multistory steel-frame structures, excitation devices, and a variable damper are performed at the Disaster Prevention Research Institute, Kyoto University, Japan. The variable damper allows external control of damping force by the electric servo-valve that regulates the oil flow through the cylinder/piston mechanism. The test results show that the variable damper was successfully controlled with high accuracy, as well as having the advantage of JDS application of the semiactive control in reducing the dynamic response of structures over the

conventional passive control. A comparison of the semiactive control algorithms to JDSs in terms of the feasibility and the advantage in the engineering application is also based on the test results.

Extensive research on the semiactive control approach has been conducted in order to reduce the seismic response of structures, induced especially by strong earthquake ground motions. The JDS, which aims to achieve the dynamic response reduction of adjacent structures through the use of connection devices with energy-absorbing capability, has been considered a promising approach to establish effective semiactive structural systems for earthquakes.

The purpose of this study is to verify experimentally the effectiveness of the application of semiactive control to the JDS. Seismic response control tests using full-scale multistory frame structures, excitation devices, and a variable damper are performed at the Disaster Prevention Research Institute, Kyoto University. The variable damper allows for external control of the damping force using the electric servo-valve that regulates the oil flow through the cylinder/piston mechanism.

Two types of semiactive control algorithms were employed, namely the linear quadratic regulator (LQR) control theory and the newly proposed pseudonegative stiffness control for JDSs. Parameter-setting strategies for the algorithms are studied prior to the tests through numerical simulations based on the modeling of the full-scale steel frame structures and the control device used in the tests.

29.3.7.1.2 Test System Set Up

As shown in Figure 29.63, the test structure of the JDS consists of two full-scale structural steel frames: a five-story frame (1×2 span) and a three-story frame (1×1 span). The dimensions of both frames are shown in Table 29.6. Natural frequencies are also shown in the table.

In this test system, mass-driver devices are used to reproduce the vibration conditions under both sinusoidal and real earthquake inputs. One-directional horizontal earthquake excitation is applied. Although three mass-driver systems can be seen in the figure, two of them are used at the same time. The accuracy of the simulated response using the mass driver devices has been verified by a series of research

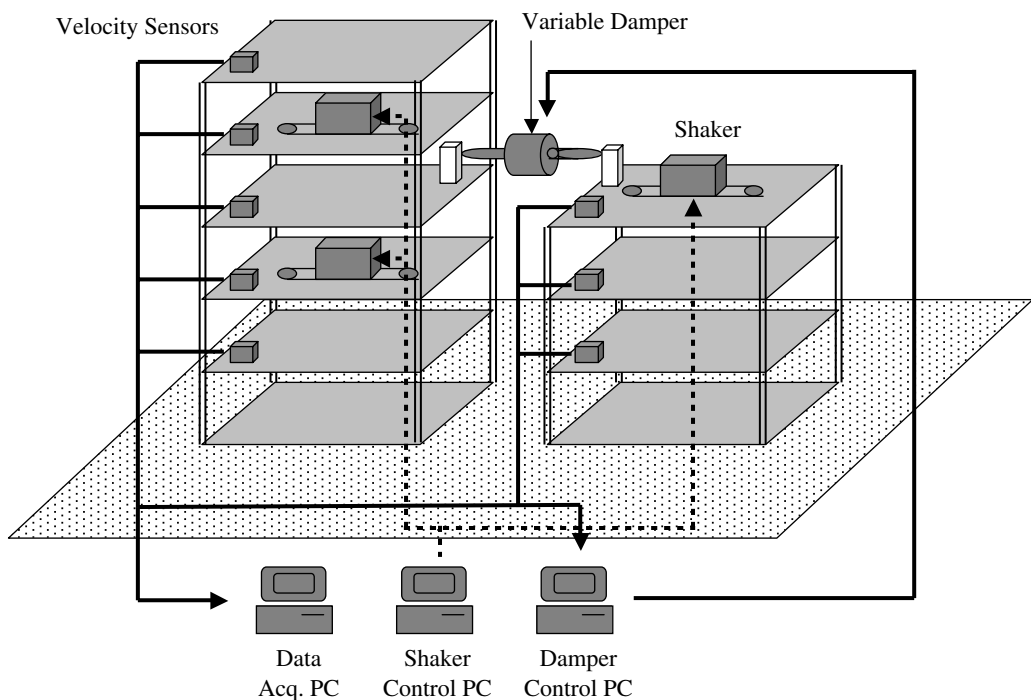

FIGURE 29.63 Schematic diagram of joint damper system.

TABLE 29.6 Test Frames and Mass-Drivers

	Five-Story	Three-Story
Height (m)	17.22	10.65
Weight (tonf)	163.1	62.1
First mode natural frequency (Hz)	1.78	2.41
Mass driver	5 ton mass at the fourth floor	2 ton mass at third floor

conducted prior to this study. Velocities, relative displacements, and absolute accelerations of all floors are measured through instrumentation. All measured responses are sent to a digital signal processing-based system for the feedback control.

As the control device in the JDS, a variable damping device (variable damper) is used in the test system. The variable damper is installed at the third story of the five-story frame so as to connect the two frames. The mechanism of the variable damper is similar to that shown in [Figure 29.56](#). It is a semiactive hydraulic damper consisting of a cylinder/piston mechanism filled with oil, double rods that connect the frames, a by-pass pipe that contains a flow control valve, and an accumulator that keeps the by-pass line pressure constant. The opening ratio of the flow control valve can be changed by a servo-controller using an external signal. The flow volume through the valve can be regulated to control the pressure loss. The delay time for the opening ratio control is sufficiently short to allow real-time control.

29.3.7.1.3 Control Algorithm

In this study, three types of control algorithms are used: linear viscous damper control, LQR control (discussed in Section 29.3.5), and pseudonegative stiffness (PNS) control. The linear viscous damper control algorithm is intended to be the reference response in the case of passive control, and the effectiveness of the semiactive control is demonstrated by comparing the other two cases with the linear viscous damper control case.

In linear viscous control algorithm, the damping force demanded of the variable damper, $F_d(t)$, is

$$F_d(t) = C_c v_r(t) \quad (29.43)$$

where C_c is the connecting damping coefficient and v_r is the relative velocity of the damper position. Real-time control of the valve opening ratio is required to generate the demanded control force, F_d , with the variable damper, even for this simplest control algorithm.

The LQR control theory is used as a semiactive control algorithm in this study, as extensively used in past studies. In the LQR control algorithm, the optimal control force, F_d , is regarded as the demanded force and the variable damper is controlled to track the demanded force as close as possible within the constraint, depending on the piston velocity. The control gain parameters are chosen on the basis of numerical simulation in consideration of the capacity of the variable damper. The control force is calculated in the following manner:

$$F_d(t) = -\mathbf{G}\mathbf{x}(t) \quad (29.44)$$

where \mathbf{G} is the optimal gain matrix given by the LQR theory and $\mathbf{x}(t)$ is the state vector for the structural frames.

If the main purpose of a JDS is the response reduction of the upper floors in the adjacent structures, the most interesting feature of the system is obtained by connecting them at lower stories with a negative stiffness element. Although this characteristic has been reported theoretically and analytically in many studies, there are many problems left in applying the active control device at the present time, mainly owing to the difficulty in realizing the negative stiffness with a passive control device. However, semiactive devices such as the variable damper can generate an apparent negative stiffness by controlling the damping. Therefore, taking into account JDS and negative stiffness, a new, simple control algorithm to realize pseudonegative stiffness with a damping element is proposed in this study. To generate the

negative stiffness, the demanded force of variable damper F_d is defined as follows:

$$F_d(t) = K_c x_r(t) + C_c v_r(t) \quad (29.45)$$

where K_c and C_c are the connecting stiffness (negative value) and the damping coefficient, respectively. The relative displacement and velocity of the damper piston, respectively, are x_r and v_r . It follows that this algorithm simulates the state in which the two frames are connected by a negative stiffness and a positive damping elements. The eigenvalue analysis is used to determine the value of K_c and C_c .

This pseudonegative stiffness algorithm has a great advantage in practical application. Most of the previously proposed control algorithms require direct measurement of the structural system to produce feedback and to calculate the demanded control force. That means that a considerable number of sensors should be installed in the object structure. Considering practical application, it is difficult to install many sensors because of the economical disadvantage. On the other hand, for the pseudonegative stiffness algorithm, only the relative displacement and velocity are used for feedback and a sensor is required only at the damper. In addition to the simplicity in installation, the required parameters are limited to the connecting stiffness and damping.

29.3.7.1.4 Test Results

The response of variable damper to sinusoidal input with 1.8 Hz (max 10 gal), which is approximately the first resonance frequency in the connected state, is shown in Figure 29.64. The five-story top-floor velocity response in the LQR control theory and pseudonegative stiffness are smaller than that in the viscous damper; especially, the peak value in pseudo negative stiffness is improved at 25% compared with that in the viscous damper, though the velocities at the top story of the three-story frame are almost equal for all control algorithms. On the other hand, the LQR control theory can reduce the peak response of both frames as compared with the viscous damper. When the object is to moderate the response of total system, the LQR theory is the most effective algorithm of the three being compared. Based on the test, semiactive controls based on the LQR control theory and pseudonegative stiffness can reduce the peak responses of the total system more effectively than viscous damper-type passive control.

For the earthquake excitation (El-Centro 1940 N–S and Kobe 1995 N–S, scaled to 20 gal max), the influence of the friction of the variable damper appears in the dynamic characteristics of the variable damper in every control algorithm because of the relatively small responses. The relative velocity and displacement responses of the variable damper in both semiactive controls are larger than that in the viscous damper. Judging from the test result, it is confirmed that the variable damper is controlled effectively in the different control algorithm for real earthquake inputs. With respect to the velocity response of the top story of the three-story frame, the responses are not very different when different control algorithms are used. On the other hand, for the five-story top-floor response, both semiactive controls can reduce the response more effectively than the passive control to both real

FIGURE 29.64 Variable damper responses in the sinusoidal excitation test: (a) at the top story of five-story frame; (b) at the top story of three-story frame.

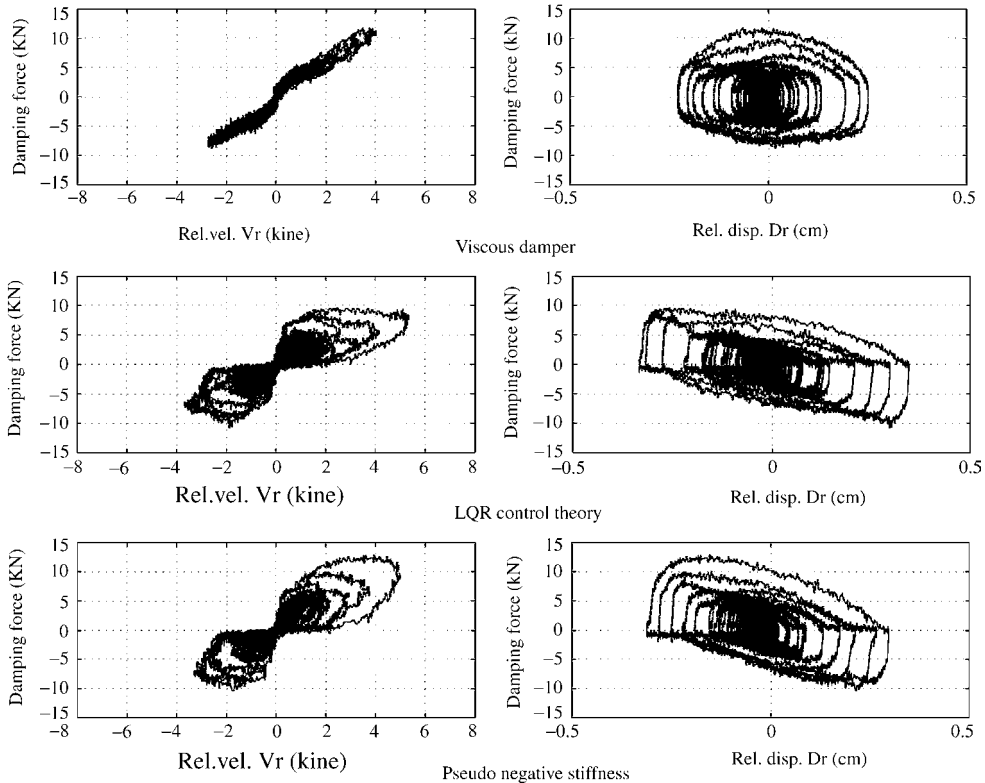

FIGURE 29.65 (a) Viscous-type control, (b) LQR-type control, and (c) pseudonegative stiffness-type control under El-Centro 1940 N–S scaled to 20 gal max.

earthquake excitations. Semiactive controls are more effective than passive control to reduce the response of the top story of the five-story frame in the earthquake excitation cases.

Figure 29.65 shows the hysteretic loops resulting from viscous-type, LQR-type, and pseudonegative stiffness-type controls under El-Centro 1940 N–S, scaled to 20 gal max. It is obvious that the pseudonegative hysteretic loop can be achieved experimentally by using a variable damper.

29.3.7.2 Application of Structural Control Technologies to Seismic Retrofit of a Cable-Stayed Bridge

29.3.7.2.1 Background of Study

Owing to severe damage to bridges caused by the Hyogo-ken Nanbu earthquake in 1995, very high ground accelerations (level II design) are now required in the new bridge design specification set in 1996, in addition to the relatively frequent earthquake motion (level I design) by which old structures were designed and constructed. Hence, the seismic safety of cable-stayed bridges that were built before the present specification has to be reviewed and seismic retrofit has to be done, if it is found necessary.

In order to study the effectiveness of passive and semiactive control on the seismic retrofit of a cable-stayed bridge, numerical analyses on a model is carried out. An existing cable-stayed bridge that has fixed-hinge connections between the deck and towers is modeled and its connections are replaced with isolation bearings and dampers. The isolation bearings are assumed to be elastic or hysteretic type. The dampers are linear and variable type. The objective is to increase the damping ratio of the bridge by using passive and semiactive control technologies. The calculation of the structural damping ratio at the main mode is feasible, as the passive or semiactive control method produces certain hysteretic loops under

FIGURE 29.66 Side view of the Tempozan Bridge.

harmonic motion, and the main mode has an effective modal mass that is larger than 90% of the total mass. SSI effects on the structural damping ratio are also studied.

The Tempozan Bridge (Hanshin Highway Public Corporation, 1992), built in 1988, is a three-span continuous steel cable-stayed bridge that is situated on reclaimed land and crosses the mouth of the Aji River, Osaka, Japan. The total length of the bridge is 640 m with a center span of 350 m, and the lengths of the side spans are 170 and 120 m (Figure 29.66). The main towers are A-shaped to improve the torsional rigidity. The cable in the superstructure is a two-plane fan pattern multicable system with nine stay cables each plane. The bridge is supported on a 35 m thick soft layer and the foundation consists of cast-in-place RC piles of 2 m in diameter. The main deck is fixed at both towers to resist horizontal seismic forces. The bridge is relatively flexible, with a predominant period of 3.7 sec. As to the seismic design in the transverse direction, the main deck is fixed at the towers and the end piers.

Figure 29.67 shows the original design spectrum used for designing the bridge and the new design spectrum specified in the bridge design specification set in 1996 for level I and level II earthquakes (Japan Roadway Association, 1996). A level II earthquake has type I (interplate type)

FIGURE 29.67 Design spectra for bridges.

and type II (intraplate type). As can be seen in the figure, the new design spectrum shows higher acceleration response in all period ranges than the original one.

29.3.7.2.2 Basic Concept of Seismic Retrofit

If the deck is connected with very flexible bearings to the towers, the induced seismic forces will be kept to minimum values, but the deck may have a large displacement response. On the other hand, a very stiff connection between the deck and the towers will result in a lower deck displacement response but will attract much higher seismic forces during an earthquake. This is the case in the original bridge structure, the Tempozan Bridge. Therefore, it is important to replace the existing fixed-hinge bearings with special bearings or devices at the deck-tower connection both to reduce seismic forces and to absorb large seismic energy and reduce the response amplitudes. Additionally, energy-absorbing devices may also be put between the deck-ends and piers; however, this will attract relatively large lateral force of the piers, and therefore this kind of method has been avoided for this bridge at this time.

The bridge model that represents the existing Tempozan Bridge is termed the “original bridge model.” The bridge model with the spring and damper (viscous, hysteretic, and semiactive) between the deck and the towers is termed the “retrofitted bridge model.” The original and retrofitted bridge models are shown in Figure 29.68. The original structure system has fixed-hinge connections between the towers and the deck and rollers connection between the deck-ends and piers, so that the deck longitudinal movement is constrained by the towers (Figure 29.68a). For the retrofitted bridge, the isolation bearings and dampers connect the deck to the towers (Figure 29.68b).

The cables are modeled by truss elements. The towers and deck are modeled by beam elements, and the isolation bearings are modeled by spring elements. The models were analyzed by a commercial finite element program (Prakash and Powell, 1993). The moment–curvature relationship of the members is calculated based on the sectional properties of members and material used.

29.3.7.2.3 Modal Shape Analysis

The first modes of the structures are interesting here because these modes have the largest contribution to the longitudinal movement of the bridge (also see Chapters 3 and Chapter 4). The mode shapes of the original bridge and the retrofitted bridge are shown in Figure 29.69. The first mode shape of the original structure is shown in Figure 29.69a. The natural period (T) of this mode is 3.75 sec (frequency = 0.266 Hz), which is close to the design value for the bridge (3.7 sec, frequency = 0.270 Hz; Hanshin Highway Public Corporation, 1992). This first mode shape has the effective modal mass as a percentage of the total mass of 84%.

For the retrofitted structure, the stiffness of the bearings is an important issue, as large stiffness produces a large bearing force. However, very flexible connections produce a large displacement response. Therefore, based on a study on a simplified model of the bridge under seismic motion, the bearing stiffness

FIGURE 29.68 Cable-stayed bridge models: (a) original structure system; (b) retrofitted structure system.

FIGURE 29.69 First mode shapes of (a) original structure and (b) retrofitted structure.

that produces retrofitted main period (T') 1.7 times the original main period (T) was chosen. This bearing stiffness makes the energy-absorbing devices work well in reducing seismic-induced force and displacement. The main natural period (T') of the retrofitted bridge then becomes 6.31 sec and the effective modal mass as a percentage of total mass is 92%.

It is clear from the figures that smaller curvatures are found at the towers and the decks of the retrofitted structure than in the original structure. This shows that the retrofitted structure is expected to produce smaller moments at the towers and the decks than the original structure during a seismic attack.

29.3.7.2.4 Time-History Analysis

The models were analyzed by a commercial finite element program (Prakash and Powell, 1993), which produces a piece-wise dynamic time history using Newmark's constant average acceleration ($\beta = 1/4$) integration of the equations of motion, governing the response of a nonlinear structure to a chosen base excitation. The input earthquake motions were type I-III-3, I-III-2, and I-III-1 earthquakes, which are artificial acceleration data used for design in Japan for soft soil condition. Those data are intended to be type I (interplate type). With numerical comparison (Figure 29.67), type I earthquake motion gives higher effect to the bridge than type II motion, in longer period range.

Table 29.7 shows the seismic response effects because of different kinds of bearings and dampers: fixed-hinge bearings for the original bridge model; elastic bearings, elastic bearings plus viscous dampers, and hysteretic bearings for the retrofitted bridge models. The input earthquake was type I-III-3 earthquake data and was in the longitudinal direction.

From the table, it is clearly seen that if only elastic bearings are used for seismic retrofit, then the sectional forces are reduced to about 40% of the original ones. However, the displacement response is increased to 176% of the original one. By adding viscous dampers to the elastic bearings, the sectional forces can be reduced to about 25% of the original ones, and the displacement response is reduced to 63% of the original. Thus, the viscous dampers together with bearings work to reduce the seismic response of retrofitted bridge. The structural damping ratio is calculated as 35%.

If hysteretic bearings are used for seismic retrofit, the sectional forces are reduced to about 29% of the original ones and the displacement response is reduced to 67% of the original one. The equivalent structural damping ratio is calculated as 13.1% by using pushover analysis to obtain a hysteretic loop at the main mode. The hysteretic bearings are modeled by a bilinear model, and the second stiffness of the hysteretic bearings is 0.03 times the initial stiffness and produces a first mode natural period of 6.31 sec.

TABLE 29.7 Maximum Earthquake Responses and Damping Ratios in Longitudinal Direction

Items	Original Structure	Retrofitted Structure		
		Elastic Bearings	Elastic Bearings + Viscous Damping	Hysteretic Bearings

29.3.7.2.5 Soil–Structure Interaction Effect

One method to study the SSI effects is to take into account the effects of flexible foundations and the radiation of energy from foundations. In this method, the cable-stayed bridge is idealized as in Figure 29.70 (Kawashima and Unjoh, 1991). The subsoil supporting the foundation was assumed to be an elastic half space. The subsoil was assumed to be elastic with no energy dissipation. The foundation was idealized as a rigid massless circular plate. The radius of the rigid circular plate was simply assumed so that it gives the same surface area as the foundation. Dynamic stiffness of the foundation was assumed in a frequency independent form:

FIGURE 29.70 Cable-stayed bridge model with flexible foundation and energy radiating from foundation.

$$K_x = \frac{8G_s a}{2 - \nu} \quad C_x = \frac{\pi G_s a^2}{V_s} \tag{29.46}$$

$$K_r = \frac{8G_s a^3}{3(1 - \nu)} \quad C_r = \frac{0.25\pi\sqrt{2(1 - \nu)/(1 - 2\nu)}G_s a^4}{V_s} \tag{29.47}$$

in which K_x and C_x represent the spring and damping coefficient for sway motion, and K_r and C_r represent those for rocking motion. V_s and a represent shear wave velocity of subsoils and the radius of foundation, respectively.

The result shows that SSI increases the natural period and the damping ratio of the original structure. However, the damping ratio of the retrofitted structure is reduced and the effectiveness of the bearings and dampers in reducing seismic responses is also reduced (Table 29.8). This is mainly because the SSI model introduces flexibility at the base. A flexible base will reduce the frequency of the structure. A smaller frequency will reduce the effectiveness of viscous damping devices in absorbing earthquake energy. Moreover, a flexible base will increase the elastic strain energy of the structure that reduces the damping ratio. If the SSI model possesses an elemental damping ratio, as is a usual case for the soil, the structural damping ratio will also be influenced by the SSI-model damping characteristics.

29.3.7.2.6 Semiactive Control

The semiactive control herein uses the pseudonegative stiffness control algorithm (Iemura and Pradono, 2003) so that the sum of the damper force and bearing force (plus other connecting stiffness forces) are expected to produce a hysteresis loop that is as close as possible to that of rigid–perfectly plastic

TABLE 29.8 Maximum Earthquake Responses and Damping Ratios (SSI Included)

Items	Original Structure	Retrofitted Structure	
		Elastic Bearings + Viscous Damping	Hysteretic Bearings
Deck displacement (m)	2.78	2.57	2.77
Tower moment ^a (MN m)	1,500	800	882
Tower axial force ^a (kN)	36,200	12,500	19,800
Cable force (kN)	12,300	3,010	4,470
Deck moment (MN m)	228	58	86
Deck axial force (kN)	31,900	9,100	12,300
Foundation displacement (m)	0.171	0.079	0.093
Damping ratio (%)	3.1	23	9.3
Natural period (sec)	5.04	7.66	5.13 and 7.46 ^b

^a Base of tower AP3.
^b Initial and postyielding stiffness.

force–deformation characteristics (Figure 29.71a). Moreover, no residual displacement is expected at the bearings after an earthquake attack, because the hysteresis loop is velocity dependent. Figure 29.71 shows ideal and realistic force–deformation characteristics of the variable damper that can produce artificial rigid–perfectly plastic force–deformation characteristics by using variable damper.

One algorithm that can approach the hysteretic loop in Figure 29.71b requires the following variable-damper force (Iemura et al., 2001):

$$F_{d,t} = K_d u_t + C_d \dot{u}_t \tag{29.48}$$

where K_d is connecting stiffness (negative value) and C_d is damping coefficient (positive value). The algorithm is practical because only displacement and velocity sensors are placed in the dampers. Therefore, each damper can have its own controller. Should a malfunction happen in one damper or controller, it will not affect the other dampers or controllers.

This algorithm produces the hysteretic loop shown in Figure 29.72b under harmonic motion. It is clear from the figure that the variable damper is superior to the linear viscous damper, because the maximum variable damper plus the connecting-stiffness force can be set to be equal to the maximum connecting-stiffness force (Figure 29.72b). One can calculate that the damping ratio of the hysteresis loop in Figure 29.72b is 53.4%. For the same damping ratio, the hysteresis loop in Figure 29.72a produces a total force 1.46 times larger than the connecting-stiffness force (Iemura and Pradono, 2003). The connecting stiffness between the deck and the tower of the retrofitted cable-stayed bridge comes from the contribution of cable stiffness, upper tower stiffness, and bearing stiffness.

The cable-stayed bridge model with isolation bearings and variable dampers controlled with the pseudonegative stiffness algorithm was analyzed by a program developed by the authors under the MATLAB (MathWorks, 2000) and SIMULINK (MathWorks, 1999) environments. The program produces a piece-wise dynamic time-history, using Newmark’s constant average acceleration ($\beta = 1/4$) integration of the equations of motion, governing the response of a nonlinear structure to a chosen base excitation. The input motions were type I-III-1, I-III-2, and I-III-3 earthquakes, which are artificial acceleration data used for design in Japan (Japan Roadway Association, 1996).

The results show that the application of the pseudonegative stiffness control algorithm is effective in reducing seismic response of the bridge model. Figure 29.73 shows the base shear-deck displacement

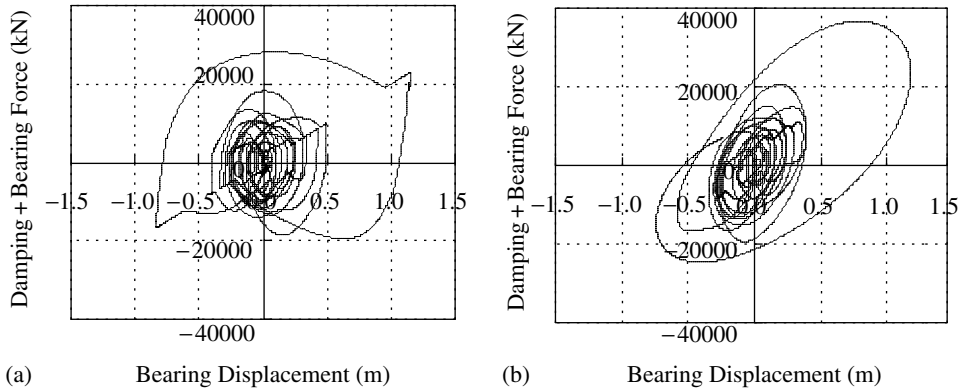

FIGURE 29.75 Damping plus bearing force vs. damping displacement relationship of a cable-stayed bridge model with (a) linear dampers, (b) pseudonegative stiffness dampers (type I-III-1 earthquake).

relationship for both bridges, with a linear damper and pseudonegative stiffness damper, respectively, under type I-III-1 earthquake input. The bridge model with pseudonegative stiffness dampers shows lower base shear than that of the bridge with linear damper.

Figure 29.74 shows the hysteretic loops produced by both linear dampers and pseudonegative stiffness dampers (at tower AP3). The damping force produced by the pseudonegative stiffness damper is larger than that of the linear damper. However, the total force of damping plus the isolation bearing is lower for the pseudonegative stiffness damper (Figure 29.75). Therefore, the base shear of the cable-stayed bridge model is lower for the pseudonegative stiffness dampers.

Summary

Particular considerations must be made during the design of long-span bridges with regard to safety during earthquakes. These include: the wave-passage effect caused by the different times at which seismic waves arrive at different supports; the incoherence effect due to loss of coherency of the motion caused by either reflections and refractions of the waves in the inhomogeneous ground medium or the difference in the manner of superposition of waves from an extended source arriving at various supports; and the local effect because of the differences in soil conditions at different supports and the manner in which these influence the amplitude and frequency content of the bedrock motion. This chapter deals with the random vibration approach to analyzing these structures, which is based on a statistical characterization of the set of motions at the supports. This approach is particularly suitable for dealing with the above spatially varying input motions. The computational problems may be largely overcome by the pseudo excitation method. This approach is presented here. Numerical comparisons are given to show the

accuracy of the method and its capability of dealing with the spatial effects and nonstationary effects. Further topics related to this chapter are discussed in [Chapter 5](#).

30.1 Introduction

Seismic computations of long-span structures have long been an issue of great concern. Such computations are usually executed numerically using schemes in the time domain (i.e., time history). For short-span bridges, all supports can be assumed to move uniformly and the response-spectrum method (RSM) is a suitable computation tool. For long-span bridges, however, various spatial effects such as the wave-passage effect, the incoherence effect, the local site effect, and so on, may be important. Such spatial effects cannot be dealt with directly by the conventional RSM. Instead, the time-history method (THM) is the most widely used method for these systems. The time-history scheme requires solving the dynamic equations for a number of seismic acceleration samples. The results are then processed statistically to produce the quantities required by the designs. This process is rather complex and requires a considerable computational effort. As a result, more efficient and effective methods are under investigation.

Seismic motions are random (stochastic) in nature (Housner, 1947). Spatial effects of long-span bridges can be analyzed using the random-vibration approach (see also Chapter 5). In the last two decades, many scholars and experts (Lee and Penzien, 1983; Dumanoglu and Severn, 1990; Lin et al., 1990; Berrah and Kausel, 1992; Kiureghian and Neuenhofer, 1992; Ernesto and Vanmarcke, 1994) have made great progress in promoting the seismic random analysis of long-span structures and its engineering applications. Although available computational methods still need further improvement both in precision and efficiency, the random-vibration approach, as a theoretically advanced tool, has been gradually accepted by the earthquake engineering community. For example, it has been adopted by the European Bridge Code (European Committee for Standardization, 1995).

Developed recently (Lin, 1992; Lin et al., 1994a, 1995a, 1995b, 1997a, 1997b; Lin and Zhan, 2003), the pseudoexcitation method (PEM) is an accurate and highly efficient approach to the stationary and nonstationary random seismic analysis of long-span structures. For typical three-dimensional finite element models of long-span bridges with thousands of degrees of freedom (DoF) and dozens of supports, when using 100 to 300 modes for mode-superposition analysis, the seismic responses can be implemented quickly and accurately on a standard personal computer. Numerical results show that the wave-passage effect is of particular importance for the seismic analysis of long-span bridges, and the incoherence effect is of comparatively less importance. The details will be given in this chapter. The PEM has been successfully applied to some practical engineering analyses (Wang et al., 1999; Liu and Liu, 2000; Xue et al., 2000; Fan et al., 2001), and has been proven to be quite effective.

30.1.1 Basic Concepts of Random Vibration

30.1.1.1 Stationary Random Process

The probabilistic properties of stationary random processes are independent of time. A random process is said to be *strictly stationary* (or *strongly stationary*) if its probability density function does not change with time. However, such a condition is very difficult to satisfy in practical engineering problems. Therefore, a *wide-sense stationary* (or *weakly stationary*) process is defined for which only the mean value and autocorrelation function of the process are not permitted to vary with time.

A random variable x is said to be Gaussian-distributed if its probability density can be written in the form

$$p(x) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left(-\frac{(x - \bar{x})^2}{2\sigma^2}\right) \quad (30.1)$$

in which σ is the standard deviation of x , and the variance is given by

$$\sigma^2 = \int_{-\infty}^{\infty} (x - \bar{x})^2 p(x) dx \quad (30.2)$$

FIGURE 30.1 Probability density functions of Gaussian random variables.

Probability density functions of typical Gaussian random processes are shown in Figure 30.1, in which \bar{x} is the mean value given by the abscissa (horizontal coordinate) of the peak value. A smaller σ corresponds to a narrower and higher peak.

For a random process $x(t)$, if the joint probability density function of its values $x(t_1), x(t_2), \dots, x(t_n)$ at n arbitrary time instants is Gaussian, then $x(t)$ is said to be a Gaussian random process. Since the joint probability density function depends only on the mean values and covariances of the n values, a weakly stationary Gaussian random process is also strongly stationary.

If a stationary random process has statistical properties that can be computed by taking the time average of an arbitrary sample over a sufficiently long period, the process is said to be *ergodic*. A typical seismic ground motion record is usually assumed to be a Gaussian and ergodic stationary random process. Its *expected value* (i.e., mean value) can be computed by

$$E[x(t)] = \bar{x}(t) = \int_{-\infty}^{+\infty} x(t)p(x, t)dx \quad (30.3)$$

in which $p(x, t)$ is the probability density function of $x(t)$.

In order to investigate the relation between the values of a random process $x(t)$ at two different times, the autocorrelation function of $x(t)$ is defined as

$$R_{xx}(\tau) = E[x(t)x(t + \tau)] = \lim_{T \rightarrow \infty} \frac{1}{T} \int_{-T/2}^{T/2} x(t)x(t + \tau)dt \quad (30.4)$$

A stationary random process, denoted as $x(t)$, is not absolutely integrable in a region of $t \in (-\infty, \infty)$. Therefore, a subsidiary function $x_T(t)$ is defined:

$$x_T(t) = \begin{cases} x(t) & \text{when } -T/2 \leq t \leq T/2 \\ 0 & \text{elsewhere} \end{cases} \quad (30.5)$$

Obviously, $x_T(t)$ is absolutely integrable within $t \in (-\infty, \infty)$. Therefore, its *Fourier transformation* (see [Appendix 2A](#) and [Chapter 10](#)) can be computed by

$$X_T(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} x_T(t)\exp(j\omega t)dt \quad (30.6)$$

Let

$$S_{xx}(\omega) = \lim_{T \rightarrow \infty} \frac{1}{T} |X_T(\omega)|^2 \quad (30.7)$$

Equation 30.7 is the definition of the auto-PSD (power spectral density) function of $x(t)$.

Note that the repeated subscripts in R_{xx} or S_{xx} can be represented by just one; that is, they can be denoted as R_x or S_x . When $x(t)$ is a zero-mean stationary random process, its variance is given by

$$\sigma_x^2 = \int_{-\infty}^{\infty} S_{xx}(\omega)d\omega \tag{30.8}$$

Figure 30.2 gives the auto-PSD curves of four typical stationary random processes, which show the energy distribution with frequency for each kind of random process. The energy of a narrowband random process is concentrated within a narrow frequency band (see Figure 30.2b) whereas the energy of a wideband random process is distributed over a rather wide frequency range, as shown in Figure 30.2c. The energy of a *white noise* process is distributed uniformly over an infinite region, $\omega \in (-\infty, \infty)$, as shown in Figure 30.2d. Using such a random process model results in mathematical convenience. However, the white noise process does not physically exist. A single harmonic random wave has nonzero values only at two isolate frequencies $\pm \omega_0$ (see Figure 30.2a), and its initial phase angle φ is usually regarded as uniformly distributed over $[0, 2\pi)$.

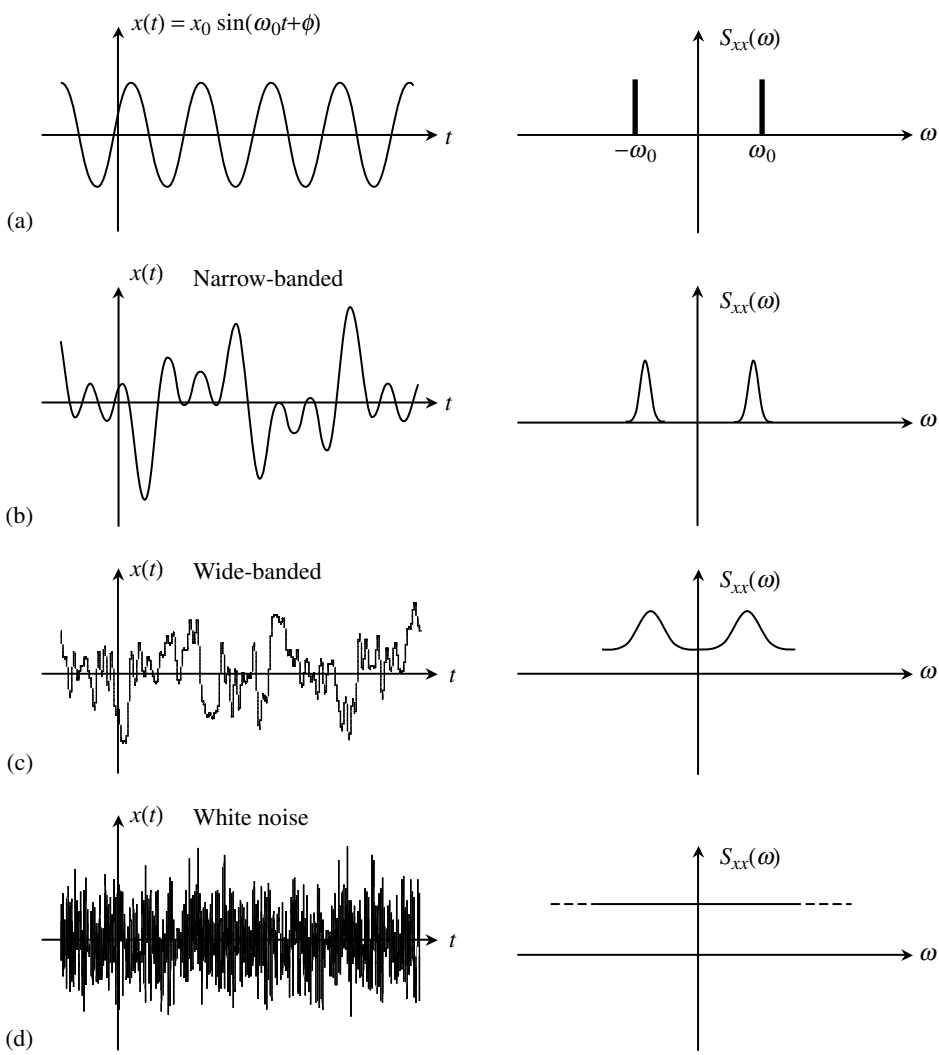

FIGURE 30.2 Auto-PSD curves of four typical stationary random processes.

The auto-PSD $S_{xx}(\omega)$ of a stationary random process $x(t)$ has the following properties:

1. $S_{xx}(\omega)$ is a nonnegative real number; that is

$$S_{xx}(\omega) \geq 0 \quad (30.9)$$

This can be judged from the definition of auto-PSD functions, that is, Equation 30.7.

2. $S_{xx}(\omega)$ is an even function; that is

$$S_{xx}(\omega) = S_{xx}(-\omega) \quad (30.10)$$

This can also be deduced from Equation 30.7.

3. The auto-PSDs of the derivatives of $x(t)$ can be computed from $S_{xx}(\omega)$ directly by

$$S_{\dot{x}\dot{x}}(\omega) = \omega^2 S_{xx}(\omega), \quad S_{\ddot{x}\ddot{x}}(\omega) = \omega^4 S_{xx}(\omega) \quad (30.11)$$

30.1.1.1 Wiener–Khinchine Theorem

Wiener and Khinchine proved that for an arbitrary stationary random process $x(t)$, its auto-PSD $S_{xx}(\omega)$ and autocorrelation function $R_{xx}(\tau)$ are a Fourier transform pair; that is

$$S_{xx}(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{xx}(\tau) \exp(-j\omega\tau) d\tau \quad (30.12)$$

$$R_{xx}(\tau) = \int_{-\infty}^{\infty} S_{xx}(\omega) \exp(j\omega\tau) d\omega \quad (30.13)$$

According to this theorem, if either of $S_{xx}(\omega)$ or $R_{xx}(\tau)$ has been found, the other can be directly obtained.

If stationary random processes $x(t)$ and $y(t)$ are both ergodic, then their cross-correlation function can be computed in terms of their sample functions $\hat{x}(t)$ and $\hat{y}(t)$:

$$R_{xy}(\tau) = \lim_{T \rightarrow \infty} \frac{1}{T} \int_{-T/2}^{T/2} \hat{x}(t) \hat{y}(t + \tau) dt \quad (30.14)$$

$$R_{yx}(\tau) = \lim_{T \rightarrow \infty} \frac{1}{T} \int_{-T/2}^{T/2} \hat{y}(t) \hat{x}(t + \tau) dt \quad (30.15)$$

Also, their cross-PSD functions can be defined by means of the Fourier transforms of the corresponding cross-correlation functions:

$$S_{xy}(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{xy}(\tau) \exp(-i\omega\tau) d\tau \quad (30.16)$$

$$S_{yx}(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{yx}(\tau) \exp(-i\omega\tau) d\tau \quad (30.17)$$

For more details, see Lin (1967).

30.1.1.2 Nonstationary Random Process

Nonstationary random processes are generally short in duration. Their basic characteristic is that the statistical properties vary significantly with time. An example is the process of a typical earthquake record, for which the medium flat segment is often regarded as a stationary random process in order to simplify the structural analysis. However, such simplification sometimes causes significant errors. For instance, some long-span bridges are very flexible, with fundamental periods of approximately 15 to 20 sec. The period of the strong earthquake portion of a typical earthquake record is only approximately 20 to 30 sec. For such slender long-span bridges, the seismic excitations exhibit clear nonstationary characteristics. In order to avoid computational complexities in the structural analyses, such excitations are usually assumed to be stationary random processes. This chapter shows that the analysis of such nonstationary random responses is made very simple by using PEM.

Nonstationary random processes are not ergodic because their statistical properties vary with time. In earthquake engineering, the evolutionary random process defined by Priestly (1967) has been investigated extensively. It is expressed in terms of the Riemann–Stieltjes integration as

$$f(t) = \int_{-\infty}^{\infty} A(\omega, t) \exp(i\omega t) d\alpha(\omega) \quad (30.18)$$

in which $\alpha(\omega)$ satisfies the relations

$$x(t) = \int_{-\infty}^{\infty} \exp(i\omega t) d\alpha(\omega) \quad (30.19)$$

$$E[d\alpha^*(\omega_1) d\alpha(\omega_2)] = S_{xx}(\omega_1) \delta(\omega_2 - \omega_1) d\omega_1 d\omega_2 \quad (30.20)$$

Here, $x(t)$ is a zero-mean stationary random process, with auto-PSD $S_{xx}(\omega)$, $A(\omega, t)$ is a deterministic slowly varying nonuniform modulation function, and δ is a Dirac delta function. The variance of $f(t)$ is

$$\sigma_f^2(t) = \int_{-\infty}^{\infty} S_{ff}(\omega) d\omega = \int_{-\infty}^{\infty} |A(\omega, t)|^2 S_{xx}(\omega) d\omega \quad (30.21)$$

The PSD of $f(t)$ as given by

$$S_{ff}(\omega, t) = |A(\omega, t)|^2 S_{xx}(\omega) \quad (30.22)$$

is known as an evolutionary power spectral density function.

Responses of structures subjected to nonstationary random excitations expressed by Equation 30.18 are not easy to compute. Therefore, the nonuniform modulation assumption is often replaced by a uniform modulation assumption; that is, the nonuniform modulation function $A(\omega, t)$ is replaced by a uniform modulation function $g(t)$. Thus, Equation 30.18 reduces to

$$f(t) = \int_{-\infty}^{\infty} g(t) \exp(i\omega t) dZ(\omega) = g(t)x(t) \quad (30.23)$$

FIGURE 30.3 A uniformly modulated evolutionary random excitation $f(t)$.

Equation 30.18 and Equation 30.23 are known as the nonuniformly modulated and uniformly modulated evolutionary random processes, respectively.

Figure 30.3 shows a stationary random process $x(t)$ and the corresponding uniformly modulated evolutionary random excitation $f(t)$ with a given modulation function $g(t)$.

30.1.2 Three Methods for Structural Seismic Analysis

30.1.2.1 Response Spectrum Method

The equations of motion of a linear multi-DoF structure subjected to a ground acceleration excitation $\ddot{x}_g(t)$ can be written as (see Chapter 3 and Chapter 8)

$$\mathbf{M}\ddot{\mathbf{y}} + \mathbf{C}\dot{\mathbf{y}} + \mathbf{K}\mathbf{y} = -\mathbf{M}\mathbf{e}\ddot{x}_g(t) \quad (30.24)$$

in which \mathbf{M} , \mathbf{C} , and \mathbf{K} are the $n \times n$ mass, damping, and stiffness matrices of the structure, and \mathbf{e} is the index vector of inertia forces. For short-span structures, all supports can be assumed to move uniformly with the same ground acceleration $\ddot{x}_g(t)$. If the structure under consideration has a very large number of DoF, Equation 30.24 can be solved by using the mode-superposition scheme (see Chapter 3). First, the lowest q natural angular frequencies ω_j ($j = 1, 2, \dots, q, q \ll n$) and the corresponding $n \times q$ mass normalized mode matrix Φ should be extracted. Then, $\mathbf{y}(t)$ can be decomposed in terms of these modes:

$$\mathbf{y}(t) = \Phi \mathbf{u}(t) = \sum_{j=1}^q u_j \boldsymbol{\varphi}_j \quad (30.25)$$

With proportional damping assumed (see Chapter 3 and Chapter 19), Equation 30.24 can be decoupled into q single-DoF equations

$$\ddot{u}_j + 2s_j\omega_j\dot{u}_j + \omega_j^2 u_j = -\gamma_j\ddot{x}_g(t) \quad (30.26)$$

in which s_j is the j th damping ratio and γ_j is the j th modal participation factor

$$\gamma_j = \boldsymbol{\varphi}_j^T \mathbf{M} \mathbf{e} \quad (30.27)$$

According to the response spectrum theory, the solution of Equation 30.26 is

$$u_j = \gamma_j \alpha_j g / \omega_j^2 \quad (30.28)$$

in which g is the gravity acceleration and α_j is the value of the ground acceleration response spectrum (ARS) at frequency ω_j . If the k th element of \mathbf{y} , denoted as y_k , is required, then the k th elements of all \mathbf{y}_j ($j = 1, 2, \dots, q$) are taken to compose a vector \mathbf{y}_k , which is then used in the computation of the response (or demand) y_k :

$$y_k = \sqrt{\mathbf{y}_k^T \mathbf{R}_c \mathbf{y}_k} \quad (30.29)$$

Here, \mathbf{R}_c is the correlation matrix representing the degree of correlation between all participating modes. Based on random-vibration theory, Wilson and Kiureghian (1981) have derived the expression for its elements as

$$R_{ij} = \frac{8\sqrt{\xi_i \xi_j}(\xi_i + r\xi_j)r^{3/2}}{(1 - r^2)^2 + 4\xi_i \xi_j r(1 + r^2) + 4(\xi_i^2 + \xi_j^2)r^2} \quad (30.30)$$

in which $r = \omega_j/\omega_i$. This is the widely used Complete Quadratic Combination (CQC) algorithm in the RSM. If the correlation coefficients between all modes are neglected, that is, if $R_{ij} = \delta_{ij}$ (Dirac delta function), then \mathbf{R}_c becomes a unity (identity) matrix and Equation 30.29 reduces to the square root of the sum of squares (SRSS) algorithm.

The RSM, as outlined above, is very popular in the seismic analysis of short-span structures. Some extensions have been published (Lee and Penzien, 1983; Dumanoglu and Severn, 1990; Lin et al., 1990;

Berrah and Kausel, 1992; Kiureghian and Neuenhofer, 1992; Ernesto and Vanmarcke, 1994) in order to deal with the seismic analysis of long-span structures. However, the efficiency and accuracy still need further improvement before they can be widely accepted in engineering practice.

30.1.2.2 Time-History Method

Assume that all supports move uniformly with the same acceleration $\ddot{x}_g(t)$, which is now given in a discrete numerical form. Equation 30.24 can now be solved using the Newmark method, the Wilson- θ method (Clough and Penzien, 1993), or the precise integration method (Zhong and Williams, 1995). In these THMs, the structural parameters can be modified at any time. Therefore, this method is good for nonlinear problems for which structural parameters often vary with time, for example in seismic elastoplastic analysis. A major disadvantage of THMs is that the computational results rely heavily on the selected ground acceleration records. In general, a number of records must be selected for structural analyses, and statistical results are then used in the designs. In order to reduce the computational effort, usually only about three to ten records are used for statistical purposes.

When the wave passage effect needs to be taken into account, the same ground acceleration record is applied to different supports with time lags and this generates \ddot{x}_b on the right-hand side of Equation 30.78. If the incoherence effect between the supports must also be considered, then the process for generating \ddot{x}_b becomes rather complicated (Deodatis, 1990). In fact, real records of this type are difficult to find.

30.1.2.3 Random Vibration Method

The random vibration approach is appealing for seismic random analysis of long-span structures. Previously, because of its high complexity and low efficiency, it was not accepted as a method of analysis by practicing engineers. However, this situation has changed considerably in recent years. Let us still begin with Equation 30.24, which we can also apply to structures subjected to uniform stationary random ground excitations. Now $\ddot{x}_g(t)$ is a zero-mean Gaussian stationary random process with a known auto-PSD $S_a(\omega)$ representing acceleration excitations uniformly applied to all supports of the structure. By means of the modal superposition scheme, that is, Equation 30.25 to Equation 30.27, the traditional CQC method can be established (Clough and Penzien, 1993):

$$S_{yy}(\omega) = \sum_{j=1}^q \sum_{k=1}^q \gamma_j \gamma_k \boldsymbol{\varphi}_j \boldsymbol{\varphi}_k^T H_j^*(\omega) H_k(\omega) S_a(\omega) \quad (30.31)$$

in which $\boldsymbol{\varphi}_j$ and γ_j are the j th mode and the j th modal participation factor, and

$$H_j = (\omega_j^2 - \omega^2 + 2i\zeta_j\omega\omega_j)^{-1} \quad (30.32)$$

is the j th frequency-response function. For a real long-span bridge, the number of structural DoF n usually ranges from 10^3 to 10^4 , and the numbers of ω and q typically range from 10^2 to 10^3 . Equation 30.31 includes all quadratic terms of the participating modes, and it must be repeatedly computed for dozens or hundreds of frequencies. Although it is a simple form of excitation, the computational effort is still considerable. Therefore, in engineering practice, the following SRSS method obtained by neglecting all $j \neq k$ terms in Equation 30.31, is generally used in place of the above CQC method:

$$S_{yy}(\omega) = \sum_{j=1}^q \gamma_j^2 \boldsymbol{\varphi}_j \boldsymbol{\varphi}_j^T |H_j(\omega)|^2 S_a(\omega) \quad (30.33)$$

This is frequently recommended in academic literature. The SRSS formula is an approximation of Equation 30.31 that neglects the cross-correlation terms between participating modes, thereby reducing the computational effort to about $1/q$ of that required by Equation 30.31. However, this approximation can be used only for lightly damped structures for which the participating frequencies must be sparsely spaced. For most structures (in particular their three-dimensional structural models), some participating frequencies are often closely spaced. Hence, the applicability of the SRSS approximation is

somewhat questionable. It will be seen in the next section that PEM will produce results identical to those from Equation 30.31 with much less computational effort.

The random-vibration analysis outlined above is executed in terms of power spectral densities in the frequency domain and therefore it is also referred to as the power-spectrum method.

A diagonal element $S_{\xi\xi}$ in the PSD matrix represents the auto-PSD of a random response ξ . Assume that this response is significant only within the frequency domain $\omega \in [\omega_L, \omega_U]$. Thus, the i th spectral moment of ξ can be computed by

$$\lambda_i = 2 \int_0^\infty \omega^i S_{\xi\xi}(\omega) d\omega \approx 2 \int_{\omega_L}^{\omega_U} \omega^i S_{\xi\xi}(\omega) d\omega \quad (30.34)$$

The PSD values at the negative frequencies do not have any intuitive physical significance and so the single-sided PSD $G_{xx}(\omega)$ is defined for applications in many engineering fields:

$$G_{xx}(\omega) = \begin{cases} 2S_{xx}(\omega) & \omega \geq 0 \\ 0 & \omega < 0 \end{cases} \quad (30.35)$$

Thus, Equation 30.34 becomes

$$\lambda_i = \int_0^\infty \omega^i G_{\xi\xi}(\omega) d\omega \approx \int_{\omega_L}^{\omega_U} \omega^i G_{\xi\xi}(\omega) d\omega \quad (30.36)$$

For general multiple input ($\mathbf{x}(t) = \{x_1(t), x_2(t), \dots, x_n(t)\}^T$) and multiple output ($\mathbf{y}(t) = \{y_1(t), y_2(t), \dots, y_m(t)\}^T$) problems (or MIMO problems), the response (i.e., output) PSD matrix $\mathbf{S}_{yy}(\omega)$ can be computed using the excitation (i.e., input) PSD matrix $\mathbf{S}_{xx}(\omega)$:

$$\mathbf{S}_{yy}(\omega) = \mathbf{H}^* \mathbf{S}_{xx}(\omega) \mathbf{H}^T \quad (30.37)$$

in which \mathbf{H} is the frequency-response function matrix. Also, the cross-PSD matrices between the excitations and responses can be computed from

$$\mathbf{S}_{xy}(\omega) = \mathbf{S}_{xx}(\omega) \mathbf{H}^T \quad (30.38)$$

$$\mathbf{S}_{yx}(\omega) = \mathbf{H}^* \mathbf{S}_{xx}(\omega) \quad (30.39)$$

Equation 30.37 to Equation 30.39 have simple forms and are comparatively convenient for engineering applications. However, they must be executed for dozens or hundreds of discrete frequencies. For complex structures, such matrix operations may require extensive effort. PEM, which will be introduced in the next section, is a better alternative than these equations.

If the first N modes are used in the modal superposition analysis, numerical tests for seven bridges show that taking $[\omega_L, \omega_U] = [0.7\omega_1, 1.2\omega_N]$ seems to be a good choice for the integration interval, where ω_1 and ω_N are the first and the N th natural angular frequencies of the structure.

It is inconvenient for engineers to take such spectral moments for practical designs. However, some approaches have been suggested to estimate structural responses (or demands) in terms of these spectral moments. Two popular approaches are described next.

30.1.2.3.1 Davenport Approach

With the seismic excitations assumed to be zero-mean stationary Gaussian processes, an arbitrary linear response of the structure subjected to such excitations, denoted $y(t)$, will also possess the same probability characteristic. It is also assumed that if a given barrier (threshold) a is sufficiently high, the peaks of $y(t)$ above this barrier will appear independently. Let $N(t)$ be the number of upcrossing of a within the time interval $(0, t]$, then $N(t)$ will be a Poisson process with a stationary increment (Davenport, 1961). Denote the extreme value of $y(t)$, that is, the maximum value of all peaks by their absolute values, within the earthquake duration $[0, T_s]$ as y_e , and the standard deviation of $y(t)$ as σ_y . Define η as the dimensionless parameter of y_e , and ν as the mean zero-crossing rate, which can be

expressed as

$$\eta = y_e/\sigma_y, \quad \nu = \sqrt{\lambda_2/\lambda_0}/\pi \quad (30.40)$$

Based on these assumptions, the probability distribution of η can be derived as

$$P(\eta) = \exp[-\nu T_s \exp(-\eta^2/2)], \quad \eta > 0 \quad (30.41)$$

The expected value of η , known as the peak factor, is approximately given by

$$E(\eta) \approx (2 \ln \nu T_s)^{1/2} + \gamma/(2 \ln \nu T_s)^{1/2} \quad (30.42)$$

and its standard deviation is

$$\sigma_\eta \approx \pi/(12 \ln \nu T_s)^{1/2} \quad (30.43)$$

in which $\gamma = 0.5772$ is the Euler constant, while the expected value of y_e is approximately

$$E[y_e] = E[\eta]\sigma_y \quad (30.44)$$

This quantity is the demand usually required by engineers.

30.1.2.3.2 Vanmarcke Approach

In the preceding paragraph, the barrier a was assumed to be sufficiently high. Therefore, the peaks of $y(t)$ above this barrier will appear independently, and $N(t)$ can be regarded as a Poisson process. Vanmarcke (1972) considered that the barrier a should not be very high. Therefore, the Poisson process assumption should be replaced by the two-state Markov process assumption and the probability distribution of η becomes

$$P(\eta) = \left[1 - \exp\left(-\frac{\eta^2}{2}\right) \right] \exp\left[-\nu T_s \frac{1 - \exp(-\sqrt{\pi/2} q^{1.2} \eta)}{\exp(\eta^2/2) - 1} \right] \quad (30.45)$$

in which ν and T_s have the same meanings as the above, while the shape factor for the response PSD is

$$\delta_0 = (1 - \lambda_1^2/(\lambda_0 \lambda_2))^{1/2} \quad (30.46)$$

Here, δ_0 is a bandwidth parameter with values ranging from zero to one. For a narrowband process, δ_0 is close to zero. Based on the probability distribution function shown in Equation 30.45, Kiureghian (1980) proposes the following approximate expressions for the peak factor $E(\eta)$ and standard deviation σ_η when $10 \leq \nu\tau \leq 1000$ and $0.11 \leq q \leq 1$, which are of interest in earthquake engineering:

$$E(\eta) = (2 \ln \nu_e T_s)^{1/2} + \frac{\gamma}{(2 \ln \nu_e T_s)^{1/2}} \quad (30.47)$$

$$\sigma_\eta = \begin{cases} \frac{1.2}{(2 \ln \nu_e T_s)^{1/2}} - \frac{5.4}{13 + (2 \ln \nu_e T_s)^{3.2}} & \nu_e T_s > 2.1 \\ 0.65 & \nu_e T_s \leq 2.1 \end{cases} \quad (30.48)$$

in which

$$\nu_e = \begin{cases} (1.63q^{0.45} - 0.38)\nu_0 & \delta_0 < 0.69 \\ \nu_0 & \delta_0 \geq 0.69 \end{cases} \quad (30.49)$$

Gupta and Trifunac (1998) made numerical experiments to compare the above two models using 1000 simulated time-history excitations. Their research shows that for most practical purposes in earthquake engineering studies, the effect of the dependence among level crossings is not significant.

30.1.2.4 Comparisons of the Three Seismic-Analysis Methods

The RSM is the most popular method for the seismic analysis of short-span structures. Some extensions have been made to allow this method to be used in the seismic analysis of long-span structures.

However, the accuracy and efficiency still need further improvement for practical applications. The THM can be used in the seismic analysis of long-span structures without theoretical difficulties. However, its major disadvantages are that it requires a good selection of the ground acceleration record samples and its computational cost is very high. The random-vibration method is appealing because of its statistical nature. In the past, the random vibration computation of complex structures has been very costly. This issue has received much attention in the last two decades. As will be described below, PEM has remarkably improved this situation. Now, long-span structures with thousands of DoF and dozens of supports can be computed far more quickly and accurately on a personal computer.

30.2 Seismic Random-Excitation Fields

30.2.1 Power Spectral Density of Spatially Varying Ground Acceleration

For multiple excitation problems, the PSD matrices of ground acceleration excitations have the form

$$\mathbf{S}_{xx}(i\omega) = \begin{bmatrix} S_{\ddot{x}_1\ddot{x}_1}(i\omega) & S_{\ddot{x}_1\ddot{x}_2}(i\omega) & \cdots & S_{\ddot{x}_1\ddot{x}_N}(i\omega) \\ S_{\ddot{x}_2\ddot{x}_1}(i\omega) & S_{\ddot{x}_2\ddot{x}_2}(i\omega) & \cdots & S_{\ddot{x}_2\ddot{x}_N}(i\omega) \\ \cdots & \cdots & \cdots & \cdots \\ S_{\ddot{x}_N\ddot{x}_1}(i\omega) & S_{\ddot{x}_N\ddot{x}_2}(i\omega) & \cdots & S_{\ddot{x}_N\ddot{x}_N}(i\omega) \end{bmatrix} \quad (30.50)$$

in which

$$S_{\ddot{x}_k\ddot{x}_l}(i\omega) = \rho_{kl}(i\omega) \sqrt{S_{\ddot{x}_k}(\omega) S_{\ddot{x}_l}(\omega)} \quad (30.51)$$

$$\rho_{kl}(i\omega) = |\rho_{kl}(i\omega)| \exp[i\theta_{kl}(\omega)] \quad (30.52)$$

and $\rho_{kl}(i\omega)$ is the acceleration coherence function between the k th and l th supports. Its norm must satisfy the relation $|\rho_{kl}(i\omega)| \leq 1$. The values of $S_{\ddot{x}_k}(\omega)$ and $S_{\ddot{x}_l}(\omega)$ in Equation 30.51 can be different due to local effects. However, earthquake records show that the structural responses due to the difference between $S_{\ddot{x}_k}(\omega)$ and $S_{\ddot{x}_l}(\omega)$ are in general of relatively low significance. The factor $\exp[i\theta_{kl}(\omega)]$ expresses the wave passage effect, which can be further expressed as

$$\exp[i\theta_{kl}(\omega)] = \exp[-i\omega d_{kl}^L/v_{\text{app}}] \quad (30.53)$$

in which d_{kl} is the horizontal distance between the two supports; d_{kl}^L is the projection of d_{kl} along the propagation direction of the seismic waves; and v_{app} is the apparent velocity of seismic waves along the surface. Assume that the time lags between the supports and the origin of the reference coordinate system are t_1, t_2, \dots, t_N , respectively. Without losing generality, let $t_l \geq t_k$ (when $l > k$). Then $d_{kl}^L/v_{\text{app}} = t_l - t_k$, and so Equation 30.53 becomes

$$\exp[i\theta_{kl}(\omega)] = \exp[i\omega(t_k - t_l)] \quad (30.54)$$

The factor $|\rho_{kl}(i\omega)|$ reflects the incoherence effect (Kiureghian and Neuenhofer, 1992). Some mathematical models of $\rho_{kl}(i\omega)$ have been established based on practical earthquake records, which will be shown in the next section. Using Equation 30.51 to Equation 30.54, Equation 30.50 can be written as

$$\mathbf{S}(i\omega) = \mathbf{B}^* \mathbf{J} \mathbf{R} \mathbf{J} \mathbf{B} \quad (30.55)$$

in which

$$\mathbf{B} = \text{diag}[\exp(-i\omega t_1), \exp(-i\omega t_2), \dots, \exp(-i\omega t_N)] \quad (30.56)$$

$$\mathbf{J} = \text{diag}[\sqrt{S_{\ddot{x}_1}}, \sqrt{S_{\ddot{x}_2}}, \dots, \sqrt{S_{\ddot{x}_N}}] \quad (30.57)$$

$$\mathbf{R} = \begin{bmatrix} 1 & |\rho_{12}| & \cdots & |\rho_{1N}| \\ |\rho_{21}| & 1 & \cdots & |\rho_{2N}| \\ \cdots & \cdots & \cdots & \cdots \\ |\rho_{N1}| & |\rho_{N2}| & \cdots & 1 \end{bmatrix} \quad (30.58)$$

30.2.2 Several Coherence Models

A number of coherence models have been established based on practical earthquake records. Some of them are outlined below.

30.2.2.1 Feng–Hu Model

$$|\rho_{kl}(\omega, d_{kl})| = \exp[-(\rho_1 \omega + \rho_2) d_{kl}] \quad (30.59)$$

in which ρ_1 and ρ_2 are the coherence parameters. According to the Hai-Cheng earthquake records (China) and the Niigata earthquake records (Japan), the values of these parameters are (Feng and Hu, 1981):

Hai-Cheng: $\rho_1 = 2 \times 10^{-5} \text{ sec/m}$, $\rho_2 = 88 \times 10^{-4} \text{ m}^{-1}$

Niigata: $\rho_1 = 4 \times 10^{-4} \text{ sec/m}$, $\rho_2 = 19 \times 10^{-4} \text{ m}^{-1}$

30.2.2.2 Harichandran–Vanmarcke Model

$$|\rho_{kl}(\omega, d_{kl})| = A \exp\left[-\frac{2d}{\alpha\theta(\omega)}(1 - A + \alpha A)\right] + (1 - A) \exp\left[-\frac{2d}{\alpha\theta(\omega)}(1 - A + \alpha A)\right] \quad (30.60)$$

in which

$$\theta(\omega) = K[1 + (\omega/\omega_0)^b]^{-1/2} \quad (30.61)$$

According to the acceleration records of the SMART-1 array (Harichandran and Vanmarcke, 1986), the parameters in Equations 30.60 and Equations 30.61 are: $A = 0.736$, $\alpha = 0.147$, $K = 5210$, $\omega_0 = 6.85 \text{ rad/sec}$, $b = 2.78$.

30.2.2.3 Loh–Yeh Model

$$|\rho_{kl}(\omega, d_{kl})| = \exp\left[-\alpha \frac{\omega d_{kl}}{2\pi v_{\text{app}}}\right] \quad (30.62)$$

in which α is the wave-number of the seismic waves. According to the 40 acceleration records of the SMART-1 array (Loh and Yeh, 1988), $\alpha = 0.125$ is proposed. Parameters v_{app} and d_{kl} have been explained above.

30.2.2.4 Oliveira–Hao–Penzien Model

$$|\rho_{kl}(\omega, d_{kl})| = \exp(-\beta_1 d_{kl}^L - \beta_2 d_{kl}^T) \exp(-[\alpha_1 \sqrt{d_{kl}^L} - \alpha_2 \sqrt{d_{kl}^T}](\omega/2\pi)^2) \quad (30.63)$$

in which $\alpha_i = (2\pi a_i/\omega) + (\omega b_i/2\pi) + c_i$. d_{kl}^L and d_{kl}^T are the projections of d_{kl} along the propagation direction of the seismic waves and along its normal direction, respectively. Based on 17 acceleration records of the SMART-1 array (Oliveira et al., 1991), parameters $\beta_1, \beta_2, a_1, a_2, b_1, b_2, c_1$, and c_2 are given for each of these records.

30.2.2.5 Luco–Wong Model

$$|\rho_{kl}| = \exp \left[- \left(\frac{\alpha \omega d_{kl}}{v_s} \right)^2 \right] \quad (30.64)$$

in which α is the coherence factor, d_{kl} is the horizontal distance between the k th and l th supports and v_s is the shear wave velocity (Luco and Wong, 1986).

30.2.2.6 Qu–Wang–Wang Model

T. Qu, J. Wang, and Q. Wang (QWW) (Qu et al., 1996) proposed the following model

$$|\rho_{kl}| = \exp \left[-a(\omega) d_{kl}^{b(\omega)} \right] \quad (30.65)$$

in which

$$a(\omega) = a_1 \omega^2 + a_2, \quad b(\omega) = b_1 \omega + b_2 \quad (30.66)$$

$a_1 = 0.00001678$, $a_2 = 0.001219$, $b_1 = -0.0055$, $b_2 = 0.7674$. This model was established based on the statistics of dozens of records from four closely located arrays with SMART-1 as the leading one. This model has given reasonable results in some applications in China.

30.2.3 Generation of Ground Acceleration Power Spectral Density Curves from Acceleration Response Spectrum Curves

In order to carry out the seismic random vibration analysis of important long-span bridges, the local seismic motion PSD (usually the acceleration PSD) must be established by specialists. For bridges of less importance, however, such seismic acceleration PSD can be derived from the local ARS curve. Two methods to perform the transformation are given below.

30.2.3.1 Kaul Method

Kaul (1978) proposed an approximate transformation method that consists of the two equations

$$S(\omega_0) = \frac{4\xi R_a^2(\xi, \omega_0)}{\pi \omega_0 r^2} \quad (30.67)$$

$$r^2 = 2 \ln \left[\left(-\frac{\pi}{\omega_0 T_s} \ln p \right)^{-1} \right] \quad (30.68)$$

in which $R_a(\xi, \omega_0)$ is the ARS curve of the seismic absolute acceleration when the damping ratio is ξ and the natural angular frequency is ω_0 (usually ξ takes 0.05); $S(\omega_0)$ is the equivalent PSD curve corresponding to the given ARS curve; T_s is the seismic duration; and p is the probability of the peaks that do not cross with the given positive or negative barriers — usually $p = 0.85$ is assumed.

30.2.3.2 Iteration Scheme

An iteration-based scheme for the transformation has been proposed (Sun and Jiang, 1990), which produces more accurate equivalent PSD curve than the Kaul method. For a given ARS curve $R_a(\xi, \omega_0)$, in order to transform it into an equivalent PSD curve $S(\omega)$, specify its initial values $S^0(\omega_i) = S_i$, for $i = 1, 2, \dots, N$. Then the standard deviation of the acceleration response for a SDOF system can be computed from

$$\sigma_0(\xi, \omega_0) = \left[\int_0^\infty S(\omega) \frac{1 + 4\xi^2(\omega/\omega_0)^2}{(1 - (\omega/\omega_0)^2)^2 + 4\xi^2(\omega/\omega_0)^2} d\omega \right]^{1/2} \quad (30.69)$$

The peak factor r is

$$r = \sqrt{2 \ln(vT_s)} + 0.5772 / \sqrt{2 \ln(vT_s)} \quad (30.70)$$

in which T_s is the period of the strong earthquake portion. The average zero-crossing rate is approximately $\nu = \sqrt{\lambda_2/\lambda_0}/\pi \approx \omega_0/\pi$.

The acceleration responses computed by means of Equation 30.69 and Equation 30.70 are

$$A_m(\xi, \omega_0) = r\sigma_0(\xi, \omega_0) \quad (30.71)$$

The percentage errors between $R_a(\xi, \omega_0)$ and $A_m(\xi, \omega_0)$ can be computed from

$$E(\omega_0) = \frac{|R_a(\xi, \omega_0) - A_m(\xi, \omega_0)|}{R_a(\xi, \omega_0)} \times 100\% \quad (30.72)$$

Compute $E(\omega_0)$ for each frequency. If $E(\omega_0)$ is found to be greater than the given tolerance ε for at least one frequency, modify all PSD values according to the following equation

$$S^{k+1}(\omega_i) = S^k(\omega_i)R_a^2(\xi, \omega_i)/A_m^2(\xi, \omega_i), \quad i = 1, 2, \dots, N \quad (30.73)$$

and then repeat the computations of Equation 30.69 to Equation 30.72. The above process is continued until Equation 30.72 is satisfied at all frequencies.

30.2.4 Seismic Equations of Motion of Long-Span Structures

For long-span structures subjected to differential ground motion, the equations of motion in the global coordinate system (assumed to be fixed to the center of the Earth) can be written in partitioned form as

$$\begin{bmatrix} \mathbf{M}_s & \mathbf{M}_{sb} \\ \mathbf{M}_{sb}^T & \mathbf{M}_b \end{bmatrix} \begin{Bmatrix} \ddot{\mathbf{x}}_s \\ \ddot{\mathbf{x}}_b \end{Bmatrix} + \begin{bmatrix} \mathbf{C}_s & \mathbf{C}_{sb} \\ \mathbf{C}_{sb}^T & \mathbf{C}_b \end{bmatrix} \begin{Bmatrix} \dot{\mathbf{x}}_s \\ \dot{\mathbf{x}}_b \end{Bmatrix} + \begin{bmatrix} \mathbf{K}_s & \mathbf{K}_{sb} \\ \mathbf{K}_{sb}^T & \mathbf{K}_b \end{bmatrix} \begin{Bmatrix} \mathbf{x}_s \\ \mathbf{x}_b \end{Bmatrix} = \begin{Bmatrix} \mathbf{0} \\ \mathbf{p}_b \end{Bmatrix} \quad (30.74)$$

in which the subscript m represents the master DoF, that is, the support displacements, while the subscript s represents the slave DoF. The absolute displacement vector \mathbf{x}_s can be decomposed into the two parts

$$\mathbf{x}_s = \mathbf{y}_s + \mathbf{y}_r \quad (30.75)$$

where \mathbf{y}_s is the quasi-static displacement vector (Clough and Penzien, 1993), which satisfies

$$\mathbf{y}_s = -\mathbf{K}_s^{-1}\mathbf{K}_{sb}\mathbf{x}_b \quad (30.76)$$

Substituting Equation 30.75 and Equation 30.76 into Equation 30.74 gives

$$\mathbf{M}_s\ddot{\mathbf{y}}_r + \mathbf{C}_s\dot{\mathbf{y}}_r + \mathbf{K}_s\mathbf{y}_r = \mathbf{M}_s\mathbf{K}_s^{-1}\mathbf{K}_{sb}\ddot{\mathbf{x}}_b + (\mathbf{C}_s\mathbf{K}_s^{-1}\mathbf{K}_{sb} - \mathbf{C}_{sb})\dot{\mathbf{x}}_b \quad (30.77)$$

It should be pointed out that Equation 30.77 cannot be reduced to the conventional Equation 30.24 when \mathbf{x}_b represents uniform ground displacements (Clough and Penzien, 1993). This is because Equation 30.74 assumes the damping forces to be proportional to the absolute velocity vector $\{\dot{\mathbf{x}}_s^T, \dot{\mathbf{x}}_b^T\}^T$. In order to avoid this inconsistency, the damping forces should be assumed to be proportional to the relative velocity vector $\{\dot{\mathbf{y}}_r^T, 0\}^T$ in Equation 30.74. This leads to the equations

$$\mathbf{M}_s\ddot{\mathbf{y}}_r + \mathbf{C}_s\dot{\mathbf{y}}_r + \mathbf{K}_s\mathbf{y}_r = \mathbf{M}_s\mathbf{K}_s^{-1}\mathbf{K}_{sb}\ddot{\mathbf{x}}_b \quad (30.78)$$

for uniform ground motion

$$\ddot{\mathbf{x}}_b = \mathbf{e}_b\ddot{\mathbf{x}}_g \quad (30.79)$$

Note that the following rigid displacement condition is satisfied:

$$\begin{bmatrix} \mathbf{K}_s & \mathbf{K}_{sb} \\ \mathbf{K}_{sb}^T & \mathbf{K}_b \end{bmatrix} \begin{Bmatrix} \mathbf{e}_s \\ \mathbf{e}_b \end{Bmatrix} = \begin{Bmatrix} \mathbf{0} \\ \mathbf{0} \end{Bmatrix} \quad (30.80)$$

Its second half gives

$$\mathbf{K}_{sb}\mathbf{e}_b = -\mathbf{K}_s\mathbf{e}_s \quad (30.81)$$

Substituting Equation 30.79 into Equation 30.78 and using Equation 30.81 gives Equation 30.24.

30.2.5 Seismic Waves and Their Geometrical Expressions

Seismic waves can be divided into body waves and surface waves. Body waves include longitudinal waves (or pressure waves, primary waves or P waves) and transverse waves (or shear waves, secondary waves or S waves). Surface waves include Rayleigh waves and Love waves. For P waves, the soil particles move parallel to the traveling direction of waves; for S waves, however, their motion is normal to the wave traveling direction (see Figure 30.4). For horizontal shear waves (SH waves), all particles move horizontally. For vertical shear waves (SV waves), all particles move vertically.

Assume that both x and y axes lie in the horizontal plane. The angle between axis x and the horizontal traveling direction of these waves is β , as shown in Figure 30.5. Thus, the acceleration components along the coordinate axes can be expressed by the components parallel, or normal, to the wave traveling direction, that is, for P waves

$$\begin{aligned} \ddot{x}_i &= \ddot{u}_i \cos \beta, & \ddot{y}_i &= \ddot{u}_i \sin \beta, \\ \ddot{z}_i &= 0 \end{aligned} \quad (30.82)$$

for SH waves

$$\begin{aligned} \ddot{x}_i &= -\ddot{u}_j \sin \beta, & \ddot{y}_i &= \ddot{u}_j \cos \beta, \\ \ddot{z}_i &= 0 \end{aligned} \quad (30.83)$$

and for SV waves

$$\ddot{x}_i = 0, \quad \ddot{y}_i = 0, \quad \ddot{z}_i = \ddot{u}_k \quad (30.84)$$

In the equations of motion of an multi-DoF system under uniform ground excitations, that is, Equation 30.24, \mathbf{e} is the index vector of inertia forces. Its mathematical expressions for the different waves are:

for P waves

$$\mathbf{e} = \mathbf{e}_x \cos \beta + \mathbf{e}_y \sin \beta \quad (30.85)$$

for SH waves

$$\mathbf{e} = -\mathbf{e}_x \sin \beta + \mathbf{e}_y \cos \beta \quad (30.86)$$

for SV waves

$$\mathbf{e} = \mathbf{e}_z \quad (30.87)$$

Clearly, for P waves, $\mathbf{e} = \mathbf{e}_x$ when $\beta = 0$ and $\mathbf{e} = \mathbf{e}_y$ when $\beta = 90^\circ$.

FIGURE 30.4 Particle motion directions for P and S waves.

FIGURE 30.5 Transform of ground acceleration components.

If a structure has N supports, its ground acceleration excitations along the wave traveling direction can be expressed by the N -dimensional vector

$$\ddot{\mathbf{u}}_b = \{\ddot{u}_1, \ddot{u}_2, \dots, \ddot{u}_N\}^T \quad (30.88)$$

The m -dimensional ground acceleration vector in Equation 30.78 is

$$\ddot{\mathbf{x}}_b = \{\ddot{x}_1, \ddot{x}_2, \dots, \ddot{x}_m\}^T \quad (30.89)$$

The relation between these two vectors is

$$\ddot{\mathbf{x}}_b = \mathbf{E}_{mN} \ddot{\mathbf{u}}_b \quad (30.90)$$

in which \mathbf{E}_{mN} is a $m \times N$ block-diagonal matrix

$$\mathbf{E}_{mN} = \text{diag}[\mathbf{e}_\beta, \mathbf{e}_\beta, \dots, \mathbf{e}_\beta]_{m \times N} \quad (30.91)$$

If only three translations are considered for each support, then $m = 3N$ and each submatrix \mathbf{e}_β would be

$$\begin{Bmatrix} \cos \beta \\ \sin \beta \\ 0 \end{Bmatrix}, \begin{Bmatrix} -\sin \beta \\ \cos \beta \\ 0 \end{Bmatrix} \text{ and } \begin{Bmatrix} 0 \\ 0 \\ 1 \end{Bmatrix}$$

for the P, SH and SV waves, respectively.

Using Equation 30.90, Equation 30.76 and Equation 30.78 can be rewritten as

$$\mathbf{y}_s = -\mathbf{K}_s^{-1} \mathbf{K}_{sb} \mathbf{E}_{mN} \mathbf{u}_b \quad (30.92)$$

$$\mathbf{M}_s \ddot{\mathbf{y}}_r + \mathbf{C}_s \dot{\mathbf{y}}_r + \mathbf{K}_s \mathbf{y}_r = \mathbf{M}_s \mathbf{K}_s^{-1} \mathbf{K}_{sb} \mathbf{E}_{mN} \ddot{\mathbf{u}}_b \quad (30.93)$$

30.3 Pseudoexcitation Method for Structural Random Vibration Analysis

30.3.1 Structures Subjected to Stationary Random Excitations

30.3.1.1 Single Stationary Random Excitations

The basic principle of the PEM for structural stationary random vibration analysis can be explained by Figure 30.6. Consider a linear system subjected to a zero-mean stationary random excitation $x(t)$

FIGURE 30.6 Basic principle of pseudoexcitation method (stationary analysis).

(see Figure 30.6a) and with a given PSD $S_{xx}(\omega)$. Suppose that for two arbitrarily selected responses $y(t)$ and $z(t)$, the auto-PSD $S_{yy}(\omega)$ and cross-PSD $S_{yz}(\omega)$ are desired. Figure 30.6b gives the conventional formulas for computing these PSD functions. $H_y(\omega)$ and $H_z(\omega)$ are the frequency-response functions, that is, if $x(t)$ is replaced by a sinusoidal excitation $\exp(i\omega t)$, the harmonic responses of $y(t)$ and $z(t)$ would be $H_y(\omega)\exp(i\omega t)$ and $H_z(\omega)\exp(i\omega t)$, respectively. Thus, if $x(t)$ is replaced by a sinusoidal excitation (Lin et al., 1994b)

$$\tilde{x} = \sqrt{S_{xx}(\omega)}\exp(i\omega t) \quad (30.94)$$

the responses of $y(t)$ and $z(t)$ would be $\tilde{y} = \sqrt{S_{xx}(\omega)}H_y(\omega)\exp(i\omega t)$ and $\tilde{z} = \sqrt{S_{xx}(\omega)}H_z(\omega)\exp(i\omega t)$ (see Figure 30.6c). It can be readily verified that

$$\tilde{y}^*\tilde{y} = \sqrt{S_{xx}(\omega)}H_y^*(\omega)\exp(-i\omega t)\sqrt{S_{xx}(\omega)}H_y(\omega)\exp(i\omega t) = |H_y(\omega)|^2 S_{xx}(\omega) = S_{yy}(\omega) \quad (30.95)$$

$$\tilde{y}^*\tilde{z} = \sqrt{S_{xx}(\omega)}H_y^*(\omega)\exp(-i\omega t)\sqrt{S_{xx}(\omega)}H_z(\omega)\exp(i\omega t) = H_y^*(\omega)S_{xx}(\omega)H_z(\omega) = S_{yz}(\omega) \quad (30.96)$$

If $\mathbf{y}(t)$ and $\mathbf{z}(t)$ are two arbitrarily selected random response vectors of the structure, and $\tilde{\mathbf{y}} = \mathbf{a}_y\exp(i\omega t)$ and $\tilde{\mathbf{z}} = \mathbf{a}_z\exp(i\omega t)$ are the corresponding harmonic response vectors due to the pseudo-excitation (30.94), it can also be proven that the PSD matrices of $\mathbf{y}(t)$ and $\mathbf{z}(t)$ are

$$\mathbf{S}_{yy}(\omega) = \tilde{\mathbf{y}}^*\tilde{\mathbf{y}}^T = \mathbf{a}_y^*\mathbf{a}_y^T \quad (30.97)$$

$$\mathbf{S}_{yz}(\omega) = \tilde{\mathbf{y}}^*\tilde{\mathbf{z}}^T = \mathbf{a}_y^*\mathbf{a}_z^T \quad (30.98)$$

This means that the auto- and cross-PSD functions of two arbitrarily selected random responses can be computed using the corresponding pseudoharmonic responses.

Now, consider a structure subjected to a single seismic random excitation. Its equations of motion are

$$\mathbf{M}\ddot{\mathbf{y}} + \mathbf{C}\dot{\mathbf{y}} + \mathbf{K}\mathbf{y} = -\mathbf{M}\mathbf{e}\ddot{x}_g(t) \quad (30.99)$$

in which the ground acceleration $\ddot{x}_g(t)$ is a stationary random process. Its PSD $S_{\ddot{x}_g}(\omega)$ is known and \mathbf{e} is a given constant vector, indicating the distribution of inertia forces. In order to solve Equation 30.99, let the pseudoground acceleration be

$$\ddot{x}_g(t) = \sqrt{S_{\ddot{x}_g}(\omega)}\exp(i\omega t) \quad (30.100)$$

then Equation 30.99 becomes

$$\mathbf{M}\ddot{\tilde{\mathbf{y}}} + \mathbf{C}\dot{\tilde{\mathbf{y}}} + \mathbf{K}\tilde{\mathbf{y}} = -\mathbf{M}\mathbf{e}\sqrt{S_{\ddot{x}_g}(\omega)}\exp(i\omega t) \quad (30.101)$$

and its stationary solution is

$$\tilde{\mathbf{y}}(t) = \mathbf{a}_y(\omega)\exp(i\omega t) \quad (30.102)$$

Using its first q normalized modes for mode-superposition, then (Clough and Penzien, 1993)

$$\mathbf{a}_y(\omega) = \sum_{j=1}^q \gamma_j H_j \boldsymbol{\phi}_j \sqrt{S_{xx}(\omega)} \quad (30.103)$$

in which ω_j , $\boldsymbol{\phi}_j$, \mathbf{s}_j , H_j and γ_j are the j th natural angular frequency, mass normalized mode, damping ratio, frequency-response function, and mode participation factor, respectively. According to PEM, the PSD matrix of \mathbf{y} is

$$\mathbf{S}_{yy}(\omega) = \tilde{\mathbf{y}}^*\tilde{\mathbf{y}}^T = \mathbf{a}_y^*(\omega)\mathbf{a}_y^T(\omega) \quad (30.104)$$

Substituting Equation 30.102 into Equation 30.104 and expanding it also gives Equation 30.31. This means these two equations are mathematically identical. However, the computational effort required by Equation 30.104 is approximately only $1/q^2$ of that required by Equation 30.31. Therefore, Equation 30.104 is also known as the fast CQC algorithm (Lin, 1992).

Example 30.1 Derivation of the Kanai–Tajimi PSD Formula

Consider the system shown in Figure 30.7(a). The single-layered homogeneous soil and the super single-DoF structure can be modeled by the system of Figure 30.7(b). Assume that the horizontal acceleration of the bedrock \ddot{x}_0 is a stationary random process with white noise spectrum S_0 . The ground displacement relative to the bedrock is y , and the displacement of the superstructure (assumed to be an single-DoF system) relative to the ground is x . The effective horizontal shear-resistant stiffness of the soil layer is k_g , while the corresponding damping coefficient is c_g . Assuming that m is very small in comparison with the equivalent ground mass m_g , then the equation of motion of the effective ground mass is

$$m_g \ddot{y} + c_g \dot{y} + k_g y = -m_g \ddot{x}_0 \quad (\text{i})$$

or

$$\ddot{y} + 2\varsigma_g \omega_g \dot{y} + \omega_g^2 y = -\ddot{x}_0 \quad (\text{ii})$$

in which $\omega_g^2 = k_g/m_g$, $2\varsigma_g \omega_g = c_g/m_g$.

Now, form the horizontal pseudoacceleration for the bedrock

$$\ddot{x}_0 = \sqrt{S_0} \exp(i\omega t) \quad (\text{iii})$$

Substituting it into Equation ii gives

$$\ddot{y} + 2\varsigma_g \omega_g \dot{y} + \omega_g^2 y = -\sqrt{S_0} \exp(i\omega t) \quad (\text{iv})$$

Its right-hand side is harmonic. Therefore, the stationary solution of \tilde{y} is

$$\tilde{y} = \frac{-\sqrt{S_0}}{\omega_g^2 - \omega^2 + 2i\varsigma_g \omega_g \omega} \exp(i\omega t) \quad (\text{v})$$

The pseudoabsolute displacement of the ground is

$$\tilde{x}_g = \tilde{x}_0 + \tilde{y} \quad (\text{vi})$$

The corresponding pseudoabsolute acceleration is

$$\ddot{\tilde{x}}_g = \ddot{\tilde{x}}_0 + \ddot{\tilde{y}} = \sqrt{S_0} \exp(i\omega t) \left[1 + \frac{\omega^2}{\omega_g^2 - \omega^2 + 2i\varsigma_g \omega_g \omega} \right] = \sqrt{S_0} \exp(i\omega t) \frac{\omega_g^2 + 2i\varsigma_g \omega_g \omega}{\omega_g^2 - \omega^2 + 2i\varsigma_g \omega_g \omega} \quad (\text{vii})$$

Using PEM, the PSD of $\ddot{\tilde{x}}_g$ is

$$S_{\ddot{\tilde{x}}_g}(\omega) = \ddot{\tilde{x}}_g^* \ddot{\tilde{x}}_g = S_0 \frac{\omega_g^4 + 4\varsigma_g^2 \omega_g^2 \omega^2}{(\omega_g^2 - \omega^2)^2 + 4\varsigma_g^2 \omega_g^2 \omega^2} \quad (\text{viii})$$

This is exactly the Kanai–Tajimi filtered white noise spectrum formula (Clough and Penzien, 1993).

FIGURE 30.7 Structural modeling for Kanai–Tajimi PSD formula.

30.3.1.2 Multiple Stationary Random Excitations

Consider a linear structure subjected to a number of stationary random excitations, which are denoted as an m -dimensional stationary random process vector $\mathbf{x}(t)$ with known PSD matrix $\mathbf{S}_{xx}(\omega)$. It is a Hermitian matrix and so it can be decomposed, for example, by using its eigenpairs $\boldsymbol{\psi}_j$ and d_j ($j = 1, 2, \dots, r$), into

$$\mathbf{S}_{xx}(\omega) = \sum_{j=1}^r d_j \boldsymbol{\psi}_j^* \boldsymbol{\psi}_j^T \quad (r \leq m) \quad (30.105)$$

in which r is the rank of $\mathbf{S}_{xx}(\omega)$. Next, form the r pseudoharmonic excitations

$$\tilde{\mathbf{x}}_j(t) = \sqrt{d_j} \boldsymbol{\psi}_j \exp(i\omega t) \quad (j = 1, 2, \dots, r) \quad (30.106)$$

By applying each of these pseudoharmonic excitations, two arbitrarily selected response vectors $\mathbf{y}_j(t)$ and $\mathbf{z}_j(t)$ of the structure, which can be displacements, internal forces, or other linear responses, may be easily obtained and expressed as

$$\tilde{\mathbf{y}}_j(t) = \mathbf{a}_{yj}(\omega) \exp(i\omega t) \quad (30.107)$$

$$\tilde{\mathbf{z}}_j(t) = \mathbf{a}_{zj}(\omega) \exp(i\omega t) \quad (30.108)$$

The corresponding PSD matrices can be computed by means of the following formulas (Lin et al., 1994a; Zhong, 2004):

$$\mathbf{S}_{yy}(\omega) = \sum_{j=1}^r \tilde{\mathbf{y}}_j^*(t) \tilde{\mathbf{y}}_j^T(t) = \sum_{j=1}^r \mathbf{a}_{yj}^*(\omega) \mathbf{a}_{yj}^T(\omega) \quad (30.109)$$

$$\mathbf{S}_{yz}(\omega) = \sum_{j=1}^r \tilde{\mathbf{y}}_j^*(t) \tilde{\mathbf{z}}_j^T(t) = \sum_{j=1}^r \mathbf{a}_{yj}^*(\omega) \mathbf{a}_{zj}^T(\omega) \quad (30.110)$$

The method used to decompose $\mathbf{S}_{xx}(\omega)$ into the form of Equation 30.105 is not unique. In fact, the Cholesky scheme is perhaps the most efficient and convenient way to do it; that is, $\mathbf{S}_{xx}(\omega)$ is decomposed into

$$\mathbf{S}_{xx}(\omega) = \mathbf{L}^* \mathbf{D} \mathbf{L}^T = \sum_{j=1}^r d_j \mathbf{l}_j^* \mathbf{l}_j^T \quad (r \leq m) \quad (30.111)$$

in which \mathbf{L} is a lower triangular matrix with all its diagonal elements equal to unity and \mathbf{D} is a real diagonal matrix with r nonzero diagonal elements d_j . The implementation of Cholesky decomposition for a Hermitian matrix is very similar to that for a real symmetric matrix (Wilkinson and Reinsch, 1971).

Example 30.2 A Massless Trolley Subjected to Excitations with Phase-Lags

The massless trolley shown in Figure 30.8 is connected to two abutments by springs and viscous dashpots (linear viscous dampers) as shown. The abutments move distances $x_1(t)$ and $x_2(t)$ with spectral densities S_0 (constant), but $x_2(t) = x_1(t - T)$, in which T is a fixed time difference. The response spectral density of the trolley displacement $S_{yy}(\omega)$ is to be determined. The equation of motion of the trolley is (Newland, 1975)

$$(c_1 + c_2)\dot{y} + (k_1 + k_2)y = k_1 x_1 + c_1 \dot{x}_1 + k_2 x_2 + c_2 \dot{x}_2 \quad (i)$$

Since the PSD of $x_1(t)$ is S_0 , the pseudoexcitation corresponding to $x_1(t)$ is

$$\tilde{x}_1(t) = \sqrt{S_0} \exp(i\omega t) \quad (ii)$$

Because $x_2(t) = x_1(t - T)$, we have

$$\tilde{x}_2(t) = \sqrt{S_0} \exp[i\omega(t - T)] \quad (\text{iii})$$

Clearly

$$\dot{\tilde{x}}_1(t) = i\omega\sqrt{S_0} \exp(i\omega t), \quad (\text{iv})$$

$$\dot{\tilde{x}}_2(t) = i\omega\sqrt{S_0} \exp[i\omega(t - T)]$$

Substituting the above equations into Equation i gives the harmonic equation

$$\begin{aligned} (c_1 + c_2)\dot{\tilde{y}} + (k_1 + k_2)\tilde{y} \\ = [(k_1 + i\omega c_1) + (k_2 + i\omega c_2) \\ \exp(-i\omega T)] \exp(i\omega t) \end{aligned} \quad (\text{v})$$

Its solution can be readily obtained as

$$\tilde{y} = \frac{k_1 + i\omega c_1 + (k_2 + i\omega c_2) \exp(-i\omega T)}{k_1 + k_2 + i\omega(c_1 + c_2)} \exp(i\omega t) \quad (\text{vi})$$

Hence,

$$S_{yy} = \tilde{y}^* \tilde{y} = \frac{k_1^2 + k_2^2 + c_1^2 \omega^2 + c_2^2 \omega^2 + 2(k_1 k_2 + c_1 c_2 \omega^2) \cos \omega T + 2(k_1 c_2 \omega - k_2 c_1 \omega) \sin \omega T}{(k_1 + k_2)^2 + (c_1 + c_2)^2 \omega^2} S_0 \quad (\text{vii})$$

This result is identical to that given by Newland (1975). However, the process given here is quite simple.

FIGURE 30.8 Two-phase input trolley.

30.3.2 Structures Subjected to Nonstationary Random Vibration

30.3.2.1 Structures Subjected to Uniformly Modulated Evolutionary Random Excitations

30.3.2.1.1 Single Excitation Problems

The basic principle of the PEM for nonstationary random vibration analyses can be described by Figure 30.9. Consider a linear system subjected to an evolutionary random excitation (see Figure 30.9a)

$$f(t) = g(t)x(t) \quad (30.112)$$

in which $g(t)$ is a slowly varying modulation function, while $x(t)$ is a zero-mean stationary random process with auto-PSD $S_{xx}(\omega)$. The deterministic functions $g(t)$ and $S_{xx}(\omega)$ are both assumed to be given.

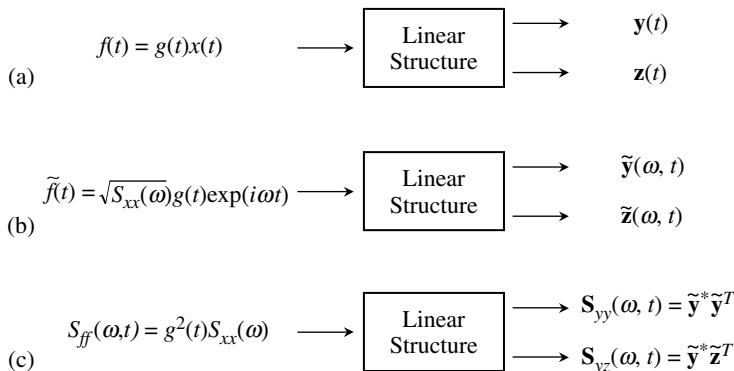

FIGURE 30.9 Basic principle of pseudoexcitation method (nonstationary analysis).

The auto-PSD of $f(t)$ (see Figure 30.9b) is

$$S_{ff}(\omega, t) = g^2(t)S_{xx}(\omega) \quad (30.113)$$

In order to compute the PSD functions of various linear responses due to the action of $f(t)$, we note that the pseudoexcitation has the form

$$\tilde{f}(\omega, t) = g(t)\sqrt{S_{xx}(\omega)}\exp(i\omega t) \quad (30.114)$$

Now suppose that $\mathbf{y}(t)$ and $\mathbf{z}(t)$ are two arbitrarily selected response vectors (see Figure 30.9a) and $\tilde{\mathbf{y}}(\omega, t)$ and $\tilde{\mathbf{z}}(\omega, t)$ are the corresponding transient responses due to the pseudoexcitation $\tilde{f}(\omega, t)$ with the structure initially at rest (see Figure 30.9b). It has been proven (Lin et al., 1994a; Lin et al., 2004) that the desired PSD matrices of $\mathbf{y}(t)$ and $\mathbf{z}(t)$ are

$$\mathbf{S}_{yy}(\omega, t) = \tilde{\mathbf{y}}^*(\omega, t)\tilde{\mathbf{y}}^T(\omega, t) \quad (30.115)$$

$$\mathbf{S}_{yz}(\omega, t) = \tilde{\mathbf{y}}^*(\omega, t)\tilde{\mathbf{z}}^T(\omega, t) \quad (30.116)$$

as shown in Figure 30.9c.

Now, consider the Equation 30.99 of a linear structure subjected to the evolutionary random excitation $\ddot{x}_g(t) = g(t)x(t)$. The pseudoground acceleration is now $\ddot{x}_g(t) = g(t)\sqrt{S_{xx}(\omega)}\exp(i\omega t)$. Substituting this into the right-hand side of Equation 30.99 gives the deterministic equations

$$\mathbf{M}\ddot{\tilde{\mathbf{y}}} + \mathbf{C}\dot{\tilde{\mathbf{y}}} + \mathbf{K}\tilde{\mathbf{y}} = -\mathbf{M}\mathbf{e}g(t)\sqrt{S_{xx}(\omega)}\exp(i\omega t) \quad (30.117)$$

For seismic problems, the structure is initially at rest, that is, $\tilde{\mathbf{y}} = \dot{\tilde{\mathbf{y}}} = 0$ when $t = 0$. Thus, the time history of $\tilde{\mathbf{y}}(\omega, t)$ can be computed using the Newmark or Wilson- θ schemes. Furthermore, any other linear pseudo response vectors, denoted as $\tilde{\mathbf{u}}(\omega, t)$ and $\tilde{\mathbf{v}}(\omega, t)$, can be computed from $\tilde{\mathbf{y}}(\omega, t)$. The response PSD matrices of $\mathbf{u}(t)$ and $\mathbf{v}(t)$ can also be accurately computed by using their pseudoresponses $\tilde{\mathbf{u}}(\omega, t)$ and $\tilde{\mathbf{v}}(\omega, t)$

$$\mathbf{S}_{uu}(\omega, t) = \tilde{\mathbf{u}}^*(\omega, t)\tilde{\mathbf{u}}^T(\omega, t) \quad (30.118)$$

$$\mathbf{S}_{uv}(\omega, t) = \tilde{\mathbf{u}}^*(\omega, t)\tilde{\mathbf{v}}^T(\omega, t) \quad (30.119)$$

Example 30.3 Single-Degree of Freedom System Subjected to Suddenly Applied Stationary Random Excitation

Consider the following single-DoF example, which was first given by Caughey and Stumpf (1961) and has been widely used to compare the efficiency and precision of various methods:

$$\ddot{y} + 2\varsigma\omega_0\dot{y} + \omega_0^2y = f(t) = g(t)x(t), \quad y(0) = \dot{y}(0) = 0 \quad (i)$$

in which

$$g(t) = \begin{cases} 1.0 & t \geq 0 \\ 0 & t < 0 \end{cases} \quad (ii)$$

and $x(t)$ is a zero-mean-valued stationary random process with its PSD $S_{xx}(\omega)$ given. Now, constitute a pseudo excitation

$$\tilde{f}(t) = \sqrt{S_{xx}(\omega)}\exp(i\omega t) \quad (t \geq 0) \quad (iii)$$

Thus, the motion equation that should be solved is

$$\ddot{y} + 2\varsigma\omega_0\dot{y} + \omega_0^2y = \sqrt{S_{xx}(\omega)}\exp(i\omega t), \quad \tilde{y}(0) = \dot{\tilde{y}}(0) = 0 \quad (iv)$$

The solution of this simple equation is

$$\tilde{y}(\omega, t) = H \left\{ \exp(i\omega t) - \exp(-\varepsilon t) \left[\cos \omega_e t + \frac{i\omega + \varepsilon}{\omega_e} \sin \omega_e t \right] \right\} \sqrt{S_{xx}(\omega)} \quad (\text{v})$$

in which

$$H = (\omega_0^2 - \omega^2 + 2i\varsigma\omega_0\omega)^{-1}, \quad \varepsilon = \varsigma\omega_0, \quad \omega_e = \omega_0\sqrt{1 - \varsigma^2} \quad (\text{vi})$$

Therefore, the auto-PSD of y is

$$S_{yy}(\omega, t) = \tilde{y}^* \tilde{y} = |\tilde{y}|^2 = |H|^2 \left\{ \left[\exp(-\varepsilon t) \left(\frac{\varepsilon}{\omega_e} \sin \omega_e t + \cos \omega_e t \right) - \cos \omega t \right]^2 + \left[\exp(-\varepsilon t) \frac{\omega}{\omega_e} \sin \omega_e t - \sin \omega t \right]^2 \right\} S_{xx}(\omega) \quad (\text{vii})$$

This result is identical to the exact solution given by Caughey and Stumpf (1961), who used a more complicated process and expressed it less concisely as

$$S_{yy}(\omega, t) = |H|^2 [1 + \exp(-2\varepsilon t)] \left[1 + \frac{2\omega_0}{\omega_e} \varsigma \sin \omega_e t \cos \omega_e t - \exp(\varepsilon t) \left(2 \cos \omega_e t + \frac{2\omega_0}{\omega_e} \varsigma \sin \omega_e t \right) \cos \omega t - \exp(\varepsilon t) \frac{2\omega}{\omega_e} \sin \omega_e t \sin \omega t + \frac{(\omega_0 \varsigma)^2 - \omega_e^2 + \omega^2}{\omega_e^2} \sin^2 \omega_e t \right] S_{xx}(\omega) \quad (\text{viii})$$

30.3.2.1.2 Multiple Excitation Problems

Fully coherent excitations. In order to include the phase-lags between ground excitations, that is, the wave passage effect, the evolutionary random excitation vector $\mathbf{f}(t)$ to which the structure is subjected should be

$$\mathbf{f}(t) = \begin{Bmatrix} F_1(t) \\ F_2(t) \\ \vdots \\ F_n(t) \end{Bmatrix} = \begin{Bmatrix} a_1 g(t - t_1) F(t - t_1) \\ a_2 g(t - t_2) F(t - t_2) \\ \vdots \\ a_n g(t - t_n) F(t - t_n) \end{Bmatrix} = \mathbf{G}(t) \bar{\mathbf{f}}(t) \quad (30.120)$$

in which

$$\mathbf{G}(t) = \begin{bmatrix} a_1 g(t - t_1) & & & \\ & a_2 g(t - t_2) & & \\ & & \ddots & \\ & & & a_n g(t - t_n) \end{bmatrix}, \quad \bar{\mathbf{f}}(t) = \begin{Bmatrix} F(t - t_1) \\ F(t - t_2) \\ \vdots \\ F(t - t_n) \end{Bmatrix} \quad (30.121)$$

Here, all components of $\bar{\mathbf{f}}(t)$ clearly have the same form, although there are time lags $t_j (j = 1, 2, \dots, n)$ between them; $g(t)$ is the modulation function; $a_j (j = 1, 2, \dots, n)$ are given real numbers; and t_j are given constants. $F(t)$ is a stationary random process, of which the auto-PSD $S_{FF}(\omega)$ is known. The pseudo-excitations corresponding to $\{\mathbf{f}(t)\}$ are (Lin and Zhang, 2004)

$$\tilde{\mathbf{f}}(t) = \mathbf{G}(t) \mathbf{V} \mathbf{q}_0 \sqrt{S_{FF}(\omega)} \exp(i\omega t) \quad (30.122)$$

in which

$$\mathbf{R}_0 = \mathbf{q}_0 \mathbf{q}_0^T = \begin{bmatrix} 1 & 1 & \cdots & 1 \\ 1 & 1 & \cdots & 1 \\ \vdots & \vdots & \ddots & \vdots \\ 1 & 1 & \cdots & 1 \end{bmatrix} \quad (30.123)$$

$$\mathbf{V} = \text{diag}[\exp(-i\omega t_1), \exp(-i\omega t_2), \dots, \exp(-i\omega t_n)]$$

$$\mathbf{q}_0^T = \{1, 1, \dots, 1\}$$

The excitation PSD matrix can be written as

$$\mathbf{S}_{ff}(\omega, t) = \tilde{\mathbf{f}}^*(t) \tilde{\mathbf{f}}^T(t) = S_{FF}(\omega) \mathbf{G}(t) \mathbf{V}^* \mathbf{q}_0 \mathbf{q}_0^T \mathbf{V}^T \mathbf{G}^T(t) = S_{FF}(\omega) \times \begin{bmatrix} g^2(t-t_1) & g(t-t_1)g(t-t_2)\exp(i\omega(t_1-t_2)) & \cdots & g(t-t_1)g(t-t_n)\exp(i\omega(t_1-t_n)) \\ g(t-t_2)g(t-t_1)\exp(i\omega(t_2-t_1)) & g^2(t-t_2) & \cdots & g(t-t_2)g(t-t_n)\exp(i\omega(t_2-t_n)) \\ \vdots & \vdots & \ddots & \vdots \\ g(t-t_n)g(t-t_1)\exp(i\omega(t_n-t_1)) & g(t-t_n)g(t-t_2)\exp(i\omega(t_n-t_2)) & \cdots & g^2(t-t_n) \end{bmatrix} \quad (30.124)$$

An arbitrarily chosen response $\tilde{\mathbf{y}}_k(\omega, t_k)$ excited by $\tilde{\mathbf{f}}(t)$ can be computed using a numerical integration scheme and the results can be expressed as

$$\tilde{\mathbf{y}}_k(\omega, t_k) = \mathbf{a}_{yk}(\omega, t) \sqrt{S_{FF}(\omega)} \quad (30.125)$$

in which

$$\mathbf{a}_{yk}(\omega, t_k) = \int_0^{t_k} \mathbf{H}(t_k - \tau_k) \mathbf{G}(\tau_k) \mathbf{V} \mathbf{q}_0 \exp(i\omega \tau_k) d\tau_k \quad (30.126)$$

Here, $\mathbf{a}_{yk}(\omega, t)$ is the response excited by $\mathbf{G}(t) \mathbf{V} \mathbf{q}_0 \exp(i\omega t)$ and $\mathbf{H}(t)$ is the impulse-response function matrix. The cross-PSD matrix between $\mathbf{y}_k(t)$ and $\mathbf{y}_l(t)$ is

$$\mathbf{S}_{y_k y_l}(\omega, t) = \tilde{\mathbf{y}}_k^*(\omega, t) \tilde{\mathbf{y}}_l^T(\omega, t) \quad (30.127)$$

By letting $k = l$, the auto-PSD matrix of $\mathbf{y}_k(t)$ can be directly computed by Equation 30.127.

Partially coherent excitations. In addition to the time lags between excitations, if the arbitrary coherence between such nonstationary excitations is also taken into account, then the problem is more difficult. According to PEM, however, it is only required that the matrix \mathbf{R}_0 in Equation 30.123 is changed into

$$\mathbf{R} = \begin{bmatrix} 1 & \rho_{12} & \cdots & \rho_{1n} \\ \rho_{21} & 1 & \cdots & \rho_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ \rho_{n1} & \rho_{n2} & \cdots & 1 \end{bmatrix} \quad (30.128)$$

in which ρ_{ij} reflects the coherence between the excitations at points i and j , and matrix \mathbf{R} is usually symmetric and positive definite or semipositive definite. Denoting its rank as $r(r \geq 1)$, \mathbf{R} can be

expressed as

$$\mathbf{R} = \sum_{j=1}^r \alpha_j \boldsymbol{\Psi}_j^* \boldsymbol{\Psi}_j^T \quad (30.129)$$

This means that the global excitation PSD matrix is decomposed into r matrices with rank unity where the j th of them corresponds to the pseudoexcitation

$$\tilde{\mathbf{f}}_j(t) = \mathbf{G}(t) \mathbf{V} \boldsymbol{\Psi}_j \sqrt{\alpha_j S_{FF}(\omega)} \exp(i\omega t) \quad (30.130)$$

If $\tilde{\mathbf{y}}_{kj}(t)$ and $\tilde{\mathbf{y}}_{lj}(t)$ are two arbitrary responses due to $\tilde{\mathbf{f}}_j(t)$, then

$$\mathbf{S}_{y_k y_l}(\omega, t) = \sum_{j=1}^r \tilde{\mathbf{y}}_{kj}^*(t) \tilde{\mathbf{y}}_{lj}^T(t) \quad (30.131)$$

By letting $k = l$, the auto-PSD matrix of $\mathbf{y}_k(t)$ can be directly computed by Equation 30.131.

30.3.2.2 Structures Subjected to Nonuniformly Modulated Evolutionary Random Excitations

30.3.2.2.1 Single Excitation Problems

Consider a nonuniformly modulated evolutionary random excitation $f(t)$ (Priestly, 1967)

$$f(t) = \int_{-\infty}^{\infty} A(\omega, t) \exp(i\omega t) d\alpha(\omega) \quad (30.132)$$

in which $A(\omega, t)$ is a given nonuniform modulation function and α satisfies the equation

$$E[d\alpha^*(\omega_1) d\alpha(\omega_2)] = S_{xx}(\omega) \delta(\omega_2 - \omega_1) d\omega_1 d\omega_2 \quad (30.133)$$

Here, $S_{xx}(\omega_1)$ is the auto-PSD of the stationary random process $x(t)$.

The Riemann–Stieltjes integration in Equation 30.132 causes difficulties in conventional computations. However, this problem can be conveniently solved using PEM as follows. First, constitute the following pseudoexcitation (Lin et al., 1997a, 1997b):

$$\tilde{f}(\omega, t) = A(\omega, t) \sqrt{S_{xx}(\omega)} \exp(i\omega t) \quad (30.134)$$

Second, replace $g(t)$ in Equation 30.117 by $A(\omega, t)$ to yield

$$\mathbf{M}\ddot{\tilde{\mathbf{y}}} + \mathbf{C}\dot{\tilde{\mathbf{y}}} + \mathbf{K}\tilde{\mathbf{y}} = -\mathbf{M}\mathbf{e}A(\omega, t)\sqrt{S_{xx}(\omega)}\exp(i\omega t) \quad (30.135)$$

Third, with the structure initially at rest, compute the time history, $\tilde{\mathbf{y}}(\omega, t)$, for any arbitrary frequency ω , and the required time histories $\tilde{\mathbf{u}}(\omega, t)$ and $\tilde{\mathbf{v}}(\omega, t)$. Finally, the PSD matrices of $\mathbf{u}(t)$ and $\mathbf{v}(t)$ can be computed from

$$\mathbf{S}_{uu}(\omega, t) = \tilde{\mathbf{u}}^*(\omega, t) \tilde{\mathbf{u}}^T(\omega, t) \quad (30.136)$$

$$\mathbf{S}_{uv}(\omega, t) = \tilde{\mathbf{u}}^*(\omega, t) \tilde{\mathbf{v}}^T(\omega, t) \quad (30.137)$$

Evidently, the PEM is nearly identical for uniformly or nonuniformly modulated evolutionary random excitations. The unique difference is the use of either $A(\omega, t)$ or $g(t)$ in the pseudoexcitation expressions, see Equation 30.114 and Equation 30.134.

30.3.2.2.2 Multiple Excitation Problems

For multiple nonstationary random excitation problems, the PEM-based analysis process for uniformly modulated evolutionary random excitations can be immediately extended to that for nonuniformly modulated evolutionary random excitations if the modulation function $g(t)$ is replaced by $A(\omega, t)$.

All other formulas remain exactly the same. The difference in computational effort from using different modulation functions is negligible.

30.3.3 Precise Integration Method

30.3.3.1 Precise Integration of Exponential Matrices

Structural equations of motion, for example, Equation 30.99, can be written as

$$\mathbf{M}\ddot{\mathbf{y}} + \mathbf{G}\dot{\mathbf{y}} + \mathbf{K}\mathbf{y} = \mathbf{f}(t) \quad (30.138)$$

in which \mathbf{M} , \mathbf{G} , and \mathbf{K} are given time-invariant $n \times n$ matrices, respectively, and $\mathbf{f}(t)$ is the given external force vector. The initial displacement $\mathbf{y}(t)$ and the initial velocity $\dot{\mathbf{y}}(t)$ of the system are specified. The equation of motion, Equation 30.138, combined with the identity $\dot{\mathbf{y}} = \dot{\mathbf{y}}$ leads to the first-order equations of motion in the state space being

$$\dot{\mathbf{v}} = \mathbf{H}\mathbf{v} + \mathbf{r} \quad (30.139)$$

in which

$$\mathbf{H} = \begin{bmatrix} \mathbf{0} & \mathbf{I} \\ \mathbf{B} & \mathbf{D} \end{bmatrix}, \quad \mathbf{v} = \begin{Bmatrix} \mathbf{y} \\ \dot{\mathbf{y}} \end{Bmatrix}, \quad \mathbf{r} = \begin{Bmatrix} \mathbf{0} \\ \mathbf{M}^{-1}\mathbf{f}(t) \end{Bmatrix}, \quad \mathbf{B} = -\mathbf{M}^{-1}\mathbf{K}, \quad \mathbf{D} = -\mathbf{M}^{-1}\mathbf{G} \quad (30.140)$$

The homogeneous solution of Equation 30.139 is

$$\mathbf{v}_h(t) = \mathbf{T}(\tau)\mathbf{c} \quad (30.141)$$

in which

$$\mathbf{T}(\tau) = \exp(\mathbf{H}\tau) \quad (30.142)$$

Consider the current integration interval $t \in [t_k, t_{k+1}]$, $\tau = t - t_k$. When $\tau = 0$ or $t = t_k$, $\mathbf{T}(\tau) = \mathbf{I}$ and, therefore, \mathbf{c} is a constant vector. If the particular solution to Equation 30.139, $\mathbf{v}_p(t)$, is temporarily assumed to have been found, then the general solution of Equation 30.139 is

$$\mathbf{v}(t) = \mathbf{T}(\tau)(\mathbf{v}(t_k) - \mathbf{v}_p(t_k)) + \mathbf{v}_p(t) \quad (30.143)$$

In order to compute $\mathbf{T}(\tau)$ accurately, it is desirable to subdivide the step τ into $m = 2^N$ equal intervals, that is,

$$\Delta t = \tau/m = 2^{-N}\tau \quad (30.144)$$

For application purposes, the use of $N = 20$ is sufficient, because it leads to $\Delta t \approx 10^{-6}\tau$. Such a small Δt is, in general, much smaller than the highest natural period of any practical discretized system.

Using the Taylor series expansion, we have

$$\exp(\mathbf{H} \times \Delta t) \approx \mathbf{I} + \mathbf{T}_{a0} \quad (30.145)$$

in which

$$\mathbf{T}_{a0} = (\mathbf{H} \times \Delta t) + (\mathbf{H} \times \Delta t)^2/2! + (\mathbf{H} \times \Delta t)^3/3! + (\mathbf{H} \times \Delta t)^4/4! \quad (30.146)$$

Substituting Equation 30.145 into Equation 30.142 gives

$$\mathbf{T}(\tau) = (\exp(\mathbf{H} \times \Delta t))^m = (\mathbf{I} + \mathbf{T}_{a0})^m \quad (30.147)$$

Note that

$$\mathbf{I} + \mathbf{T}_{ai} = (\mathbf{I} + \mathbf{T}_{a,i-1})^2 = (\mathbf{I} + 2 \times \mathbf{T}_{a,i-1} + \mathbf{T}_{a,i-1} \times \mathbf{T}_{a,i-1}), \quad (i = 1, 2, \dots, N) \quad (30.148)$$

so that

$$\mathbf{I} + \mathbf{T}_{aN} = (\mathbf{I} + \mathbf{T}_{a,N-1})^2 = (\mathbf{I} + \mathbf{T}_{a,N-2})^4 = \dots = (\mathbf{I} + \mathbf{T}_{a0})^m = \mathbf{T}(\tau) \quad (30.149)$$

Equation 30.148 and Equation 30.149 suggest the following computing strategy. In order to avoid the loss of significant digits in the matrix $\mathbf{T}(\tau)$, it is necessary to compute \mathbf{T}_{a1} directly from \mathbf{T}_{a0} , \mathbf{T}_{a2} directly from \mathbf{T}_{a1} , and so on, by using

$$\mathbf{T}_{ai} = 2 \times \mathbf{T}_{a,i-1} + \mathbf{T}_{a,i-1} \times \mathbf{T}_{a,i-1}, \quad (i = 1, 2, \dots, N) \quad (30.150)$$

Then $\mathbf{T}(\tau)$ should be computed from

$$\mathbf{T}(\tau) \approx \mathbf{I} + \mathbf{T}_{aN} \quad (30.151)$$

In Equation 30.151, the approximation is caused by the truncation of the Taylor expansion of Equation 30.146. It is generally negligibly small because when $N = 20$, the first term ignored by the truncation is of the order $O(\Delta t^5) = 10^{-30} O(\tau^5)$, which is on the order of the round-off errors of a typical computer.

30.3.3.2 Particular Solutions and Precise Integration Formulas for Various Forms of Loading

30.3.3.2.1 Linear Loading Form (HPD-L Form)

Assume that the loading varies linearly within the time step (t_k, t_{k+1}) , that is,

$$\mathbf{r} = \mathbf{r}_0 + \mathbf{r}_1 \times (t - t_0) \quad (30.152)$$

in which \mathbf{r}_0 and \mathbf{r}_1 are time-invariant vectors. The particular solution of Equation 30.139 is then (Lin et al., 1995a, 1995b; Zhong, 2004)

$$\mathbf{v}_p(t) = (\mathbf{H}^{-1} + \mathbf{I}t)(-\mathbf{H}^{-1}\mathbf{r}_1) - \mathbf{H}^{-1}(\mathbf{r}_0 - \mathbf{r}_1 t_k) \quad (30.153)$$

Substituting Equation 30.152 into Equation 30.143 gives the HPD-L (High Precision Direct integration-Linear) integration formula

$$\mathbf{v}(t_{k+1}) = \mathbf{T}(\tau)(\mathbf{v}(t_k) + \mathbf{H}^{-1}(\mathbf{r}_0 + \mathbf{H}^{-1}\mathbf{r}_1)) - \mathbf{H}^{-1}(\mathbf{r}_0 + \mathbf{H}^{-1}\mathbf{r}_1 + \mathbf{r}_1 \tau) \quad (30.154)$$

30.3.3.2.2 Sinusoidal Loading Form (HPD-S Form)

If the applied loading is sinusoidal within the time region $t \in (t_k, t_{k+1})$, then

$$\mathbf{r}(t) = \mathbf{r}_1 \sin \omega t + \mathbf{r}_2 \cos \omega t \quad (30.155)$$

in which \mathbf{r}_1 and \mathbf{r}_2 are time-invariant vectors. Substituting Equation 30.155 into Equation 30.139 enables the particular solution to be obtained (Lin et al., 1995a, 1995b; Zhong, 2004)

$$\mathbf{v}_p(t) = \mathbf{v}_1 \sin \omega t + \mathbf{v}_2 \cos \omega t \quad (30.156)$$

in which

$$\mathbf{v}_1 = (\omega \mathbf{I} + \mathbf{H}^2/\omega)^{-1}(\mathbf{r}_2 - \mathbf{H}\mathbf{r}_1/\omega) \quad \mathbf{v}_2 = (\omega \mathbf{I} + \mathbf{H}^2/\omega)^{-1}(-\mathbf{r}_1 - \mathbf{H}\mathbf{r}_2/\omega) \quad (30.157)$$

Substituting Equation 30.156 into Equation 30.143 gives the general solution of Equation 30.139, that is, the HPD-S direct integration formula

$$\mathbf{v}(t_{k+1}) = \mathbf{T}(\tau)(\mathbf{v}(t_k) - \mathbf{v}_1 \sin \omega t_k - \mathbf{v}_2 \cos \omega t_k) + \mathbf{v}_1 \sin \omega t_{k+1} + \mathbf{v}_2 \cos \omega t_{k+1} \quad (30.158)$$

The time interval $\tau = t_{k+1} - t_k$ can cover an arbitrary segment, or even many periods, of a sinusoidal wave because, no matter how large the step size may be, exact responses will be obtained provided the matrix $\mathbf{T}(\tau)$ has been generated accurately, without any instability occurring.

30.3.3.2.3 Exponentially Decaying Sinusoidal Loading Form (HPD-E Form)

Suppose that the applied loading varies according to the following exponentially decaying sinusoidal law within the time region $t \in (t_k, t_{k+1})$:

$$\mathbf{r}(t) = \exp(\alpha t)(\mathbf{r}_1 \sin \omega t + \mathbf{r}_2 \cos \omega t) \quad (30.159)$$

in which \mathbf{r}_1 and \mathbf{r}_2 are time-invariant vectors. Substituting Equation 30.159 into Equation 30.139 enables the particular solution to be obtained (Lin et al., 1995a, 1995b; Zhong, 2004) as

$$\mathbf{v}_p(t) = \exp(\alpha t)(\mathbf{v}_1 \sin \omega t + \mathbf{v}_2 \cos \omega t) \quad (30.160)$$

in which

$$\mathbf{v}_1 = ((\alpha \mathbf{I} - \mathbf{H}^2) + \omega^2 \mathbf{I})^{-1}((\alpha \mathbf{I} - \mathbf{H})\mathbf{r}_1 + \omega \mathbf{r}_2) \quad (30.161)$$

$$\mathbf{v}_2 = ((\alpha \mathbf{I} - \mathbf{H}^2) + \omega^2 \mathbf{I})^{-1}((\alpha \mathbf{I} - \mathbf{H})\mathbf{r}_2 - \omega \mathbf{r}_1)$$

Thus, substituting Equation 30.161 into Equation 30.143 gives the general solution of Equation 30.139, that is, the HPD-E direct integration formula

$$\mathbf{v}(t_{k+1}) = \mathbf{T}(\tau)(\mathbf{v}(t_k) - \exp(\alpha t_k)(\mathbf{v}_1 \sin \omega t_k + \mathbf{v}_2 \cos \omega t_k)) + \exp(\alpha t_{k+1})(\mathbf{v}_1 \sin \omega t_{k+1} + \mathbf{v}_2 \cos \omega t_{k+1}) \quad (30.162)$$

The time interval is $\tau = t_{k+1} - t_k$.

30.4 Long-Span Structures Subjected to Stationary Random Ground Excitations

30.4.1 The Solution of Equations of Motion Using the Pseudoexcitation Method

In Equation 30.93, the PSD matrix of $\ddot{\mathbf{u}}_b$, that is, $\mathbf{S}(i\omega)$ in Equation 30.55, is an N -dimensional Hermitian matrix, while \mathbf{R} is an N -dimensional real symmetric matrix. Both matrices are usually positive definite or semipositive definite. If the rank of \mathbf{R} is r ($r \leq N$), then by using Equation 30.111 it can be readily decomposed into the product of an $N \times r$ matrix \mathbf{Q} and its transposition; that is

$$\mathbf{R} = \mathbf{Q}\mathbf{Q}^T \quad (30.163)$$

Thus, Equation 30.55 can be written as

$$\mathbf{S}(i\omega) = \mathbf{B}^* \mathbf{J} \mathbf{Q} \mathbf{Q}^T \mathbf{J} \mathbf{B} = \mathbf{P}^* \mathbf{P}^T \quad (30.164)$$

in which

$$\mathbf{P} = \mathbf{B} \mathbf{J} \mathbf{Q} \quad (30.165)$$

To solve Equation 30.93, the right-hand side $\ddot{\mathbf{u}}_b$ can be replaced by the pseudoground acceleration

$$\ddot{\mathbf{U}}_b = \mathbf{P} \exp(i\omega t) \quad (30.166)$$

Thus, Equation 30.93 becomes the following sinusoidal equations of motion:

$$\mathbf{M}_s \ddot{\mathbf{Y}}_r + \mathbf{C}_s \dot{\mathbf{Y}}_r + \mathbf{K}_s \mathbf{Y}_r = \mathbf{M}_s \mathbf{K}_s^{-1} \mathbf{K}_{sb} \mathbf{E}_{mN} \mathbf{P} \exp(i\omega t) \quad (30.167)$$

The stable solution of Equation 30.167 is the pseudorelative displacement vector $\tilde{\mathbf{Y}}_r$, whilst the pseudostatic displacement vector $\tilde{\mathbf{Y}}_s$ can be computed by

$$\tilde{\mathbf{Y}}_s = \frac{1}{\omega^2} \mathbf{K}_s^{-1} \mathbf{K}_{sb} \mathbf{E}_{mN} \mathbf{P} \exp(i\omega t) \quad (30.168)$$

Thus, the pseudoabsolute displacement vector is

$$\tilde{\mathbf{X}}_s = \tilde{\mathbf{Y}}_r + \tilde{\mathbf{Y}}_s \quad (30.169)$$

If necessary, any arbitrary pseudointernal force vector $\tilde{\mathbf{N}}_s$ can be computed from $\tilde{\mathbf{X}}_s$ by means of a quasi-static analysis. Then, the corresponding PSD matrix is

$$\mathbf{S}_{N_s N_s}(\omega) = \tilde{\mathbf{N}}_s^* \tilde{\mathbf{N}}_s^T \quad (30.170)$$

If it is assumed that $S_{\ddot{x}_1} = S_{\ddot{x}_2} = \dots = S_{\ddot{x}_N}$, denoted as S_a , then Equation 30.165 becomes

$$\mathbf{P} = \sqrt{S_a} \mathbf{BQ} \quad (30.171)$$

If only the wave passage effect is considered, that is, all $|\rho_{ij}| = 1$ in Equation 30.58, then matrix \mathbf{Q} will reduce to a vector \mathbf{q}_0 with all its elements unity; that is

$$\mathbf{Q} = \mathbf{q}_0 = \{1, 1, \dots, 1\}^T \quad (30.172)$$

Thus, Equation 30.171 reduces to

$$\mathbf{P} = \sqrt{S_a} \mathbf{e}_0 \quad (30.173)$$

in which \mathbf{e}_0 is a complex vector

$$\mathbf{e}_0 = \{\exp(-i\omega t_1), \exp(-i\omega t_2), \dots, \exp(-i\omega t_N)\}^T \quad (30.174)$$

Therefore, when only the wave passage effect is considered, Equation 30.167 reduces to

$$\mathbf{M}_s \ddot{\mathbf{y}}_r + \mathbf{C}_s \dot{\mathbf{y}}_r + \mathbf{K}_s \mathbf{y}_r = \mathbf{M}_s \mathbf{K}_s^{-1} \mathbf{K}_{sb} \mathbf{E}_{mN} \mathbf{e}_0 \sqrt{S_a} \exp(i\omega t) \quad (30.175)$$

Furthermore, if the structure is subjected to a uniform ground motion, then the vector \mathbf{e}_0 in Equation 30.174 should be replaced by \mathbf{q}_0 , and so Equation 30.175 can be further reduced to

$$\mathbf{M}_s \ddot{\mathbf{y}}_r + \mathbf{C}_s \dot{\mathbf{y}}_r + \mathbf{K}_s \mathbf{y}_r = \mathbf{M}_s \mathbf{K}_s^{-1} \mathbf{K}_{sb} \mathbf{E}_{mN} \mathbf{q}_0 \sqrt{S_a} \exp(i\omega t) \quad (30.176)$$

30.4.2 Numerical Comparisons with Other Methods

30.4.2.1 Song-Hua-Jiang Suspension Bridge

The Song-Hua-Jiang suspension bridge (see Figure 30.10) is located in Jilin Province of China. Its overall length is 450 m, with a main span of 240 m and a width of 28 m. The finite element model had 2076 DoF, 445 nodes (including 12 supports) and 574 elements. The static equilibrium position of the bridge included the effects of the initial tensions of the cables. The earthquake action was determined based on the Chinese National Standard (Code for Seismic Design of Buildings GB 50011-2001), which directly gives the ground ARS curve for the bridge. The PSD curve was obtained in terms of the Kaul method from which the samples of the ground acceleration time-history can be produced (Kaul, 1978). For the analyses associated with the SH and SV waves, 100 modes were used for mode-superposition, whereas for the P waves, only 30 modes were used. The apparent wave speeds used were 3 km/s for P waves and 2 km/s for SH or SV waves.

FIGURE 30.10 Song-Hua-Jiang suspension bridge.

30.4.2.1.1 All Supports Move Uniformly

Figure 30.11(a) gives the axial force distribution of this bridge along the deck due to the seismic P waves, which travel along the longitudinal direction of the deck. All supports of the bridges are assumed to move uniformly. The following four computational models were used:

1. Response spectrum method
2. Pseudoexcitation method
3. Time-history method using three samples
4. Time-history method using ten samples

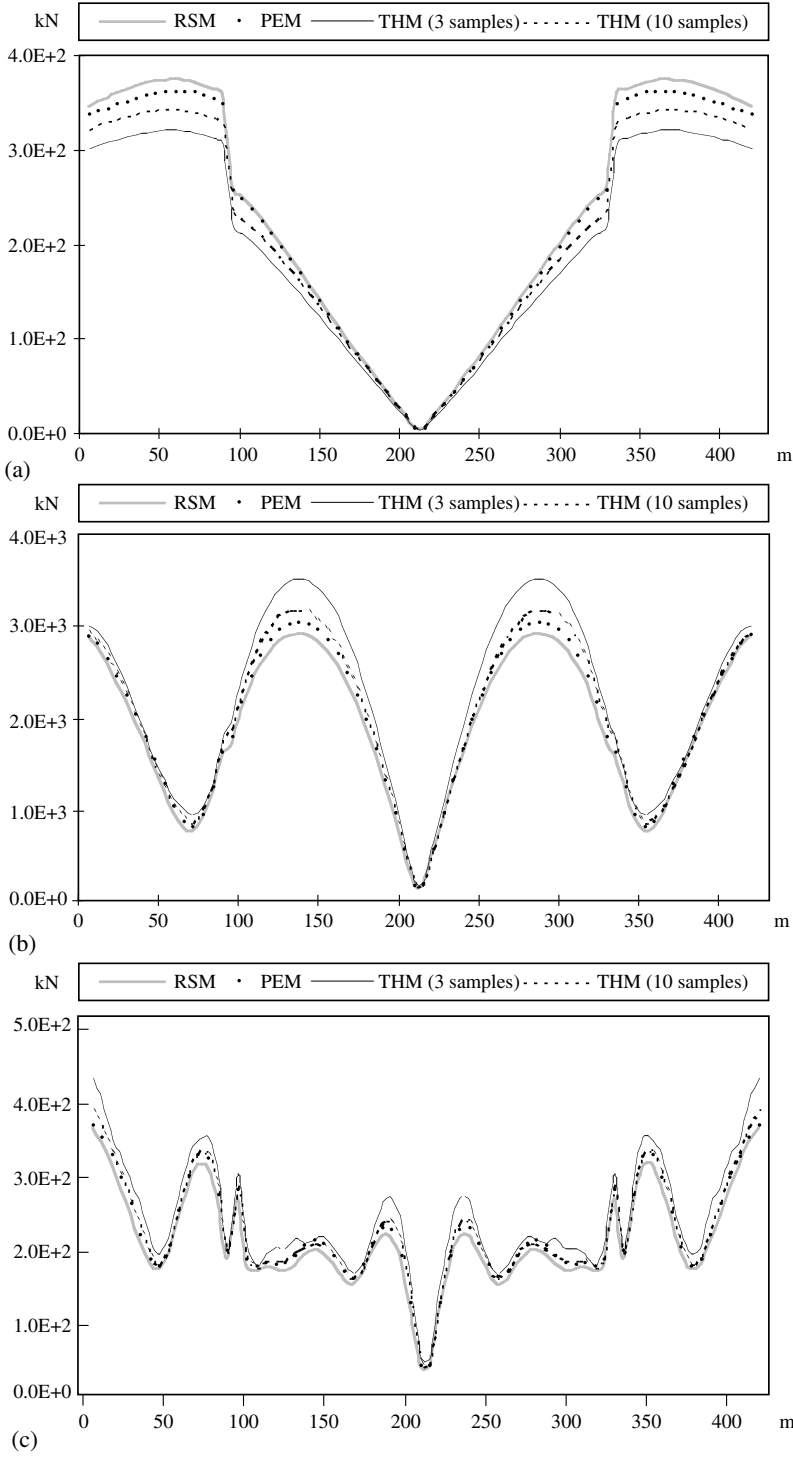

FIGURE 30.11 Deck force distribution of Song-Hua-Jiang bridge due to uniform ground motion: (a) axial force distribution along the deck under P waves; (b) transverse shear force distribution along the deck under SH waves; (c) vertical shear force distribution along the deck under SV waves.

TABLE 30.1 Central Processing Unit (CPU) Times Required by Different Methods for Stationary Analysis

Method Used	RSM (sec)	PEM (sec)	THM (for One Sample) (sec)
Uniform ground motion	80.6	15.1	29.9
Wave passage effect		24.2	36.7
Wave passage effect and incoherence effect		209.1	

Note: the CPU time for mode extraction is not included; extracting 100 modes needs 180.9 sec.

Figure 30.11(b) gives the transverse shear force distribution along the deck due to the seismic SH waves traveling along the deck. All supports move uniformly. The above four computational models were used.

Figure 30.11(c) gives the vertical shear force distribution along the deck due to the seismic SV waves traveling along the deck. All supports move uniformly. The above four computational models were also used here.

All computations were executed on a P3-750 personal computer. The computation times for different methods are listed in Table 30.1.

Figure 30.11 and Table 30.1 show that, when ground motion is assumed uniform, that is, the earthquake spatial effects are not taken into account, the RSM, PEM, and THM (using ten samples) give very close results if the excitations are properly produced. The RSM is the most popular method, but the newly developed PEM may be the more efficient one. The THM needs to be executed for a number of ground acceleration samples and so was inefficient.

30.4.2.1.2 Wave Passage Effect Is Taken into Account

Figure 30.12(a) gives the axial force distribution of the bridge along the deck due to the seismic P waves, which travel along the longitudinal direction of the deck. All supports of the bridges are assumed to move with certain time lags; that is, the wave passage effect is taken into account. The apparent P wave speed is 3 km/sec. The following four computational models were used:

1. RSM (uniform ground motion is assumed for comparison only)
2. PEM (wave passage effect is considered)
3. THM (wave passage effect is considered using three ground-acceleration samples)
4. THM (wave passage effect is considered using ten ground-acceleration samples)

Figure 30.12(b) gives the transverse shear force distribution along the deck due to the seismic SH waves traveling along the deck and Figure 30.12(c) gives the corresponding vertical shear-force distribution. The above four computational models were used.

Figure 30.12 and Table 30.1 show that when the seismic wave-passage effect is taken into account, that is, the earthquake spatial effects are partly taken into account, the PEM and THM (using ten samples) give very close results. The RSM, which does not consider the wave-passage effect, may give quite different results; these may appear larger or smaller than, or very close to, the results by the more reasonable PEM or THM analyses. Therefore, such computations are necessary for evaluating the seismic spatial effects of long-span structures. The PEM gives the most reliable results with the least computational effort and, therefore, this method is strongly recommended.

30.4.2.1.3 Wave-Passage Effect and Incoherence Effect Are Jointly Taken into Account

Figure 30.13(a) gives the axial force distribution of the bridge along the deck due to the seismic P waves, which travel along the longitudinal direction of the deck. All supports of the bridge are assumed to move with certain time lags; that is, the wave passage effect is taken into account. In addition, the incoherence effects are also taken into account. Two coherence models, that is, the Loh–Yeh model

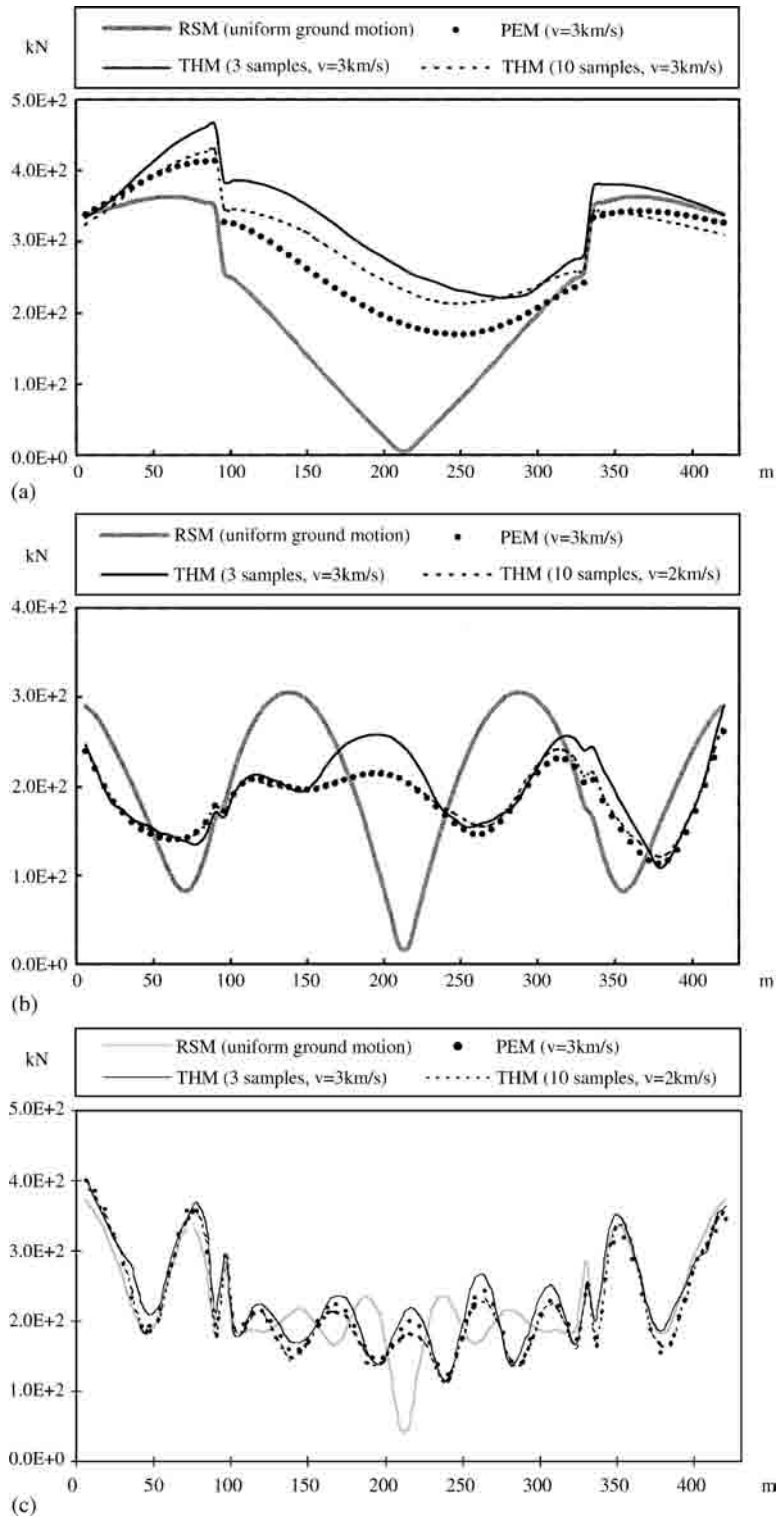

FIGURE 30.12 Deck force distribution of Song-Hua-Jiang bridge due to wave passage effect: (a) axial force distribution along the deck under P waves; (b) transverse shear force distribution along the deck under SH waves; (c) vertical shear force distribution along the deck under SV waves.

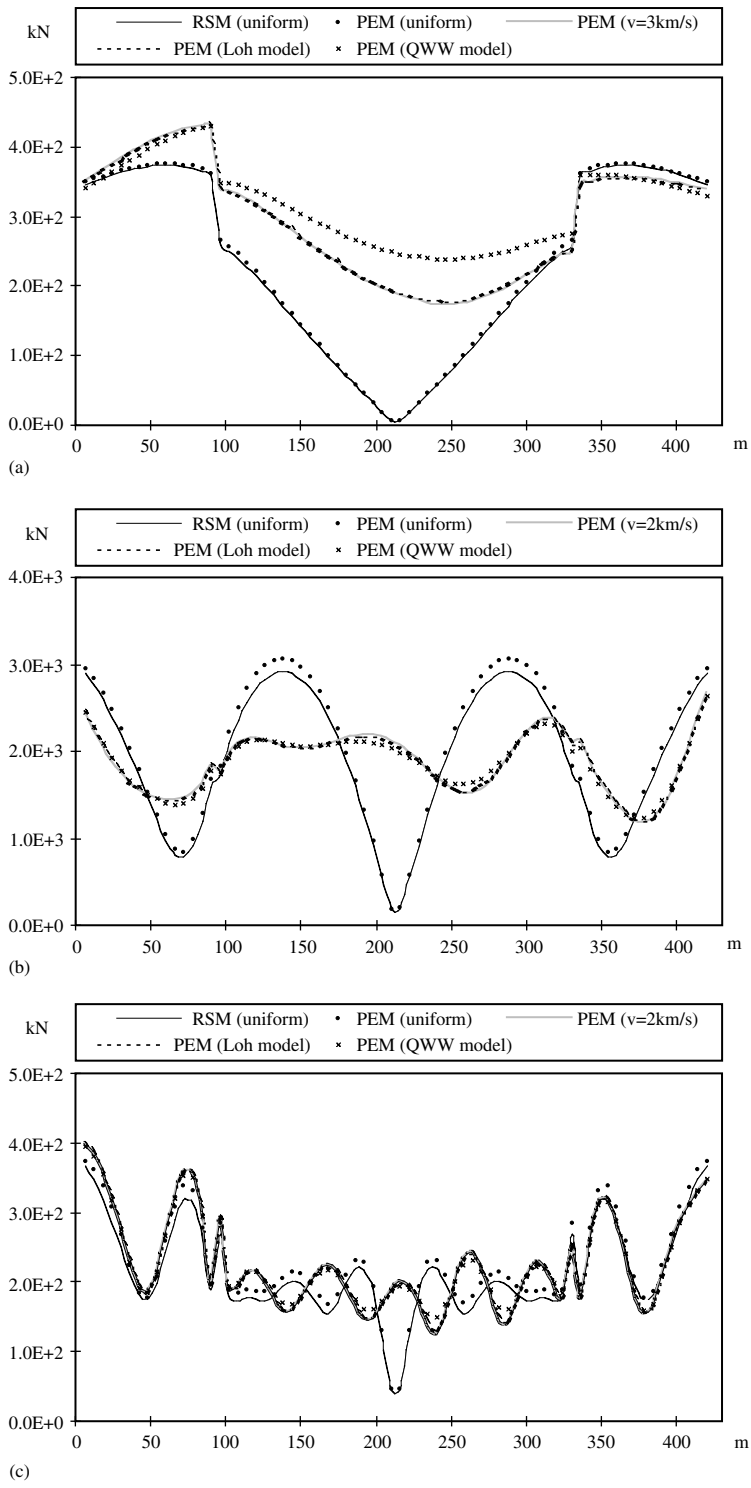

FIGURE 30.13 Deck force distribution of Song-Hua-Jiang bridge due to incoherence effect: (a) axial force distribution along the deck under P waves; (b) transverse shear force distribution along the deck under SH waves; (c) vertical shear force distribution along the deck under SV waves.

and the QWW model were used for evaluating such effects. The following five computational models were used:

1. RSM (uniform ground motion is assumed)
2. PEM (uniform ground motion is assumed)
3. PEM (wave passage effect is considered)
4. PEM (wave passage effect is considered also using the Loh–Yeh coherence model)
5. PEM (wave passage effect is considered also using the QWW coherence model)

Figure 30.13(b) gives the transverse shear force distribution along the deck due to the seismic SH waves traveling along the deck, and Figure 30.13(c) gives the corresponding vertical shear force distribution due to the seismic SV waves. For both analyses the above five computational models were used.

The above computations as well were executed on a P3-750 personal computer, and the computation times required by different methods are listed in Table 30.1.

From Figure 30.13 and Table 30.1, we can conclude that:

1. When ground motion is assumed to be uniform, the RSM and PEM give very close internal force responses (i.e., demands), with the PEM being more efficient.
2. The wave passage effect is an important factor that affects the seismic responses of long-span structures. To execute such seismic analyses, the PEM is not only theoretically quite reasonable, but also very efficient.
3. The incoherence effect appears to diverge when using different coherence models. Herein, the influence caused by the QWW model is more evident than that caused by the Loh–Yeh model. However, compared with the wave passage effect, the influence of the incoherence effect is of less importance.

30.4.2.2 San Joaquin Concrete Bridge

San Joaquin Bridge, located in California (see Figure 30.14), is a reinforced concrete bridge built in 2001. Its length is $36 + 50 + 50 + 50 + 36 = 222$ m, its width is 12 m, and the height of all piers is 16.76 m. The finite element model had 367 nodes (including 10 ground nodes) and 366 elements. Its basic natural period is 0.811s. Twenty modes were used in the mode-superposition analysis with all damping ratios being 0.05. The seismic analysis was carried out using the RSM and PEM, respectively. The RSM analysis was conducted according to the CALTRANS Code (1999) with $ARS = 0.2$ g, Type D soil profile and magnitude $M_w = 7.0$. The equivalent ground-acceleration power spectral density curve was produced by means of the Kaul method. All seismic waves were assumed to travel along the longitudinal direction of the bridge. The apparent P and S wave speeds were 3000 and 2000 m/s, respectively. The internal forces in the deck (i.e., the axial forces due to P waves, the transverse shear forces due to SH waves, and the vertical shear forces due to SV waves) were all computed using the following computational models:

1. RSM (uniform ground motion is assumed)
2. PEM (uniform ground motion is assumed)

FIGURE 30.14 Structural model of San Joaquin bridge.

3. PEM (wave-passage effect is considered)
4. PEM (wave-passage effect is considered also using the Loh–Yeh coherence model)
5. PEM (wave-passage effect is considered also using the QWW coherence model)

The computational results are shown in Figure 30.15(a)–(c). This bridge is not very long. However, similar phenomena to those found for the bridge of Example 30.1 are still found. Clearly, when the ground motion is assumed to be uniform, the RSM and PEM still give very close results. If the wave-passage effect is taken into account, then the internal force distribution with the PEM will change considerably, particularly at the midpoint of the deck. It is known that, for symmetric bridges, the antisymmetric modes will not participate in the symmetric motions under the assumption of uniform ground motion. However, when the wave-passage effect is taken into account, this conclusion does not hold. It is obvious that, even for this shorter bridge, the wave-passage effect seems to be quite significant. The incoherence effect is comparatively not so important.

30.5 Long-Span Structures Subjected to Nonstationary Random Ground Excitations

A typical strong motion earthquake record consists of three stages. In the first stage, the intensity of the ground motion increases, which mainly reflects the motion of P waves. The intensity of the ground motion remains the strongest in the second stage, which mainly reflects the motion of S waves. The ground motion will die down in the last stage. Such a complete seismic motion is usually regarded as a nonstationary random process. If the nonstationary property is assumed to take place only for the intensity of the motion, then this random process is regarded as a uniformly modulated evolutionary random process. However, if the shape of the ground motion PSD curve also varies with time (in other words, the intensity and the distribution with frequency of the ground motion energy both depend on time), then the ground motion is regarded as a nonuniformly modulated evolutionary random process. It is usually accepted that when the intensity of the seismic motion in the second stage appears quite stationary while the time interval of this stage is much longer (e.g., three times or over) than the basic period of the structure under consideration, a simplified, stationary-based random analysis may be acceptable as a substitute of the nonstationary analysis. In fact, the basic periods of many long-span bridges range from 10 to 20 sec, and the stationary portion of a typical strong earthquake is usually less than 1 min, being only 20 to 30 sec in most cases. Therefore, nonstationary analyses are appropriate for such problems. Previously, such nonstationary random analyses have been considered very difficult. However, by using the recently developed PEM, combined with the precise integration method, such analyses have become relatively easy.

30.5.1 Modulation Functions

Some popular uniform modulation functions are listed below:

$$g(t) = \begin{cases} I_0(t/t_1)^2 & 0 \leq t \leq t_1 \\ I_0 & t_1 \leq t \leq t_2 \\ I_0 \exp\{c(t - t_2)\} & t \geq t_2 \end{cases} \quad (30.177)$$

$$g(t) = \begin{cases} 1 & t \geq 0 \\ 0 & t < 0 \end{cases} \quad (30.178)$$

$$g(t) = a[\exp(-\alpha_1 t) - \exp(-\alpha_2 t)], \quad 0 \leq \alpha_1 < \alpha_2 \quad (30.179)$$

$$g(t) = \sin \beta t \quad (30.180)$$

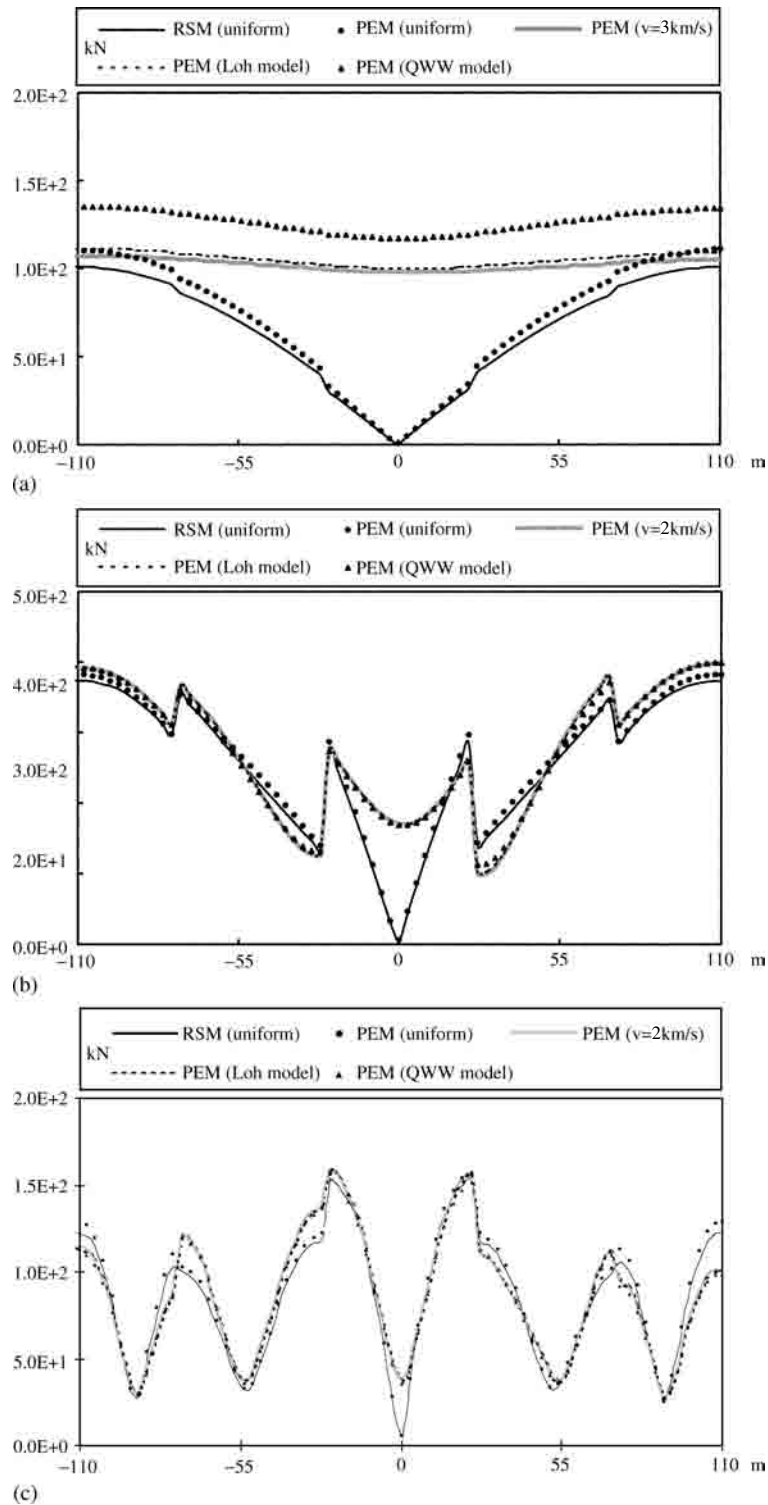

FIGURE 30.15 Deck force distribution of San Joaquin bridge due to incoherence effect: (a) axial force distribution along the deck under P waves; (b) transverse shear force distribution along the deck under SH waves; (c) vertical shear force distribution along the deck under SV waves.

Nonuniform modulation models have rarely been investigated. Lin et al. (1997a, 1997b) suggested the following nonuniform modulation model:

$$A(\omega, t) = \beta(\omega, t)g(t) = \exp\left(-\eta_0 \frac{\omega t}{\omega_\alpha t_\alpha}\right)g(t) \quad (30.181)$$

in which $g(t)$ is an amplitude modulation function; $\beta(\omega, t)$ is a frequency modulation function; and ω_α and t_α are the reference frequency and time, which are introduced to transform ω and t into dimensionless parameters. In principle, ω_α and t_α can be arbitrarily selected. Once they have been selected, the factor η_0 ($\eta_0 > 0$) can be adjusted accordingly to make the high-frequency components of the nonstationary random process decay more quickly than the low-frequency components and, thus, simulate the seismic motion more accurately. When $\eta_0 = 0$, that is, $\beta(\omega, t) = 1$, $A(\omega, t)$ reduces to the uniform modulation function $g(t)$.

30.5.2 The Formulas for Nonstationary Multiexcitation Analysis

For nonuniformly modulated multiexcitation problems, the pseudoexcitation for the corresponding stationary problems, that is, Equation 30.166, is extended to

$$\ddot{\mathbf{U}}_b(\omega, t) = \mathbf{A}(\omega, t)\mathbf{P}\exp(i\omega t) \quad (30.182)$$

in which the k th diagonal element of the $N \times N$ diagonal matrix $\mathbf{A}(\omega, t)$ is the modulation function $A_k(\omega, t)$ of the excitation which is applied to the k th support of the structure. In the case of uniformly modulated excitations, it is only necessary to replace all the nonuniform modulation functions $A_k(\omega, t)$ by the uniform modulation functions $g_k(t)$. Other formulae remain entirely unchanged. The $N \times r$ matrix \mathbf{P} can be generated by means of Equation 30.165 to Equation 30.174. Each column of $\ddot{\mathbf{U}}_b(\omega, t)$ can be regarded as a deterministic acceleration excitation vector. By substituting it into the right-hand side of Equation 30.93 and solving the equations of motion, a column of the matrix $\ddot{\mathbf{Y}}_r(\omega, t)$ can be produced.

Because $A_j(\omega, t)$ is a time-dependent and slowly varying function, the pseudoground displacement matrix can be computed approximately from

$$\tilde{\mathbf{U}}_b(\omega, t) = -\frac{1}{\omega^2}\ddot{\mathbf{U}}_b(\omega, t) \quad (30.183)$$

The pseudoquasi-static displacement matrix $\tilde{\mathbf{Y}}_s(\omega, t)$ can then be computed from Equation 30.92. Then, the PSD matrix of the absolute displacement vector $\mathbf{X}_s(\omega, t)$ is

$$\mathbf{S}_{X_s X_s}(\omega, t) = (\tilde{\mathbf{Y}}_r(\omega, t) + \tilde{\mathbf{Y}}_s(\omega, t))^* (\tilde{\mathbf{Y}}_r(\omega, t) + \tilde{\mathbf{Y}}_s(\omega, t))^T \quad (30.184)$$

If a group of pseudointernal forces, denoted as $\tilde{\mathbf{N}}_e$, has been computed, then the PSD matrix of the corresponding internal forces \mathbf{N}_e can be computed from

$$\mathbf{S}_{N_e N_e}(\omega, t) = \tilde{\mathbf{N}}_e^* \tilde{\mathbf{N}}_e^T \quad (30.185)$$

When the ground acceleration PSD matrix is known, the corresponding pseudoacceleration vector $\ddot{\mathbf{u}}_b$ is easy to generate according to Equation 30.163 to Equation 30.166. If instead, the ground displacement PSD matrix or velocity PSD matrix is known, then the acceleration PSD matrix can be obtained by multiplying the displacement or velocity PSD matrices by ω^4 or ω^2 , respectively.

30.5.3 Expected Extreme Values of Nonstationary Random Processes

The evaluation of the peak amplitude responses of structures subjected to nonstationary seismic excitations has also received much attention (Shrikhande and Gupta, 1997; Zhao and Liu, 2001). Previously, only very simple structures could be computed. However, by using the PEM, complicated structures can be analyzed, as is briefly described below.

To evaluate the expected extreme value responses of a structure subjected to nonstationary Gaussian excitations, the duration of which the intensity of the excitation peaks exceeds 50% of the maximum peak intensity denoted by $[t_0, t_0 + \tau]$ is taken as the equivalent stationary duration in order to use Equation 30.40 to Equation 30.49 to evaluate the desired expected extreme values. Provided that the time-dependent PSD of any arbitrary response $y(t)$, that is $S_{yy}(\omega, t)$, has been computed over that equivalent duration using the PEM, then the equivalent stationary PSD over that duration is

$$S'_{yy}(\omega) = \frac{1}{\tau} \int_{t_0}^{t_0+\tau} S_{yy}(\omega, t) dt \quad (30.186)$$

To compute the extreme value responses based on Equation 30.177, the parameters t_0 and τ are chosen as

$$t_0 = t_1/\sqrt{2}, \quad \tau = t_2 + \ln 2/c - t_1/\sqrt{2} \quad (30.187)$$

Thus, the equivalent stationary random responses are obtained and the subsequent processing can still use Equation 30.40 to Equation 30.49.

30.5.4 Numerical Comparisons with the Corresponding Stationary Analysis

The example of the Song-Hua-Jiang suspension bridge of the last section is used here for the seismic nonstationary random vibration analysis. The results are compared with those from the corresponding stationary random-vibration analyses with the ground assumed to move uniformly (i.e., at an apparent wave speed $v_{app} = \infty$), or to move at a limited apparent wave speed v_{app} (with the wave-passage effect is taken into account), which is 3 km/sec for P waves and 2 km/sec for S waves.

The nonstationary random excitation model $z(t) = g(t)x(t)$ was used in which the auto-PSD of $x(t)$ is assumed to be identical to that used for the stationary excitation in the preceding section. The frequency-domain parameters also remained the same. The modulation function had the form of Equation 30.177 with $t_1 = 8.0$, $t_2 = 20.0$, and $c = 0.20$. The duration of the earthquake was $t \in [0, 25]$, and the time step-size was $\Delta t = 0.5$.

The nonstationary analysis results are shown in Figure 30.16(a) to (c), and are compared with the results of the corresponding stationary random vibration analyses. Clearly, for such a long-span bridge, the wave passage effect is quite significant in its seismic analysis, as seen in Figure 30.11 to Figure 30.13. In addition, whether for uniform ground motion or for differential ground motion (i.e., the wave-passage effect is considered), the nonstationary responses are always smaller than the corresponding stationary responses. The maximum difference between their corresponding peak values may reach up to 23.1% for the present problem, as shown in Table 30.2. For very slender bridges, this nonstationary property will be even stronger.

By means of the PEM combined with the precise integration method (its HPD-E form for the modulation function used in this example), such modification can be fulfilled quickly and conveniently. The computational effort required by the nonstationary analysis is only about 25 min (see Table 30.3).

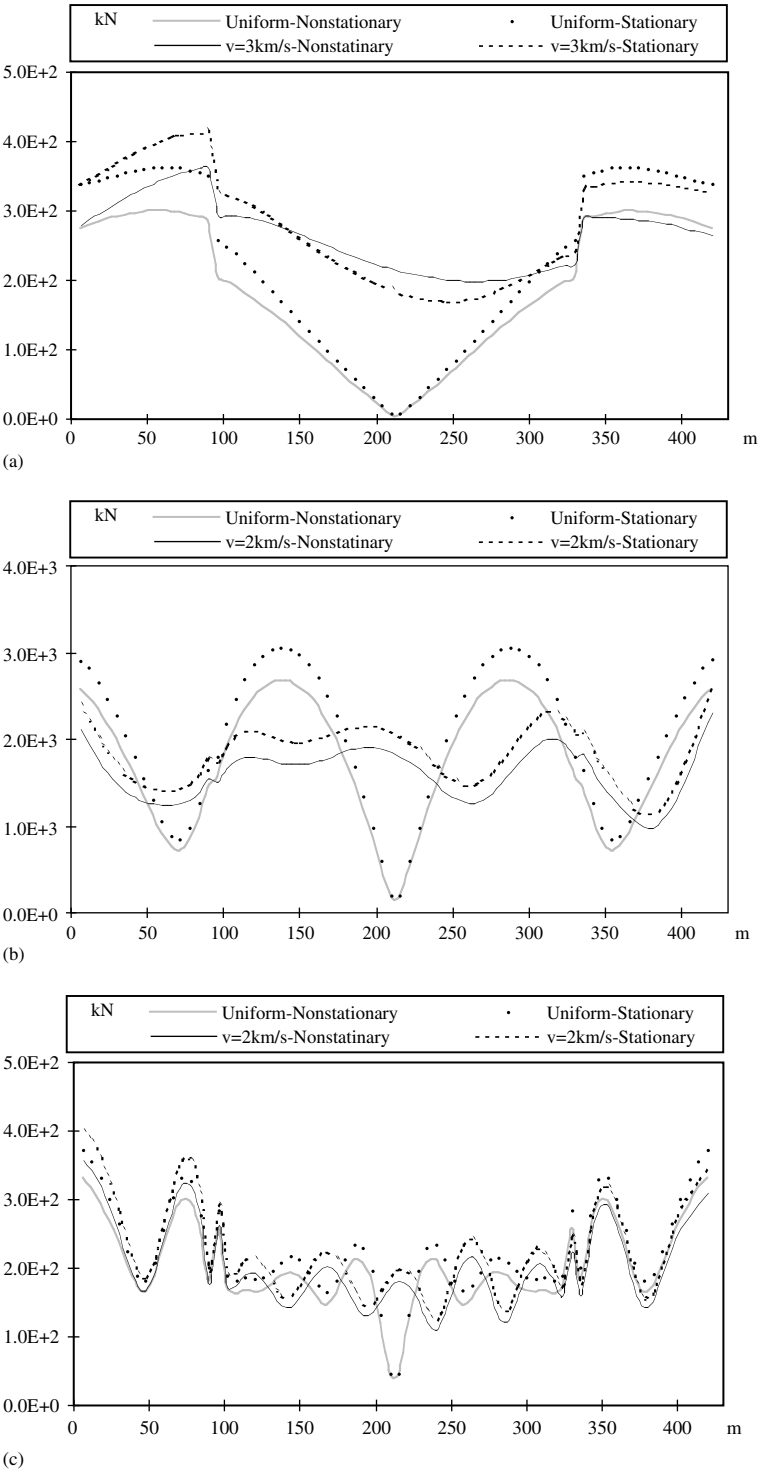

FIGURE 30.16 Deck-force distribution of Song-Hua-Jiang bridge due to uniform and differential, and stationary and nonstationary random ground motion: (a) axial force distribution along the deck under P waves; (b) transverse shear force distribution along the deck under SH waves; (c) vertical shear force distribution along the deck under SV waves.

TABLE 30.2 Comparisons of the Expected Extreme Values of Deck Internal Forces

Ground Motion	Internal Forces in the Deck (kN)	Distance from the Left End (m)	Nonstationary Responses	Stationary Responses	Increases (%)
Uniform ground motion	Axial force N due to P waves	6	274.95	337.60	22.8
	Transverse shear force F_y due to SH waves	72	712.19	832.47	16.9
	Vertical shear force F_z due to SV waves	258	146.00	165.81	13.6
Wave-passage effect	Axial force N due to P waves	420	264.51	325.61	23.1
	Transverse shear force F_y due to SH waves	270	1292.17	1515.75	17.3
	Vertical shear force F_z due to SV waves	246	134.00	152.89	14.1

TABLE 30.3 CPU Times Required by PEM for Nonstationary Analyses (Units: Seconds)

Modes Used	30	100
Uniform ground motion	450	1142
Wave passage effect	543	1479
Extracting modes	143	181

30.6 Conclusions

For short-span structures, the ground spatial effects are negligible, and the seismic analyses using RSM, PEM, or THM (with a sufficient number of samples) are relatively close to one another provided that the ground accelerations have been produced properly, and so are almost equivalent. Although they have almost the same accuracy level, their efficiencies are quite different. Of the three methods, if the structural models are rather complex (e.g., the FEM models have thousands or more DoF and need dozens or hundreds of modes for mode superposition), then the PEM will have the highest computational efficiency.

For long-span structures, the wave passage effect is an important factor for structural seismic responses. The influence may produce more conservative, or more dangerous, designs, which is difficult to predict by intuitive experience. Thus, computer-based analysis is a preferable choice. The PEM is comparatively efficient and accurate, and is recommended. If the apparent seismic wave speed is not available, then a few possible speeds can be taken for computation, with the most unfavorable results being used in the practical design. The reasonable selection of an incoherence model for a special region needs further study, but its influence seems to be much less than that caused by the wave passage effect. Therefore, for less important long-span structures, the incoherence effect can be neglected. The influence of nonstationarity is also significant for very flexible long-span structures, and should be taken into account. The PEM, combined with the precise integration method, provides a powerful tool for such nonstationary analysis.

Summary

Product qualification is intended for determining the adequacy of a product of good quality for a specific application or a range of applications. A good example is the seismic qualification of a nuclear power plant. This chapter presents test procedures used in product qualification, with emphasis on seismic qualification. Both single-frequency testing and multifrequency testing are described. Generation of test signal specifications is outlined.

31.1 Introduction

Vibration testing is used in product qualification. Here, the objective is to test the adequacy of a product of good quality for a specific use in a typical operating environment. Clearly, the nature of testing and the test requirements, including test specifications, will depend on the type of application and the class of product. In this chapter, we will consider just two types of product qualification: distribution qualification and seismic qualification. Procedures of vibration testing for other types of qualification will be similar.

31.2 Distribution Qualification

The term “distribution qualification” denotes the process by which the ability of a product to withstand a clearly defined distribution environment is established. Dynamic effects on the product due to handling loads, characteristics of packaging, and excitations under various modes of transportation (truck, rail, air, and ocean) must be properly represented in the test specifications used for distribution qualification. If a product fails a qualification test, then corrective measures and subsequent requalification are necessary prior to commercial distribution. Product redesign, packaging redesign, and modification of existing shipping procedures might be required to meet qualification requirements.

Often, the necessary improvements can be determined by analyzing data from prior tests. Proper distribution qualification will result in improved product quality (and associated reliability and performance), reduced wastage and inventory problems, cost-effective packaging, reduced shipping and handling costs, and reduced warranty and service costs.

TABLE 31.1 Comparison of Test Types

	Sine Testing	Random Testing	Narrowband Random Sweep	Broadband Random Sweep
Simultaneous multimodal (multiresonant) excitation possible?	No	Yes	No	Yes
Test duration	Long	Short	Long	Moderate
Power requirements	Low	High	Low	High
Represents a random environment?	No	Yes	Yes	Yes
Test system cost	Low	High	Moderate to high	High
Overtesting possibility	High	Low	High	Low

Random testing can more accurately represent vibrations in distribution environments. Several characteristics make it superior to sine testing. A sine test is a single-frequency test; thus, only one frequency is applied to a test object at a given instant. As a result, failure modes caused by the simultaneous excitation of two or more modes of vibration cannot be realized by sine testing, at least under steady excitations. On the other hand, in random testing, many frequencies are simultaneously applied to the test object. Therefore, conditions are more conducive to multiple-mode excitations and associated complex failures. A comparison of testing with four types of excitation signals is given in Table 31.1.

31.2.1 Drive-Signal Generation

The first step in signal synthesis for driving the exciter is to assign independent and identically distributed, random phase angles to the digitized spectral magnitude (spectral lines) of the drive spectrum. The number of lines chosen is consistent with the fast Fourier transform (FFT) algorithm that is employed and the desired numerical accuracy. The inverse Fourier transform is obtained from the resulting discrete, complex Fourier spectrum. In general, the signal thus obtained would not possess ergodicity and Gaussianity.

Stationarity can be attained by randomly shifting the signal with respect to time and summing the results. The resulting signal would also be weakly ergodic. Ergodicity is improved by increasing the duration of the signal. To obtain Gaussianity, a sufficiently large number of time-shifted signals must be summed as dictated by the central limit theorem. Furthermore, because the magnitude of a Gaussian signal almost always remains within three times its standard deviation (99.7% of the time), Gaussianity can be imposed simply by windowing the time-shifted signal. The amplitude of the window function is governed by the required standard deviation of the drive signal. Unwanted frequency components introduced as a result of sharp end transitions in each time-shifted signal component can be suppressed by properly shaping the window. This process introduces a certain degree of nonstationarity into the synthesized signal, particularly if the windowed signal segments are joined end-to-end to generate the drive signal. A satisfactory way to overcome this problem is to introduce a high overlap from one segment to the next. Because the processing time increases in proportion to the degree of overlap, however, a compromise must be reached.

In summary, for a given drive spectral magnitude the drive signal can be synthesized as follows:

1. Assign independent, identically distributed random phase values to the drive-spectral lines.
2. Perform an inverse Fourier transform of the resulting spectrum using FFT.
3. Generate a set of independent and identically distributed time-shift values.
4. Perform a time-shift of the signal obtained in Step 2 using the values from Step 3.
5. Window the time-shifted signals.
6. Join the windowed signals with a fixed overlap.

The resulting digital drive signal is converted into an analog signal using a digital-to-analog converter (DAC) and passed through a low-pass filter to remove any unwanted frequency components before it is used to drive the shaker. This procedure is illustrated in [Figure 31.1](#).

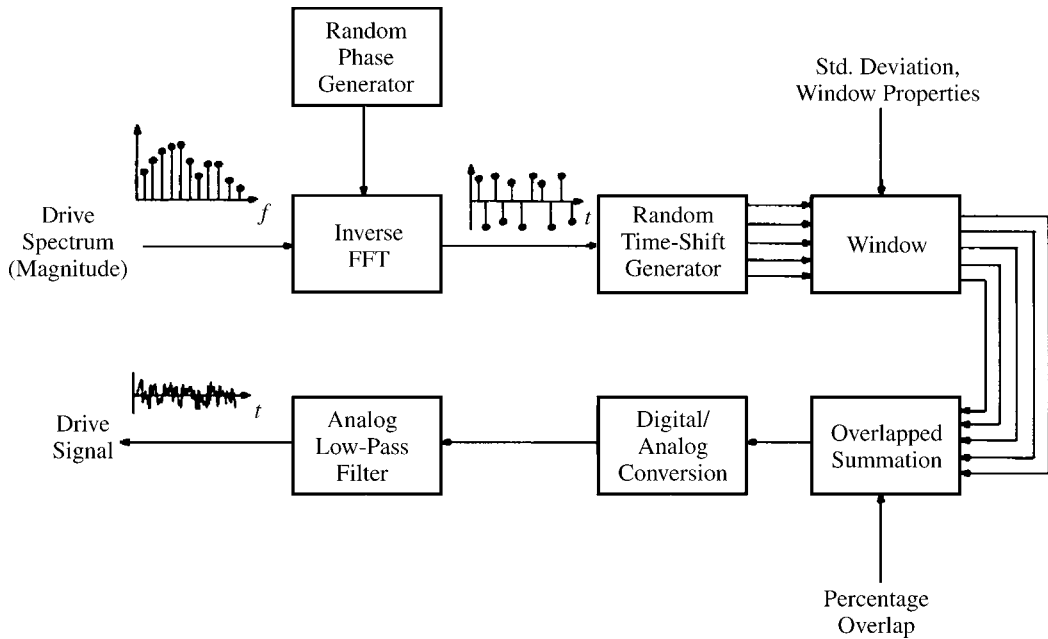

FIGURE 31.1 The synthesis of a random drive signal.

31.2.2 Distribution Spectra

The distribution environment to which a product is subjected depends on several factors. In particular, one must consider (1) the nature and severity of handling prior to and during shipment, (2) the mode of transportation (truck, rail, air cargo, ship), (3) the geographic factors, (4) the environmental conditions, (5) the characteristics of the protective packaging used, and (6) the dynamic characteristics of the product itself. These factors are complex and essentially random in nature. Laboratory simulation of such an environment is difficult even if a combination of several types of tests — e.g., vibration, shock, drop, and thermal cycling — is employed. A primary difficulty arises from the requirement that test specifications should be simple, yet accurately represent the true environment. The test must also be repeatable to allow standardization of the test procedure and to facilitate evaluation and comparison of test data. Finally, testing must be cost effective.

During transportation, a package is subjected to multi-degree-of-freedom (multi-DoF) excitations that can include rectilinear and rotational excitations at more than one location simultaneously. However, test machines are predominantly single-axis devices that generate excitations along a single direction. Thus, any attempt to duplicate a realistic distribution environment in a laboratory setting can prove futile.

An alternative might be to use trial shipments. However, because of the random nature of the distribution environment, many such trials would be necessary before the data would be meaningful. Therefore, trial shipments are not appealing from a cost-benefit point of view and also because test control and data acquisition would be difficult. Data from trial shipments are extremely useful, however, in developing qualification-test specifications and in improving existing laboratory test procedures.

A more realistic goal of testing would be to duplicate possible failure and malfunction modes without actually reproducing the distribution environment. This, in fact, is the underlying principle of testing for distribution qualification. For instance, sine tests can reproduce some types of failure caused during shipment even though the test signal does not resemble the actual dynamic environment; however, random testing is generally superior.

Test specifications are expressed in terms of distribution spectra in distribution qualification where random testing is used. Specification development begins with a sufficient collection of realistic data.

Sources of data include field measurements during trial shipments, computer simulations (e.g., Monte Carlo simulations), and previous specifications for similar products and environments. For best results, all possible modes of transportation, excitation levels, and handling severities should be included. The data, expressed as power spectral density (PSD), must be reduced to a common scale — particularly with respect to the duration of excitation — for comparison purposes. Scaling can be accomplished by applying a similarity law based on a realistic damage criterion. For example, a similarity law might relate the excitation duration and the PSD level such that the value of a suitable damage function would remain constant. Time-dependent damage criteria are developed primarily on the basis of fatigue–strength characteristics of a test product.

Owing to nonlinearities of the environment, spectral characteristics (frequency content) will change with the excitation level. If such changes are significant, then they should be properly accounted for. The influence of environmental conditions, such as temperature and humidity, must be considered as well. The PSD curves conditioned in this manner are plotted on a log–log plane to establish an envelope curve. This curve represents the worst composite environment that is typically expected. The envelope is then fitted with a small number of straight-line segments.

At this point, the PSD curve should be scaled so that the root-mean-square (RMS) value is equal to that before the straight-line segments were fitted. The resulting PSD curve can be used as the test specification. Test duration can be established from the time-scaling criterion. If the corresponding test duration is excessively long, thereby making the test impractical, then the test duration should be shortened by increasing the test level according to a realistic similarity criterion.

Product overtesting can be significant only if one reference spectrum is used to represent all possible distribution environments. Shipping procedures should thus be classified into several groups depending on the dynamic characteristics of the shipping environment and a representative reference spectrum should be determined for each group. If a range of products with significantly diverse dynamic characteristics is being qualified, then reference spectra should be modified and classified according to product type. At the testing stage, a reference spectrum must be chosen from a spectral database depending on the product type and applicable shipping procedures. Alternatively, a general composite spectrum can be developed by assigning weights to a chosen set of reference spectra and computing the weighted sum.

Vibration levels in land vehicles and aircraft can range up to several kilohertz (kHz). Ships are known to have lower levels of excitation. In general, the energy content in vibrations experienced during the distribution of computer products is known to remain within 20 Hz. Consequently, the test specification spectra (reference spectra) used in distribution qualification are usually limited to this bandwidth. The typical specification curve shown in [Figure 31.2](#) can be specified simply from the co-ordinates of the break points of the PSD curve. Intermediate values can be determined easily because the break points are joined by straight-line segments on a log–log plane.

The area beneath the PSD curve gives the required mean-square value of the test excitation. The square root of this value is the RMS value. It is specified along with the PSD curve, even though it can be determined directly from the PSD curve. An acceptable tolerance band for the control spectrum — usually ± 3 db — is also specified. Test duration should be supplied with the test specification.

31.2.3 Test Procedures

Dynamic-test systems with digital control are easy to operate. In menu-driven systems, a routine or mode is activated by picking the appropriate item from a menu that is displayed on the cathode-ray tube screen. The system asks for necessary data, and then necessary parameter values are entered into the system. Typically, the user supplies lower and upper RMS limits for test abort levels, break point co-ordinates of the reference spectrum, and test duration. The tolerance bands for test spectrum equalization and the accelerometer sensitivities are also entered. More than one test setup can be stored, a number being assigned to denote each test.

Preprogrammed tests can be modified using a similar procedure in the edit mode. Any preprogrammed test can be carried out simply by entering the corresponding test number. Computed

FIGURE 31.2 A reference spectrum for the distribution qualification of personal computers.

results, such as PSD curves and transmissibility functions, are stored for future evaluation. If desired, these results can be displayed, printed, or plotted with proper annotations and scales while the test is in progress.

Main steps of a typical test procedure are as follows:

1. Carefully examine the test object and record obvious structural defects, abnormalities, and hazardous or unsafe conditions.
2. Perform a functional test (i.e., operate the product) according to specifications and record any malfunctions and safety hazards.
Note: The test may be abandoned at this stage if the test object is defective.
3. Mount the test object rigidly on the shaker table so that the loading points and the excitation axis are consistent with standard shipping conditions and the specified test sequence.
4. Perform an exploratory test at half the specified RMS level (one fourth the specified PSD level). Monitor the response of the test package at critical locations including the control sensor location.
5. Perform the full-level test for the specified duration. Record the response data.
6. Change the orientation in accordance with the specified test sequence and repeat the test.
7. After the test sequence is completed, carefully inspect the test object and record any structural defects, abnormalities, and safety hazards.
8. Conduct a functional test and record any malfunctions, failures, and safety problems.

An exploratory test at a fraction of the specified test level is required for new product models that are being tested for the first time, or for older models that have been subjected to major design modifications. Three mutually perpendicular axes are usually tested, including the primary orientation (vertical axis) that is used for shipping. If product handling during distribution is automated, then testing only the primary axis is adequate.

When multiple tests are required, the test sequence is normally stipulated. If the test sequence is not specified, then it can be chosen such that the least-severe orientation (orientation least likely to fail) is tested first. The test is repeated for the remaining orientations, ending with the most severe one. The rationale is that with this choice of test sequence, the aging of the most severe direction would be maximized, thereby making the test more reliable.

The test report should contain the following:

1. *Description of the test object*: Serial number, size (dimensions and weight), product function (e.g., system unit, hard drive, power supply, printer, keyboard, mouse, monitor, and floppy disk drive of a personal computer), and packaging particulars. Descriptive photos are useful.
2. *Test plan*: Usually standard and attached to the report as an appendix.
3. *Test setup*: Test orientations, sensor (accelerometer) locations, details of mounting fixtures, and a brief description of the test apparatus. Photos may be included.
4. *Test procedure*: A standard attachment that is usually given according to corporate specifications.
5. *Test results*: Ambient conditions in the laboratory (e.g., temperature, humidity), pretest observations (e.g., defects, abnormalities, malfunctions), test data (e.g., reference spectrum, equalized control spectrum, drive spectrum, response time histories and corresponding spectra, transmissibility plots, coherence plots) and posttest observations.
6. *Comments and recommendations*: General comments regarding the test procedure and test item and recommendations for improving the test, product or packaging.

Names and titles of the personnel who conducted the test should be given in the test report, with appropriate signatures, dates, and location of the test facility.

Tests for distribution qualification can be conducted on both packaged products and those without any protective packaging, even though it is the packaged product that is shipped. However, the reference spectra used in the two cases are usually not the same. The spectrum used for testing a product without protective packaging is generally less severe. Response spectra that are used for testing an unpackaged product should reflect the excitations experienced by the product during packaging.

31.3 Seismic Qualification

Frequently, it is necessary to determine whether a given piece of equipment is capable of withstanding a pre-established seismic environment in a specific application. This process is known as seismic qualification. For example, electric utility companies should qualify their equipment for seismic capability before installing it in earthquake-prone geographic localities. Safety-related equipment in nuclear power plants also requires seismic qualification. Regulatory agencies usually specify the general procedures to follow in seismic qualification.

Seismic qualification by testing is appropriate for complex equipment, but in such cases, the equipment size is a limiting factor. For large systems that are relatively simple to model, qualification by analysis is suitable. Often, however, both testing and analysis are needed in the qualification of a given piece of equipment. Seismic qualification of equipment by testing is accomplished by applying a dynamic excitation by means of a shaker to the equipment, which is suitably mounted on a test table, and then monitoring structural integrity and functional operability of the equipment. Special attention should be given to the development of the dynamic-test environment, mounting features, the operability variables that should be monitored, the method of monitoring functional operability and structural integrity, and the acceptance criteria used to decide qualification.

In monitoring functional operability, the test facility would normally require auxiliary systems to load the test object or to simulate in-service operating conditions. Such systems include actuators, dynamometers, electrical-load and control-signal circuitry, fluid-flow and pressure loads, and thermal loads. In seismic qualification by analysis, a suitable model is first developed for the equipment, and then static or dynamic analysis (or computer analysis) is performed under an analytically defined dynamic environment. The analytical dynamic environment is developed on the basis of the specified dynamic environment for seismic qualification. By analytically or computationally determining system response at various locations, and by checking for such crucial parameters as relative deflections, stresses, and strains, qualification can be established.

31.3.1 Stages of Seismic Qualification

Consider the construction of a nuclear power plant. In this context, the plant owner is the customer. Actual construction of the plant is done by the plant builder, who is directly responsible to the customer concerning all equipment purchased from the equipment supplier or vendor. Often, the vendor is also the equipment manufacturer. The equipment may be purchased by the customer and handed over to the plant builder or directly purchased by the plant builder. Accordingly, the purchaser could be the plant builder or the plant owner. A regulatory agency might stipulate seismic-excitation capability requirements for the equipment used in the plant, or might specify the qualification requirements for various categories of equipment. The customer is directly responsible to the regulatory agency for adherence to these stipulations. The vendor, however, is responsible to the plant builder and the customer for the seismic capability of the equipment. The vendor may perform seismic qualification on the equipment according to required specifications. More often, however, the vendor hires the services of a test laboratory, which is the contractor, for seismic qualification of equipment in the plant. A reviewer, who is hired by the plant builder or the customer, may review the qualification procedure and the report, which are usually developed by the test laboratory by adhering to the qualification requirements. [Figure 31.3](#) gives a flowchart for test-object movement and for associated information interactions between various groups in the qualification program.

A basic step in any qualification program is the preparation of a qualification procedure. This is a document that describes in sufficient detail such particulars as the tests that will be conducted on the test object, pretest procedures, the nature of test-input excitations and the method of generating these signals, inspection and response-monitoring procedures during testing, definitions of equipment malfunction, and qualification criteria. Where analysis is also used in the qualification, the analytical methods and computer programs that will be used should be described adequately in the qualification procedure. The qualification procedure is prepared by the test laboratory (contractor), equipment particulars are obtained from the vendor or the purchaser, and the purchaser usually supplies the test environment for which the equipment will be qualified.

Before the qualification tests are conducted, the test procedure is submitted to the purchaser for approval. The purchaser normally hires a reviewer to determine whether the qualification procedure satisfies the requirements of both the regulatory agency and the purchaser. There could be several stages of revision of the test procedure until it is accepted by the purchaser upon the recommendation of the reviewer.

The approved qualification procedure is sent to the test laboratory and qualification is performed accordingly. The test laboratory prepares a qualification report that also includes the details of static or dynamic analysis when incorporated. The qualification report is sent to the purchaser for evaluation. The purchaser might obtain the services of an authority to review the qualification report. The report might have to be revised and analysis and tests might have to be repeated before a final decision is made on the qualification of the equipment. Information flow in a typical qualification program is shown in [Figure 31.4](#).

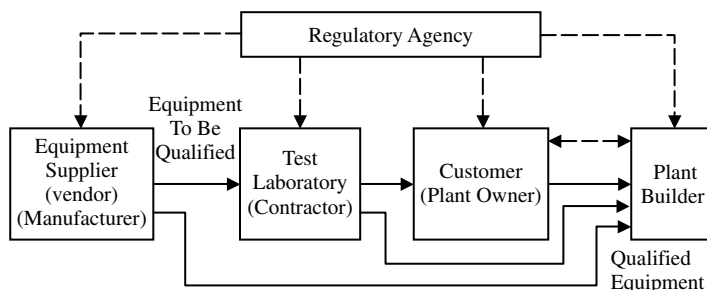

FIGURE 31.3 Test-object movement and information interactions in seismic qualification.

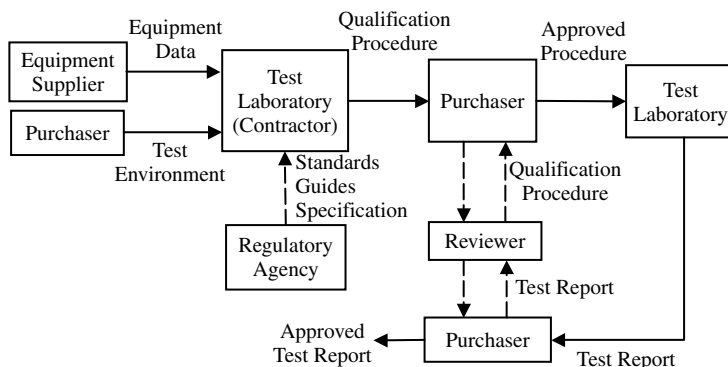

FIGURE 31.4 Information flow in a seismic qualification program.

31.3.2 Test Preliminaries

Seismic qualification tests are usually conducted by one of two methods depending on whether single-frequency or multifrequency excitation inputs are employed in the main tests. The two test categories are (1) single-frequency tests and (2) multifrequency tests. Although the second test method is more common in seismic qualification by testing, the first method is used under some conditions depending on the nature of the test object and its mounting features (for example, line-mounted vs. floor-mounted equipment). Typically, multifrequency excitations are preferred in qualification tests, and single-frequency excitations are favored in design-development and quality-assurance tests.

In single-frequency testing, amplitude of the excitation input is specified by a required input motion (RIM) curve, similar to that shown in Figure 31.5. If single-frequency dwells (e.g., sine dwell, sine beat) are employed, then the excitation input is applied to the test object at a series of selected frequency values in the frequency range of interest for that particular test environment. In such cases, dwell times (and number of beats per cycle where sine beats are employed) at each frequency point should be specified.

If a single-frequency sweep (such as a sine sweep) is employed as the excitation signal, then the sweep rate should be specified. When the single-frequency test-excitation is specified in this manner, the tests are conducted very much like multifrequency tests.

Multifrequency test are normally conducted by employing the response spectra method to represent the test-input environment. Basically, the test object is excited using a signal whose response spectrum, known as the test response spectrum (TRS), envelopes a specified response spectrum, known as the required response spectrum (RRS). Ideally, the TRS should equal the RRS but it is practically impossible to achieve this condition. Hence, multifrequency tests are conducted using a TRS that envelopes the RRS so that in significant frequency ranges, the two response spectra are nearly equal (see Figure 31.6). However, excessive conservatism, which would result in overtesting, should be avoided. It is usually acceptable to have TRS values below the RRS at a few frequency points.

The RRS is part of the data supplied to the test laboratory prior to the qualification tests being conducted. Two types of RRS are provided, representing (1) the operating-basis earthquake (OBE), and (2) the safe-shutdown earthquake (SSE). The response spectrum of the OBE represents the most severe motions produced by an earthquake under which the equipment being tested would remain functional without undue risk of malfunction or safety hazard. However, if the equipment is allowed to operate at a

FIGURE 31.5 A typical required input motion curve.

disturbance level higher than the OBE level for a prolonged period then there would be a significant risk of malfunction.

The response spectrum of the SSE represents the most severe motions produced by an earthquake that the equipment being tested could safely withstand while the entire nuclear power plant is being shutdown. However, prolonged operation (i.e., more than the duration of one earthquake) could result in equipment malfunction. In other words, equipment is designed to withstand only one SSE in addition to several OBEs.

A typical seismic qualification test would first subject the equipment to several OBE-level excitations, primarily for aging the equipment mechanically to its end-of-design-life condition, and then would subject it to one SSE-level excitation. When providing RRS test specifications, it is customary to supply only the SSE requirement. The OBE requirement is then taken as a fraction (typically, 0.5 or 0.7) of the SSE requirement.

Test response spectra corresponding to the excitation signals are generated by the test laboratory during testing. The purchaser usually supplies the test laboratory with an FM tape containing frequency components that should be combined in some ratio to generate the test-input signal.

Qualification tests are conducted according to the test procedure approved and accepted by the purchaser. The main steps of seismic qualification testing are outlined in the following subsections.

31.3.3 Single-Frequency Testing

Seismic ground motions usually pass through various support structures before they eventually are transmitted to equipment. For seismic qualification of that equipment by testing, in theory we should apply the actual excitations felt by it, and not the seismic ground motions. In an ideal case, the shaker-table motion should be equivalent to the seismic response of the supporting structure at the point of attachment of the equipment.

The supporting structure would have a particular frequency-response function between the ground location and the equipment-support location (see Figure 31.7). Consequently, it could be considered a filter that modifies seismic ground motions before they reach the equipment mounts.

In particular, the components of the ground motion that have frequencies close to a resonant frequency of the supporting structure will be felt by the equipment at a relatively higher intensity. Furthermore, the ground motion components at very high frequencies will be almost entirely filtered out by the structure. If the frequency response of the supporting structure is approximated by a lightly damped simple oscillator, then the response felt by the equipment will be almost sinusoidal, with a frequency equal to the resonant frequency of the structure.

When the equipment supporting structure has a very sharp resonance in the significant frequency range of the dynamic environment (for example, 1 to 35 Hz for seismic ground motions), it follows from the previous discussion that it is desirable to use a short-duration single-frequency test in seismic qualification of the equipment. Equipment that is supported on pipelines (valves, valve actuators, gauges, and so forth) falls into this category and is termed line-mounted equipment.

FIGURE 31.6 The TRS enveloping the RRS in a multifrequency test.

FIGURE 31.7 Schematic representation of the filtering of seismic ground motions by a supporting structure.

Resonant frequency of the supporting structure is usually not known at the time of the seismic qualification test. Consequently, single-frequency testing must be performed over the entire frequency range of interest for that particular dynamic environment.

Another situation in which single-frequency testing is appropriate is when the test object (equipment) itself does not have more than one sharp resonance in the frequency range of interest. In this case, the most prominent response of the test object occurs at its resonant frequency, even when the dynamic environment is an arbitrary excitation. Consequently, a single-frequency excitation would yield conservative test results. Equipment that has more than one predominant resonance may employ single-frequency testing provided that each resonance corresponds to a dynamic DoF (e.g., one resonance along each dynamic principal axis), and that cross coupling between these DoF is negligible.

In summary, single-frequency testing may be used where one or more of the following conditions are satisfied:

1. The supporting structure has one sharp resonance in the frequency range of interest (line-mounted equipment is included).
2. The test object does not have more than one sharp resonance in the frequency range of interest.
3. The test object has a resonance in each DoF, but the DoF are uncoupled (for which adequate verification should be provided in the test procedure).
4. The test object can be modeled as a simple dynamic system (such as a simple oscillator), for which adequate justification or verification should be provided.

Usually, the required SSE excitation level for a single-frequency test over a frequency range is specified by a curve such as the one shown in Figure 31.5. This curve is known as the RIM magnitude curve. The OBE excitation level is usually taken as a fraction (typically, 0.5 or 0.7) of the RIM values given for the SSE. For a sine-sweep test, the sweep rate and the number of sweeps in the test should also be specified. Typically, the sweep rate for seismic qualification tests is less than 1 octave/min. One sweep, from the state of rest to the maximum frequency in the range and back to the state of rest, is normally carried out in an SSE test (for example, 1–35 to 1 Hz). Several sweeps (typically, five) are performed in an OBE test.

In an SSE sine-dwell test, the dwell time for each dwell frequency should be specified. The dwell-frequency intervals should not be high (typically, a half-octave or less). For an OBE test, the dwell times are longer (typically, five times longer) than those specified for an SSE test.

For an SSE test using sine beats, the minimum number of beats and the minimum duration of excitation (with or without pauses) at each test frequency should be specified. In addition, the pause time for each test frequency should be specified when sine beats with pauses are employed. For an OBE test, the duration of excitation should be increased (as in a sine-dwell test).

The dwell time at each test frequency should be adequate to perform at least one functional-operability test. Furthermore, a dwell should be carried out at each resonant frequency of the test object as well as at those frequencies that are specified. Total duration of an SSE test should be representative of the duration of the strong-motion part of a standard safe-shutdown earthquake.

Sometimes, narrow-band random excitations may be used in situations where single-frequency testing is recommended. Narrowband random signals are those that have their power concentrated over a narrow frequency band. Such a signal can be generated for test-excitation purposes by passing a random signal through a narrow-band-pass filter. By tuning the filter to different center frequencies in narrowbands, the test-excitation frequency can be varied during testing. This center frequency of the filter should be swept up and down over the desired frequency range at a

FIGURE 31.8 A typical RRS for a narrow-band excitation test.

reasonably slow rate (e.g., 1.0 octave/min) during the test. Thus, a multifrequency test with a sharp frequency-response spectrum (the RRS), as illustrated in Figure 31.8, is adequate in cases where single-frequency testing is recommended. In this case, a requirement that has to be satisfied by the test-excitation signal is that its amplitude should be equal to or greater than the zero-period acceleration of the RRS for the test.

31.3.4 Multifrequency Testing

When equipment is mounted very close to the ground under its normal operating conditions, or if its supporting structure and mounting can be considered rigid, then seismic ground motions will not be significantly filtered before they reach the equipment mounts. In this case, the seismic excitations that are felt by the equipment will retain broadband characteristics. Multifrequency testing is recommended for seismic qualification of such equipment.

Whereas single-frequency tests are specified by means of an RIM curve along with the test duration at each frequency (or sweep rates), multifrequency tests are specified by means of an RRS curve. The test requirement in multifrequency testing is that the response spectrum of the test excitation (the TRS) felt by the equipment mounts should envelop the RRS. Note that all frequency components of the test excitation are applied simultaneously to the test object. This is in contrast to single-frequency testing, in which only one significant frequency component is applied at a given instant.

When random excitations are employed in multifrequency testing, enveloping of the RRS by the TRS may be achieved by passing the random signal produced by a signal generator through a spectrum shaper. As the analyzing frequency bandwidth (e.g., one-third octave bands, one-sixth octave bands) decreases, the flexibility of shaping the TRS improves. A real-time spectrum analyzer (or a personal computer) may be used to compute and display the TRS curve corresponding to the control accelerometer signal (see Figure 31.9). By monitoring the displayed TRS, it is possible to adjust the gains of the spectrum-shaper filter to obtain the desired TRS that would envelop the RRS.

Most test laboratories generate their multifrequency excitation signals by combining a series of sine beats that have different peak amplitudes and frequencies. Using the same method, many other signal types (such as decaying sinusoids) may be superimposed to generate a required multifrequency excitation signal. A combination of signals of different types could also be employed to produce a desired test input. A commonly used combination is a broadband random signal and a series of sine beats. In this combination, the random signal is adjusted to have a response spectrum that will envelop the broadband portion of the RRS without much conservatism. The narrow-band peaks of the RRS, which generally will not be enveloped by such a broadband response spectrum, will be covered by a suitable combination of sine beats.

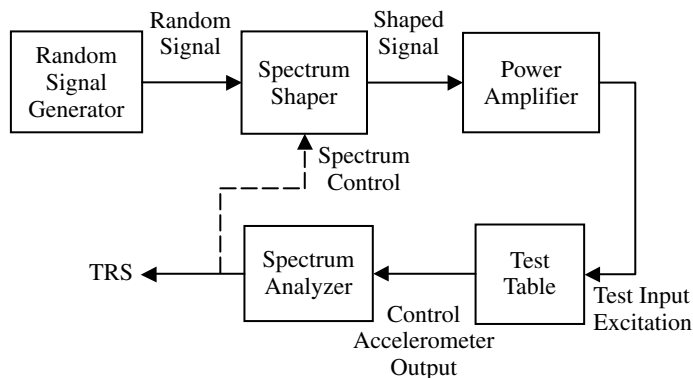

FIGURE 31.9 Matching of the TRS with the RRS in multifrequency testing.

By employing such mixed composite signals, it is possible to envelop the entire RRS without having to increase the amplitude of the test excitation to a value that is substantially higher than the ZPA of the RRS. One important requirement in multifrequency testing is that the amplitudes of the test excitation be equal to or greater than the ZPA of the RRS.

31.3.5 Generation of RRS Specifications

Seismic qualification of an object is usually specified in terms of an RRS. The excitation input that is used in seismic qualification analysis and testing should conservatively satisfy the RRS; that is, the response spectrum of the actual excitation input should envelop the RRS (without excessive conservatism, of course).

For equipment to be installed in a building or on some other supporting structure, the RRS generally cannot be obtained as the response spectrum of a modified seismic ground-motion time-history. The supporting structure usually introduces an amplification effect and a filtering effect on seismic ground motions. This amplification factor alone could be as high as three. Some of the major factors that determine the RRS for a particular seismic qualification test are as follows:

1. Nature of the building that will be qualified
2. Dynamic characteristics of the building or structure and the location (elevation and the like) where the object is expected to be installed
3. In-service mounting orientation and support characteristics of the object
4. Nature of the seismic ground motions in the geographic region where the object would be installed
5. Test severity and conservatism that is required by the purchaser or the regulator agency

The basic steps in developing the RRS for a specific seismic qualification application include the following:

1. Development of representative safe-shutdown earthquake (SSE) ground-motion time histories for the building (or support structure) location
2. Development of a suitable building (or support structure) model
3. Response analysis of the building model, using the time histories that are obtained in Step 1
4. Development of response spectra for various critical locations in the building (or support structure), using the response time histories obtained in Step 3
5. Normalization of the response spectra obtained in Step 4 to unity ZPA (that is, dividing by their individual ZPA values)
6. Identification of the similarities in the set of normalized response spectra that are obtained in Step 5 and grouping them into a small number of groups
7. Representation of each similar group by a response spectrum consisting of straight-line segments that envelop all members in the group, giving a normalized RRS for each group
8. Determination of scale factors for various locations in the building for use in conjunction with the corresponding normalized RRS curves

Representative strong-motion earthquake time histories (SSEs) are developed by suitably modifying actual seismic ground-motion time histories that have been observed in that geographic location (or a similar one), or by using a random-signal-generation (simulation) technique or any other appropriate method. These time histories may be available as either digital or analog records, depending on the way in which they are generated. If computer simulation is used in their development, then a statistical representation of the expected seismic disturbances in the particular geographic region (using geological features in the region, seismic activity data, and the like) should be incorporated in the algorithm. The intensity of the time histories can be adjusted, depending on the required test severity and conservatism.

The normalized response spectra are grouped so that the spectra that have roughly the same shape are put in the same group. In this manner, relatively few groups of normal response spectra (normalized) are

obtained. Then, the response spectra that belong to each group are plotted on the same graph paper. Next, straight-line segments are drawn to envelop each group of response spectra. This procedure results in a normalized RRS for each group of analytical response spectra.

The RRS that is used for a particular seismic qualification scheme is obtained as follows. First, the normalized RRS corresponding to the location in the building where the object would be installed is selected. The normalized RRS curve is then multiplied by the appropriate scaling factor. The scaling factor normally consists of the product of the actual ZPA value under SSE conditions at that location (as obtained from the analytical response spectrum at that location, for example) and a factor of safety that depends on the required test severity and conservatism.

In fact, three RRS curves corresponding to the vertical, east–west and north–south directions might be needed, even for single-degree-of-freedom (single-DoF) seismic qualification tests because, by mounting three control accelerometers in these three directions, triaxial monitoring could be accomplished. If only one control accelerometer is used in the test, then only one RRS curve is used. In this case, the resultant of the three orthogonal RRS curves should be used. One way to obtain the resultant RRS curve is to apply the square root of the sum of squares (SRSS) method to the three orthogonal components. Alternatively, the envelope of the three orthogonal RRS curves is obtained and multiplied by a safety factor (greater than unity).

Note that more than one building (or even many different geographic locations) could be included in the described procedure for developing RRS curves. The resulting RRS curves are then valid for the collection of buildings or geographic locations considered. When the generality of an RRS curve is extended in this manner, the test conservatism increases. This will also result in an RRS curve with a much broader band.

In practice, in a particular seismic qualification project, only a few normalized RRS curves are employed. In conjunction with these RRS curves, a table of data is provided that identifies the proper RRS curves and the scaling factors that should be used for different physical locations (for example, elevations) in various buildings that are situated at several geographic locations.

Summary

There are desirable and undesirable types and situations of mechanical vibration. Undesirable vibrations are those that cause human discomfort and hazards, structural degradation and failure, performance deterioration and malfunction of machinery and processes, and various other problems. This chapter discusses ways of either eliminating or reducing the undesirable effects of vibration. Specifically, some useful topics on design for vibration suppression and the control of vibration are addressed. General approaches to vibration mitigation may be identified from the dynamic systems point of view. Typically, a set of vibration specifications is given as simple threshold values (bounds) or frequency spectra, and the goal is to either design or control the system to meet these

specifications. Frequency-domain techniques based on transfer functions such as transmissibility and time-domain techniques using the state-space representation, optimal control, and modal control are presented. Applications considered here include vibration isolation, balancing of rotating and reciprocating machinery, whirling suppression, and passive and active control of vibration.

32.1 Introduction

Consider the schematic diagram of a vibratory system shown in Figure 32.1. Forcing excitations $f(t)$ to the mechanical system S cause the vibration responses y . Our objective is to suppress y to a level that is acceptable. Clearly, there are three general ways of doing this:

1. *Isolation.* Suppress the excitations of vibration. This method deals with f .
2. *Design modification.* Modify or redesign the mechanical system so that for the same levels of excitation, the resulting vibrations are acceptable. This method deals with S .
3. *Control.* Absorb or dissipate the vibrations using external devices, through implicit or explicit sensing and control. This method deals with y .

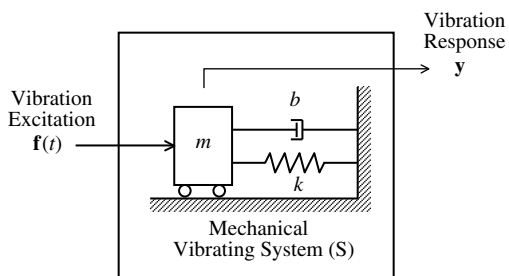

FIGURE 32.1 A vibrating mechanical system.

Within each of these three categories, several approaches can be used to achieve the objective of vibration mitigation. Essentially, each of these approaches involves designing (either complete through redesign or incremental design modification) of the system on the one hand, and controlling the vibration through external means (passive or active devices) on the other. Note that removal of faults (e.g., misalignments and malfunctions by repair or parts replacement) can also remove vibrations. This approach may fall into any of the three categories listed above.

The category of vibration isolation involves “isolating” a mechanical system (S) from vibration excitations (f) so that the excitation signals are “filtered” out or dissipated prior to reaching the system. The use of properly designed suspension systems, mounts, and damping layers falls within this category. The category of design modification will involve making changes to the components and the structure of a mechanical system according to a set of specifications and design guidelines. Balancing of rotating machinery and structural modification through modal analysis and design techniques fall into this category. The category of control will involve either passive devices (which do not use external power), such as dynamic absorbers and dampers, or active control devices (which need external power for operation). In the passive case, the control device implicitly senses the vibration response and dissipates it (as in the case of a damper) or absorbs and stores its energy where it is slowly dissipated (as in the case of a dynamic absorber). In the active case, the vibrations y are explicitly sensed through *sensors* and *transducers*. The forces that should be acted on the system to counteract and suppress vibrations are determined by a controller, and the corresponding forces or torques are applied to the system through one or more *actuators*.

Note that there may be some overlap in the three general categories of vibration mitigation that were mentioned above. For example, the addition of a mount (category 1) may also be interpreted as a design modification (category 2) or as incorporating a passive damper (category 3). It should also be noted that the general approach, commonly known as *source alteration*, may fall into either category 1 or category 2. In this case, the purpose is to alter or remove the source of vibration. The source could either be external (e.g., road irregularities that result in vehicle vibrations) — a category 1 problem, or internal (imbalance or misalignment in rotating devices that results in periodic forces, moments, and vibrations) — a category 2 problem. It can be more difficult to alter external vibration sources (e.g., resurfacing the roadways) than to modify the internal sources (e.g., balancing of rotating machinery).

Furthermore, the external source of vibration may be quite random and may not be accessible for alteration at all (e.g., aerodynamic forces on an aircraft).

32.1.1 Shock and Vibration

Sometimes, response to shock loads is considered separately from response to vibration excitations for the purpose of design and control of mechanical systems. For example, shock isolation and vibration isolation are treated under different headings in some literature. This is actually unnecessary. Even though vibration analysis predominantly involves periodic excitations and responses, transient and random oscillations (vibrations) are also commonly found in practice. The frequency band of the latter two types of signals is much broader than that of a simple periodic signal. A shock signal is transient by definition, and has a very short duration (in comparison to the predominant time constants of the mechanical system to which the shock load is applied). Hence, it will possess a wide band of frequencies. Consequently, frequency-domain techniques are still applicable. Furthermore, time-domain techniques are particularly suited to dealing with transient signals in general and shock signals in particular. In that context, a shock excitation may be treated as an impulse whose effect is to instantaneously change the velocity of an inertia element. Then, in the time domain, a shock load may also be treated as an initial-velocity excitation of an otherwise free (unforced) system.

32.2 Specification of Vibration Limits

Design and control procedures of vibration have the primary objective of ensuring that under normal operating conditions, the system of interest does not encounter vibration levels that exceed the specified values. In this context, then, the ways of specifying vibration limits become important. This section will present some common ways of vibration specification.

32.2.1 Peak Level Specification

Vibration limits for a mechanical system may be specified in either the time domain or the frequency domain. In the time domain, the simplest specification is the peak level of vibration (typically, acceleration in units of g — the acceleration due to gravity). Here, the techniques of isolation, design, or control should ensure that the peak vibration response of the system do not exceed the specified level. In this case, the entire time interval of operation of the system is monitored, and the peak values are checked against the specifications. Note that, in this case, it is the instantaneous peak value at a particular time instant that is of interest, and what is used in representing vibration is an instantaneous amplitude measure rather than an average amplitude or an energy measure.

32.2.2 Root-Mean-Square Value Specification

The root-mean-square (RMS) value of a vibration signal $y(t)$ is given by the square root of the average of the squared signal as

$$y_{\text{RMS}} = \left[\frac{1}{T} \int_0^T y^2 dt \right]^{1/2} \quad (32.1)$$

Note that, by squaring the signal, its sign is eliminated and, essentially, the energy level of the signal is used. The period T , over which the squared signal is averaged, will depend on the problem and the nature of the signal. For a periodic signal, one period is adequate for averaging. For transient signals, several time constants (typically four times the larger time constant) of the vibrating system would be sufficient. For random signals, a value that is as large as feasible should be used.

In the method of RMS value specification, the RMS value of the acceleration response (typically, acceleration in g s) is computed using Equation 32.1 and is compared with the specified value. In this method, instantaneous bursts of vibration do not have a significant effect as they are filtered out because of the integration. It is the average energy or power of the response signal that is considered. The duration of exposure enters into the picture indirectly and in an undesirable manner. For instance, a highly transient vibration signal can initially have a damaging effect. However, the larger the T that is used in Equation 32.1, the smaller the computed RMS value. Hence, in this case, the use of a large value for T would lead to diluting or masking the damage potential. In practice, the longer the exposure to a vibration signal, the greater the harm caused. Hence, when using specifications such as peak and RMS values, they have to be adjusted according to the period of exposure. Specifically, a larger specification should be used for longer periods of exposure.

32.2.3 Frequency-Domain Specification

It is not realistic to specify the limitation to vibration exposure of a complex dynamic system by just a single threshold value. Usually, the effect of vibration on a system depends on at least the following three parameters:

1. Level of vibration (peak, RMS, power, etc.).
2. Frequency content (range) of excitation.
3. Duration of exposure to vibration.

This is particularly true because the excitations that generate the vibration environment may not necessarily be a single-frequency (sinusoidal) signal and may be broadband and random. Furthermore, the response of the system to the vibration excitations will depend on its frequency transfer function, which determines its resonances and damping characteristics. Under these circumstances, it is desirable to provide specifications in a *nomograph* where the horizontal axis gives frequency (Hz) and the vertical axis could represent a motion variable such as displacement (m), velocity (m/s), or acceleration (m/s^2 or g). It is not important which of these motion variables represents the vertical axis of the nomograph. This is true because in the frequency domain

$$\text{Velocity} = j\omega \times \text{displacement}$$

$$\text{Acceleration} = j\omega \times \text{velocity}$$

and one form of motion may be easily converted into one of the remaining two motion representations. In each of the forms, assuming that the two axes of the nomograph are graduated in a logarithmic scale, the constant displacement, constant velocity, and constant acceleration lines are straight lines.

Consider a simple specification of machinery vibration limits as given by the following values:

$$\text{Displacement limit (peak)} = 0.001 \text{ m}$$

$$\text{Velocity limit} = 0.01 \text{ m/sec}$$

$$\text{Acceleration limit} = 1.0g$$

This specification may be represented in a velocity vs. frequency nomograph (log-log) as in Figure 32.2.

Usually, such simple specifications in the frequency domain are not adequate. As noted above, the system behavior will vary depending on the excitation frequency range. For example, motion sickness in humans may be predominant in low frequencies in the range of 0.1 to 0.6 Hz and passenger discomfort in

FIGURE 32.2 Operating vibration specification (nomograph) for a machine.

FIGURE 32.3 A severe-discomfort vibration specification for ground transit vehicles.

ground transit vehicles may be most serious in the frequency range of 4 to 8 Hz for vertical motion and 1 to 2 Hz for lateral motion. In addition, for any dynamic system, particularly at low damping levels, the neighborhoods of resonant frequencies should be avoided and, hence, should be specified by low vibration limits in the resonant regions. Furthermore, the duration of vibration exposure should be explicitly accounted for in specifications. For example, Figure 32.3 presents a ride comfort specification for a ground transit vehicle, where lower vibration levels are specified for longer trips.

Finally, it should be noted that the specifications we are concerned with in the present context of design and control are upper bounds of vibration. The system should perform below (within) these specifications under normal operating conditions. Test specifications are lower bounds. The test should be conducted at or above these vibration levels so that the system would meet the test specifications. Some considerations of vibration engineering are summarized in Box 32.1.

32.3 Vibration Isolation

The purpose of vibration isolation is to “isolate” the system of interest from vibration excitations by introducing an *isolator* in between them. Examples of isolators are machine mounts and vehicle suspension systems. Two general types of isolation can be identified:

1. Force isolation (related to force transmissibility)
2. Motion isolation (related to motion transmissibility)

In force isolation, vibration forces that would be ordinarily transmitted directly from a source to a supporting structure (isolated system) are filtered out by an isolator through its flexibility (spring) and dissipation (damping) so that part of the force is routed through an inertial path. Clearly, the concepts of *force transmissibility* are applicable here. In motion isolation, vibration motions that are applied at a moving platform of a mechanical system (isolated system) are absorbed by an isolator through its flexibility and dissipation so that the motion that is transmitted to the system of interest is weakened.

Box 32.1

VIBRATION ENGINEERING

Vibration mitigation approaches:

- Isolation (buffers system from excitation)
- Design modification (modifies the system)
- Control (senses vibration and applies a counteracting force: passive/active)

Vibration specification:

- Peak and RMS values
- Frequency-domain specs on a nomograph
 - *Vibration levels
 - *Frequency content
 - *Exposure duration

Note:

$$|\text{Velocity}| = \omega \times |\text{Displacement}|$$

$$|\text{Acceleration}| = \omega \times |\text{Velocity}|$$

Limiting specifications:

- Operation (design) specifications: specify upper bounds
- Testing specifications: specify lower bounds

The concepts of motion transmissibility are applicable in this case. The design problem in both cases is to select applicable parameters for the isolator so that the vibrations entering the system are below specified values within a frequency band of interest (the operating frequency range).

Let us revisit the main concepts of force transmissibility and motion transmissibility. Figure 32.4(a) gives a schematic model of force transmissibility through an isolator. Vibration force at the source is $f(t)$. In view of the isolator, the source system (with impedance Z_m) is made to move at the same speed as the isolator (with impedance Z_s). This is a parallel connection of impedances. Hence, the force $f(t)$ is split so that part of it is taken up by the inertial path (broken line) of Z_m . Only the remainder (f_s) is transmitted through Z_s to the supporting structure, which is the isolated system. Force transmissibility is

$$T_f = \frac{f_s}{f} = \frac{Z_s}{Z_m + Z_s} \quad (32.2)$$

Figure 32.4(b) gives a schematic model of motion transmissibility through an isolator. Vibration motion $v(t)$ of the source is applied through an isolator (with impedance Z_s and mobility M_s) to the isolated system (with impedance Z_m and mobility M_m). The resulting force is assumed to transmit directly from the isolator to the isolated system and hence, these two units are connected in series. Consequently, we have the motion transmissibility:

$$T_m = \frac{v_m}{v} = \frac{M_m}{M_m + M_s} = \frac{Z_s}{Z_s + Z_m} \quad (32.3)$$

It can be seen that, according to these two models, we have

$$T_f = T_m \quad (32.4)$$

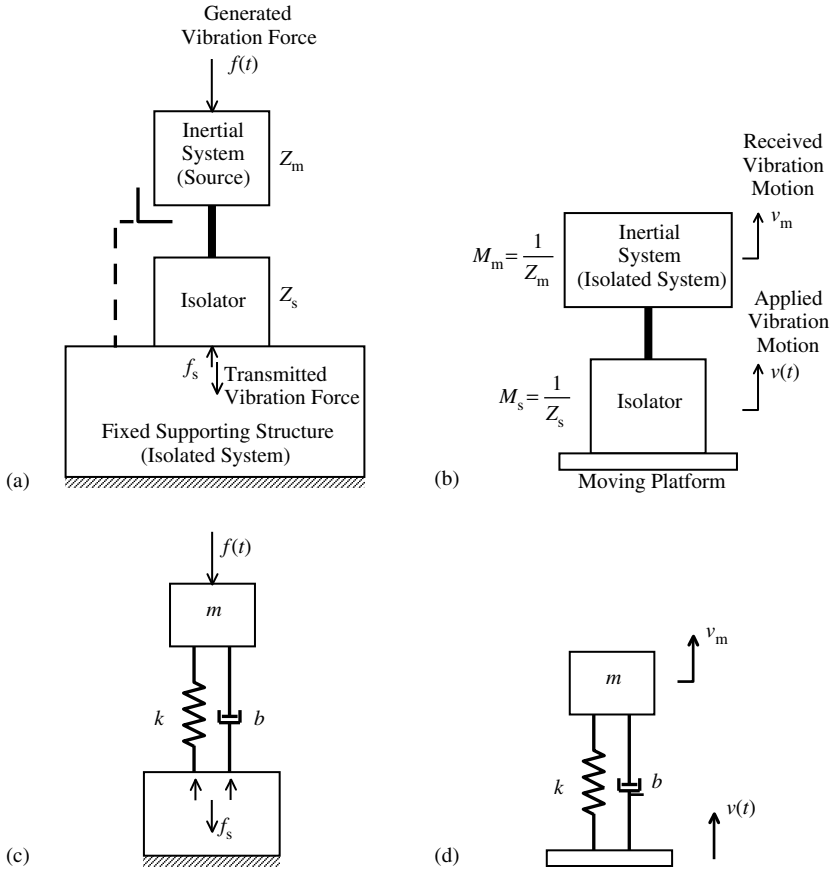

FIGURE 32.4 (a) Force isolation; (b) motion isolation; (c) force isolation example; (d) motion isolation example.

As a result, the concepts of force transmissibility and motion transmissibility may be studied using just one common transmissibility function T .

Simple examples of force isolation and motion isolation are shown in Figure 32.4(c) and (d). For both cases, the transmissibility function is given by

$$T = \frac{k + bj\omega}{(k - m\omega^2 + bj\omega)} \quad (32.5)$$

where ω is the frequency of vibration excitation. Note that the model (Equation 32.5) is not restricted to sinusoidal vibrations. Any general vibration excitation may be represented by a Fourier spectrum, which is a function of frequency ω . Then, the response vibration spectrum is obtained by multiplying the excitation spectrum by the transmissibility function T . The associated design problem is to select the isolator parameters k and b to meet the specifications of isolation.

Equation 32.5 may be expressed as

$$T = \frac{\omega_n^2 + 2\zeta\omega_n\omega}{(\omega_n^2 - \omega^2 + 2\zeta\omega_n\omega)} \quad (32.6)$$

where

$\omega_n = \sqrt{k/m}$ = undamped natural frequency of the system

$\zeta = \frac{b}{2\sqrt{km}}$ = damping ratio of the system

Equation 32.6 may be written in the nondimensional form:

$$T = \frac{1 + 2\zeta rj}{1 - r^2 + 2\zeta rj} \quad (32.7)$$

where the nondimensional excitation frequency is defined as

$$r = \omega/\omega_n$$

The transmissibility function has a phase angle as well as magnitude. In practical applications, the level of attenuation of the vibration excitation (rather than the phase difference between the vibration excitation and the response) is of primary importance. Accordingly, the transmissibility magnitude

$$|T| = \sqrt{\frac{1 + 4\zeta^2 r^2}{(1 - r^2)^2 + 4\zeta^2 r^2}} \quad (32.8)$$

is of interest. It can be shown that $|T| < 1$ for $r > \sqrt{2}$, which corresponds to the isolation region. Hence, the isolator should be designed such that the operative frequencies ω are greater than $\sqrt{2}\omega_n$. Furthermore, a threshold value for $|T|$ would be specified, and the parameters k and b of the isolator should be chosen so that $|T|$ is less than the specified threshold in the operating frequency range (which should be given). This procedure may be illustrated using an example.

Example 32.1

A machine tool and its supporting structure are modeled as the simple mass–spring–damper system shown in Figure 32.5.

1. Draw a mechanical-impedance circuit for this system in terms of the impedances of the three elements: mass (m), spring (k), and viscous damper (b).
2. Determine the exact value of the frequency ratio r in terms of the damping ratio ζ , at which the force transmissibility magnitude will peak. Show that for small ζ , this value is $r = 1$.
3. Plot $|T_f|$ vs. r for the interval $r = [0, 5]$, with one curve for each of the five ζ values 0.0, 0.3, 0.7, 1.0, and 2.0, on the same plane. Discuss the behavior of these transmissibility curves.
4. From part (3), determine for each of the five ζ values and the excitation frequency range with respect to ω_n , for which the transmissibility magnitude is:
 - Less than 1.05
 - Less than 0.5
5. Suppose that the device in Figure 32.5 has a primary, undamped natural frequency of 6 Hz and a damping ratio of 0.2. It is necessary that the system has a force transmissibility magnitude of less than 0.5 for operating frequency values greater than 12 Hz. Does the existing system meet this requirement? If not, explain how you should modify the system to meet the requirement.

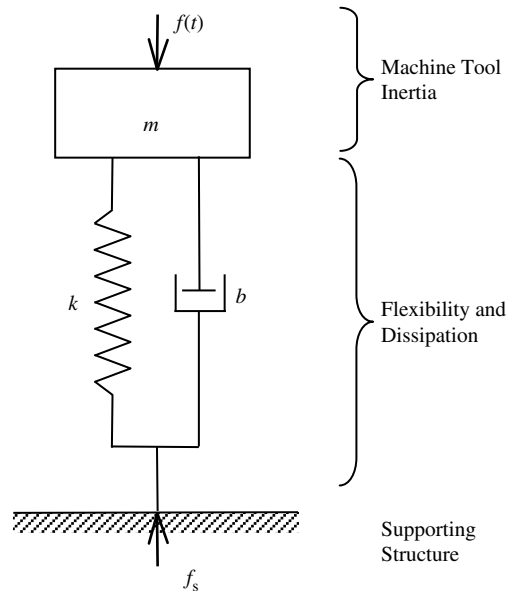

FIGURE 32.5 A simplified model of a machine tool and its supporting structure.

Solution

1. Here, the elements m , b , and f are in parallel with a common velocity v across them, as shown in Figure 32.6. In the circuit, $Z_m = mj\omega$, $Z_b = b$, and $Z_k = k/j\omega$.

Force transmissibility

$$T_f = \frac{F_s}{F} = \frac{F_s/V}{F/V} = \frac{Z_s}{Z_s + Z_0} = \frac{Z_b + Z_k}{Z_m + Z_b + Z_k} \quad (i)$$

Substitute the element impedances. We obtain

$$T_f = \frac{b + \frac{k}{j\omega}}{mj\omega + b + \frac{k}{j\omega}} = \frac{bj\omega + k}{-\omega^2 m + bj\omega + k} = \frac{j\omega b/m + k/m}{-\omega^2 + j\omega b/m + k/m} \quad (ii)$$

The last expression is obtained by dividing the numerator and the denominator by m . Now, use the fact that

$$\frac{k}{m} = \omega_n^2 \quad \text{and} \quad \frac{b}{m} = 2\zeta\omega_n$$

and divide Equation ii throughout by ω_n^2 . We obtain

$$T_f = \frac{\omega_n^2 + 2\zeta\omega_n j\omega}{\omega_n^2 - \omega^2 + 2\zeta\omega_n j\omega} = \frac{1 + 2\zeta r j}{1 - r^2 + 2\zeta r j} \quad (iii)$$

The transmissibility magnitude is

$$|T_f| = \sqrt{\frac{1 + 4\zeta^2 r^2}{(1 - r^2)^2 + 4\zeta^2 r^2}} \quad (32.9)$$

where $r = \omega/\omega_n$ is the normalized frequency.

2. To determine the peak point of $|T_f|$, differentiate the expression within the square-root sign in Equation iv and equate to zero:

$$\frac{[(1 - r^2)^2 + 2\zeta^2 r^2]8\zeta^2 r - [1 + 4\zeta^2 r^2][2(1 - r^2)(-2r) + 8\zeta^2 r]}{[(1 - r^2)^2 + 4\zeta^2 r^2]^2} = 0$$

Hence,

$$4r\{[(1 - r^2)^2 + 2\zeta^2 r^2]2\zeta^2 + [1 + 4\zeta^2 r^2][(1 - r^2) - 2\zeta^2]\} = 0$$

which simplifies to

$$r(2\zeta^2 r^4 + r^2 - 1) = 0$$

The roots are

$$r = 0 \quad \text{and} \quad r^2 = \frac{-1 \pm \sqrt{1 + 8\zeta^2}}{4\zeta^2}$$

The root $r = 0$ corresponds to the initial stationary point at zero frequency. That does not represent a peak. Taking only the positive root for r^2 and then its positive square root, the peak point of the transmissibility magnitude is given by

$$r = \frac{[\sqrt{1 + 8\zeta^2} - 1]^{1/2}}{2\zeta} \quad (iv)$$

FIGURE 32.6 The mechanical impedance circuit of the force isolation problem.

For small ζ , Taylor series expansion gives

$$\sqrt{1 + 8\zeta^2} \approx 1 + \frac{1}{2} \times 8\zeta^2 = 1 + 4\zeta^2$$

With this approximation, Equation iv equates to 1. Hence, for small damping, the transmissibility magnitude will have a peak at $r = 1$, and from Equation 32.9, its value is

$$|T_f| \approx \frac{\sqrt{1 + 4\zeta^2}}{2\zeta} \approx \frac{1 + \frac{1}{2} \times 4\zeta^2}{2\zeta}$$

or

$$|T_f| \approx \frac{1}{2\zeta} + \zeta \approx \frac{1}{2\zeta} \quad (\text{v})$$

3. The five curves of $|T_f|$ vs. r for $\zeta = 0, 0.3, 0.7, 1.0$, and 2.0 are shown in Figure 32.7. Note that these curves use the exact expression (see Equation 32.9).

From the curves, we observe the following:

1. There is always a nonzero frequency value at which the transmissibility magnitude will peak. This is the resonance.
2. For small ζ , the peak transmissibility magnitude is obtained at approximately $r = 1$. As ζ increases, this peak point shifts to the left (i.e., a lower value for peak frequency).
3. The peak magnitude decreases with increasing ζ .
4. All the transmissibility curves pass through the magnitude value 1.0 at the same frequency $r = \sqrt{2}$.
5. The isolation (i.e., $|T_f| < 1$) is given by $r > \sqrt{2}$. In this region, $|T_f|$ increases with ζ .
6. The transmissibility magnitude decreases for large r .

4. From the curves in Figure 32.7, we obtain:

- For $|T_f| < 1.05$; $r > \sqrt{2}$ for all ζ .
- For $|T_f| < 0.5$; $r > 1.73, 1.964, 2.871, 3.77, 7.075$ for $\zeta = 0.0, 0.3, 0.7, 1.0$, and 2.0 , respectively.

FIGURE 32.7 Transmissibility curves for a simple oscillator model.

5. We need

$$\sqrt{\frac{1 + 4\zeta^2 r^2}{(1 - r^2)^2 + 4\zeta^2 r^2}} < \frac{1}{2}$$

or

$$\frac{1 + 4\zeta^2 r^2}{(1 - r^2)^2 + 4\zeta^2 r^2} < \frac{1}{4}$$

or

$$4 + 16\zeta^2 r^2 < (1 - r^2)^2 + 4\zeta^2 r^2$$

or

$$r^4 - 2r^2 - 12\zeta^2 r^2 - 3 > 0$$

For $\zeta = 0.2$ and $r = 12/6 = 2$, the left-hand-side expression computes to

$$2^4 - 2 \times 2^2 - 12 \times (0.2)^2 \times 2^2 - 3 = 3.08 > 0$$

Hence, the requirement is met. In fact, since, for $r = 2$

$$\text{LHS} = 2^4 - 2 \times 2^2 - 12 \times 2^2 \zeta^2 - 3 = 5 - 48\zeta^2$$

it follows that the requirement would be met for

$$5 - 48\zeta^2 > 0$$

or

$$\zeta < \sqrt{\frac{5}{48}} = 0.32$$

If the requirement was not met (e.g., if $\zeta = 0.4$), the option would be to reduce damping.

32.3.1 Design Considerations

The *level of isolation* is defined as $1 - T$. It was noted that in the isolation region ($r > \sqrt{2}$) the transmissibility decreases (hence, the level of isolation increases) as the damping ratio ζ decreases. Thus, the best conditions of isolation are given by $\zeta = 0$. This is not feasible in practice, but we should maintain ζ as small as possible. For small ζ in the isolation region, Equation 32.8 may be approximated by

$$T = \frac{1}{(r^2 - 1)} \quad (32.10)$$

Note that T is real, in this case, of $\zeta \cong 0$, and also is positive since $r > \sqrt{2}$. However, in general, T may denote the magnitude of the transmissibility function. Substitute

$$r^2 = \omega^2/\omega_n^2 = \omega^2 m/k$$

We get

$$k = \frac{\omega^2 m T}{(1 + T)} \quad (32.11)$$

This equation may be used to determine the design stiffness of the isolator for a specified level of isolation ($1 - T$) in the operating frequency range $\omega > \omega_0$ for a system of known mass (including the isolator mass). Often, the static deflection δ_s of spring is used in design procedures and is

given by

$$\delta_s = \frac{mg}{k} \quad (32.12)$$

Substituting Equation 32.12 into Equation 32.11, we obtain

$$\delta_s = (1 + T) \frac{g}{\omega^2 T} \quad (32.13)$$

Since the isolation region is $\omega > \sqrt{2}\omega_n$ it is desirable to make ω_n as small as possible in order to obtain the widest frequency range of operation. This is achieved by making the isolator as soft as possible (k as low as possible). However, there are limits to this in terms of structural strength, stability, and availability of springs. Then, m may be increased by adding an inertia block as the base of the system, which is then mounted on the isolator spring (with a damping layer) or an air-filled pneumatic mount. The inertia block will also lower the centroid of the system, thereby providing added desirable effects of stability and reducing rocking motions and noise transmission. For improved load distribution, instead of just one spring of design stiffness k , a set of n springs, each with stiffness k/n and uniformly distributed under the inertia block, should be used.

Another requirement for good vibration isolation is low damping. Usually, metal springs have very low damping (typically ζ less than 0.01). On the other hand, higher damping is needed to reduce resonant vibrations that will be encountered during start-up and shutdown conditions when the excitation frequency will vary and pass through the resonances. In addition, vibration energy has to be effectively dissipated, even under steady operating conditions. Isolation pads made of damping material such as cork, natural rubber, and neoprene may be used for this purpose. They can provide damping ratios of the order of 0.01.

The basic design steps for a vibration isolator in force isolation are as follows:

1. The required level of isolation (1 to T) and the lowest frequency of operation (ω_0) are specified. The mass of the vibration source (m) is known.
2. Use Equation 32.11 with $\omega = \omega_0$ to compute the required stiffness k of the isolator.
3. If the component k is not satisfactory, then increase m by introducing an inertia block and recompute k .
4. Distribute k over several springs.
5. Introduce a mounting pad of known stiffness and damping. Modify k and b accordingly and compute T using Equation 32.8. If the specified T is exceeded, then modify the isolator parameters as appropriate and repeat the design cycle.

Box 32.2 gives some relations that are useful in a design for vibration isolation.

Example 32.2

Consider a motor and fan unit of a building ventilation system weighing 50 kg and operating in the speed range of 600 to 3600 rpm. Since offices are located directly underneath the motor room, a 90% vibration isolation is desired. A set of mounting springs, each having a stiffness of 100 N/cm, is available. Design an isolation system to mount the motor-fan unit on the room floor.

Solution

For an isolation level of 90%, the required force transmissibility is $T = 0.1$. The lowest frequency of operation is $\omega = (600/60)2\pi$ rad/sec. First, we try four mounting points. The overall spring stiffness is $k = 4 \times 100 \times 10^2$ N/m. Substitute in Equation 32.11.

$$4 \times 100 \times 100 = \frac{(10 \times 2\pi)^2 \times m \times 0.1}{1.1}$$

Box 32.2

VIBRATION ISOLATION

Transmissibility (force/force or motion/motion):

$$|T| = \sqrt{\frac{1 + 4\zeta^2 r^2}{(1 - r^2)^2 + 4\zeta^2 r^2}} \cong \frac{1}{(r^2 - 1)} \text{ for } r > 1 \text{ and small } \zeta$$

Properties:

1. $T_{\text{peak}} \cong \frac{\sqrt{1 + 4\zeta^2}}{2\zeta} \cong \frac{1}{2\zeta}$ for small ζ
2. T_{peak} occurs at $r_{\text{peak}} = \frac{[\sqrt{1 + 8\zeta^2} - 1]^{1/2}}{2\zeta} \cong 1$ for small ζ
3. All $|T|$ curves coincide at $r = \sqrt{2}$ for all ζ
4. Isolation region: $r > \sqrt{2}$
5. In isolation region:
 $|T|$ decreases with r (i.e., better isolation at higher frequencies)
 $|T|$ increases with ζ (i.e., better isolation at lower damping)

Design formulas:

Level of isolation = $1 - T$

Isolator stiffness:

$$k = \frac{\omega^2 m T}{(1 + T)}$$

where

m = system mass

ω = operating frequency

Static deflection:

$$\delta_s = \frac{mg}{k} = (1 + T) \frac{g}{\omega^2 T}$$

which gives $m = 111.5$ kg. Since the mass of the unit is 50 kg, we should use an inertia block of mass 61.5 kg or more.

32.3.2 Vibration Isolation of Flexible Systems

The simple model shown in Figure 32.4(c) and (d) may not be adequate in the design of vibration isolators for sufficiently flexible systems. A more appropriate model for this situation is shown in Figure 32.8. Note that the vibration isolator has an inertia block of mass m in addition to damped flexible mounts of stiffness k and damping constant b . The vibrating system itself has a stiffness K and damping constant B in addition to its mass M .

In the absence of K , B , and the inertia block (m) as in Figure 32.4(c), the vibrating system becomes a simple inertia (M). Then, y_a and y are the same and the equation of motion is

$$M\ddot{y} + b\dot{y} + ky = f(t) \quad (32.14)$$

with the force transmitted to the support structure, f_s , given by

$$f_s = b\dot{y} + ky \quad (32.15)$$

The force transmissibility in this case is

$$T_{\text{inertial}} = \frac{f_s}{f} = \frac{bs + k}{Ms^2 + bs + k} \quad (32.16)$$

with $s = j\omega$

For the flexible system and isolator shown in Figure 32.8, the equation of motion:

$$M\ddot{y}_a + B(\dot{y}_a - \dot{y}) + K(y_a - y) = f(t) \quad (32.17)$$

$$m\ddot{y} + B(\dot{y} - \dot{y}_a) + K(y - y_a) + b\dot{y} + ky = 0 \quad (32.18)$$

Hence, in the frequency domain, we have

$$(Ms^2 + Bs + K)y_a - (Bs + K)y = f \quad (32.19)$$

$$[ms^2 + (B + b)s + K + k]y = (Bs + K)y_a \quad (32.20)$$

with $s = j\omega$

Substitute Equation 32.20 into Equation 32.19 for eliminating y_a . We obtain

$$\left\{ (Ms^2 + Bs + K) \frac{[ms^2 + (B + b)s + K + k]}{(Bs + K)} - (Bs + K) \right\} y = f$$

which simplifies

$$\left\{ \frac{Ms^2[ms^2 + (B + b)s + K + k] + (Bs + K)(ms^2 + bs + k)}{(Bs + K)} \right\} y = f \quad (32.21)$$

The force transmitted to the supporting structure is still given by Equation 32.15. Hence, the transmissibility with the flexible system is

$$T_{\text{flexible}} = \frac{(Bs + K)(bs + k)}{\{Ms^2[ms^2 + (B + b)s + K + k] + (Bs + K)(ms^2 + bs + k)\}} \quad \text{with } s = j\omega \quad (32.22)$$

From Equation 32.16 and Equation 32.22, the transmissibility magnitude ratio is

$$\frac{T_{\text{flexible}}}{T_{\text{inertial}}} = \left| \frac{(Bs + K)(Ms^2 + bs + k)}{Ms^2[ms^2 + (B + b)s + K + k] + (Bs + K)(ms^2 + bs + k)} \right| \quad \text{with } s = j\omega \quad (32.23)$$

or

$$\frac{T_{\text{flexible}}}{T_{\text{inertial}}} = \left| \frac{(Ms^2 + bs + k)}{Ms^2(ms^2 + bs + k)/(Bs + K) + Ms^2 + ms^2 + bs + k} \right| \quad s = j\omega \quad (32.24)$$

In the nondimensional form, we have

$$\frac{T_{\text{flexible}}}{T_{\text{inertial}}} = \left| \frac{1 - r^2 + 2j\zeta_b r}{-r^2(1 - r_m r^2 + 2j\zeta_b r)/(r_\omega^2 + 2j\zeta_a r_\omega r) + 1 - (1 + r_m)r^2 + 2j\zeta_b r} \right| \quad (32.25)$$

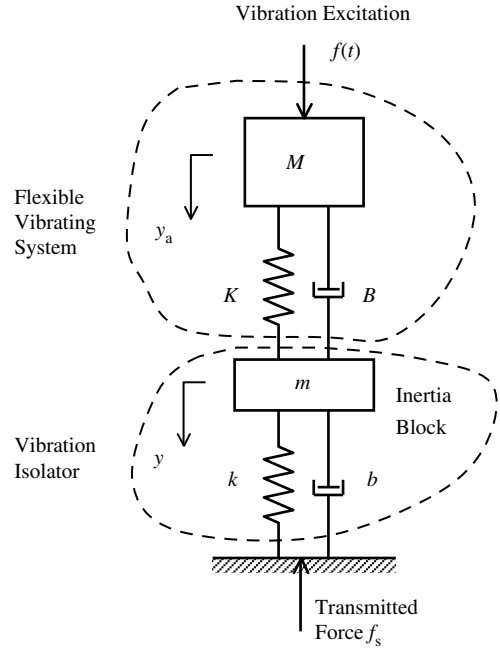

FIGURE 32.8 A model for vibration isolation of a flexible system.

FIGURE 32.9 The effect of system flexibility on the transmissibility magnitude in the undamped case (mass ratio = 1.0; natural frequency ratio = 10.0).

where

$$r = \frac{\omega}{\sqrt{k/M}}$$

$$r_m = \frac{m}{M}$$

$$r_\omega = \frac{\sqrt{K/M}}{\sqrt{k/M}} = \sqrt{\frac{K}{k}}$$

$$\zeta_a = \frac{B}{2\sqrt{KM}}$$

$$\zeta_b = \frac{b}{2\sqrt{kM}}$$

Again, the design problem of vibration isolation is to select the parameters r_m , r_ω , ζ_a , and ζ_b so that the required level of vibration isolation is realized for an operating frequency range of r .

A plot of Equation 32.25 for the undamped case with $r_m = 1.0$ and $r_\omega = 10.0$ is given in Figure 32.9. Generally, the transmissibility ratio will be zero at $r = 1$ (the resonance of the inertial system) and there will be two values of r (the resonances of the flexible system), for which the ratio will become infinity in the undamped case. The latter two neighborhoods should be avoided under steady operating conditions.

32.4 Balancing of Rotating Machinery

Many practical devices that move contain rotating components. Examples are wheels of vehicles, shafts, gear transmissions of machinery, belt drives, motors, turbines, compressors, fans, and rollers. An unbalance (imbalance) is created in a rotating part when its center of mass does not coincide with the axis

of rotation. The reasons for this *eccentricity* include the following:

1. Inaccurate production procedures (machining, casting, forging, assembly, etc.)
2. Wear and tear
3. Loading conditions (mechanical)
4. Environmental conditions (thermal loads and deformation)
5. Use of inhomogeneous and anisotropic material (which does not have a uniform density distribution)
6. Component failure
7. Addition of new components to a rotating device

For a component of mass m , eccentricity e , and rotating at angular speed ω , the centrifugal force that is generated is $m\omega^2 e$. Note the quadratic variation with ω . This rotating force may be resolved into two orthogonal components, which will be sinusoidal with frequency ω . It follows that harmonic forcing excitations are generated due to the unbalance, which can generate undesirable vibrations and associated problems.

Problems caused by unbalance include wear and tear, malfunction and failure of components, poor quality of products, and undesirable noise. The problem becomes increasingly important given the present trend of developing high-speed machinery. It is estimated that the speed of operation of machinery has doubled during the past 50 years. This means that the level of unbalance forces may have quadrupled during the same period, causing more serious vibration problems.

An unbalanced rotating component may be balanced by adding or removing material to or from the component. We need to know both the magnitude and location of the balancing masses to be added to, or removed. The present section will address the problem of component balancing for vibration suppression.

Note that the goal to remove the source of vibration (namely, the mass eccentricity) typically by adding one or more balancing mass elements. Two methods are available:

1. Static (single-plane) balancing
2. Dynamic (two-plane) balancing

The first method concerns balancing of planar objects (e.g., pancake motors, disks) whose longitudinal dimension about the axis of rotation is not significant. The second method concerns balancing of objects that have a significant longitudinal dimension. We will discuss both methods.

32.4.1 Static Balancing

Consider a disk rotating at angular velocity ω about a fixed axis. Suppose that the mass center of the disk has an eccentricity e from the axis of rotation, as shown in Figure 32.10(a). Place a fixed coordinate frame

FIGURE 32.10 (a) Unbalance in a rotating disk due to mass eccentricity; (b) rotating vector (phasor) of centrifugal force due to unbalance.

x - y at the center of rotation. The position \vec{e} of the mass center in this coordinate frame may be represented as:

1. A position vector rotating at angular speed ω .
2. A complex number, with x -coordinate denoting the real part and y -coordinate denoting the imaginary part.

The centrifugal force due to the mass eccentricity is also a vector in the direction of \vec{e} , but with a magnitude $f_o = m\omega^2 e$, as shown in Figure 32.10(b). It is seen that harmonic excitations result in both x and y directions, given by $f_o \cos \omega t$ and $f_o \sin \omega t$, respectively, where $\theta = \omega t =$ orientation of the rotating vector with respect to the x -axis. To balance the disk, we should add a mass m at $-\vec{e}$. However, we do not know the value of m and the location of \vec{e} .

32.4.1.1 Balancing Approach

1. Measure the amplitude V_u and the phase angle ϕ_1 (e.g., by the signal from an accelerometer mounted on the bearing of the disk) of the unbalance centrifugal force with respect to some reference.
2. Mount a known mass (trial mass) M_t at a known location on the disk. Suppose that its own centrifugal force is given by the rotating vector \vec{V}_w , and the resultant centrifugal force due to both the original unbalance and the final mass is \vec{V}_r .
3. Measure the amplitude V_r and the phase angle ϕ_2 of the resultant centrifugal force as in step 1, with respect to the same phase reference.

A vector diagram showing the centrifugal forces \vec{V}_u and \vec{V}_w due to the original unbalance and the trial-mass unbalance, respectively, is shown in Figure 32.11. The resultant unbalance is $\vec{V}_r = \vec{V}_u + \vec{V}_w$. Note that $-\vec{V}_u$ represents the centrifugal force due to the balancing mass. Therefore, if we determine the angle ϕ_b in Figure 32.11, it will give the orientation of the balancing mass. Suppose also that the balancing mass is M_b and it is mounted at an eccentricity equal to that of the trial mass M_t . Then,

$$\frac{M_b}{M_t} = \frac{V_u}{V_w}$$

FIGURE 32.11 A vector diagram of the single-plane (static) balancing problem.

We need to determine the ratio V_u/V_w and the angle ϕ_b . These values can be derived as follows:

$$\phi = \phi_2 - \phi_1 \quad (32.26)$$

The cosine rule gives

$$V_w^2 = V_u^2 + V_r^2 - 2V_u V_r \cos \phi \quad (32.27)$$

This will provide V_w since V_u , V_r , and ϕ are known. Apply the cosine rule again:

$$V_r^2 = V_u^2 + V_w^2 - 2V_u V_w \cos \phi_b$$

Hence,

$$\phi_b = \cos^{-1} \left[\frac{V_u^2 + V_w^2 - V_r^2}{2V_u V_w} \right] \quad (32.28)$$

Note: One may think that since we measure ϕ_1 , we know exactly where \bar{V}_u is. This is not the case because we do not know the reference line from which ϕ_1 is measured. We only know that this reference is kept fixed (through strobe synchronization of the body rotation) during measurements. Hence, we need to know ϕ_b , which gives the location of $-\bar{V}_u$ with respect to the known location of \bar{V}_w on the disk.

32.4.2 Complex Number/Vector Approach

Again, suppose that the imbalance is equivalent to a mass of M_b that is located at the same eccentricity (radius) r as the trial mass M_t . Define complex numbers (mass location vectors in a body frame)

$$\bar{M}_b = M_b \angle \theta_b \quad (32.29)$$

$$\bar{M}_t = M_t \angle \theta_t \quad (32.30)$$

as shown in Figure 32.12.

Associated force vectors are

$$\bar{V}_u = \omega^2 r e^{j\omega t} M_b \angle \theta_b \quad (32.31)$$

$$\bar{V}_w = \omega^2 r e^{j\omega t} M_t \angle \theta_t \quad (32.32)$$

or

$$\bar{V}_u = \bar{A} \bar{M}_b \quad (32.33)$$

$$\bar{V}_w = \bar{A} \bar{M}_t \quad (32.34)$$

where $\bar{A} = \omega^2 r e^{j\omega t}$ is the conversion factor (complex) from the mass to the resulting dynamic force (rotating). This factor is the same for both cases since r is the same. We need to determine \bar{M}_b .

From Equation 32.33

$$\bar{M}_b = \frac{\bar{V}_u}{\bar{A}} \quad (32.35)$$

Substitute Equation 32.34:

$$\bar{M}_b = \frac{\bar{V}_u}{\bar{V}_w} \cdot \bar{M}_t \quad (32.36)$$

However, since

$$\bar{V}_r = \bar{V}_u + \bar{V}_w \quad (32.37)$$

FIGURE 32.12 Rotating vectors of mass location.

we have

$$\vec{M}_b = \frac{\vec{V}_u}{(\vec{V}_r - \vec{V}_u)} \cdot \vec{M}_t \quad (32.38)$$

Since we know \vec{M}_t and we measure \vec{V}_u and \vec{V}_r to the same scaling factor, we can compute \vec{M}_b . Locate the balancing mass at $-\vec{M}_b$ (with respect to the body frame).

Example 32.3

Consider the following experimental steps:

Measured: Accelerometer amplitude (oscilloscope reading) of 6.0 with a phase lead (with respect to strobe signal reference, which is synchronized with the rotating body frame) of 50° .

Added: Trial mass $M_t = 20$ g at angle 180° with respect to a body reference radius.

Measured: Accelerometer amplitude of 8.0 with a phase lead of 60° (with respect synchronized strobe signal).

Determine the magnitude and location of the balancing mass.

Solution

Method 1:

We have the data

$$\phi = 60 - 50^\circ = 10^\circ$$

$$V_u = 6.0; \quad V_r = 8.0$$

Hence, from Equation 32.27:

$$V_w = \sqrt{6^2 + 8^2 - 2 \times 6 \times 8 \cos 10^\circ} = 2.37$$

Balancing mass:

$$M_b = \frac{6.0}{2.37} \times 20 = 50.63 \text{ g}$$

Equation 32.28 gives

$$\phi_b = \cos^{-1} \left[\frac{6^2 + 2.37^2 - 8^2}{2 \times 6 \times 2.37} \right] = \cos^{-1}(-0.787) = 142^\circ \text{ or } 218^\circ$$

Pick the result $0^\circ \leq \phi_b \leq 180^\circ$, as clear from the vector diagram shown in [Figure 32.11](#).

Hence,

$$\phi_b = 142^\circ$$

However,

$$\vec{M}_t = 20 \angle 180^\circ \text{ g}$$

It follows that

$$-\vec{M}_b = 50.63 \angle (180^\circ + 142^\circ) \text{ g} = 50.63 \angle 322^\circ \text{ g}$$

Method 2:

We have

$$\vec{M}_t = 20 \angle 180^\circ \text{ g}$$

$$\vec{V}_u = 6.0 \angle 50^\circ$$

$$\vec{V}_r = 8.0 \angle 60^\circ$$

Then, from Equation 32.38 we obtain

$$\vec{M}_b = \frac{6.0 \angle 50^\circ}{(8.0 \angle 60^\circ - 6.0 \angle 50^\circ)} 20 \angle 180^\circ \text{ g}$$

First, we compute

$$\begin{aligned} 8.0 \angle 60^\circ - 6.0 \angle 50^\circ &= (8.0 \cos 60^\circ + j8.0 \sin 60^\circ) - (6.0 \cos 50^\circ + j6.0 \sin 50^\circ) \\ &= (8.0 \cos 60^\circ - 6.0 \cos 50^\circ) + j(8.0 \sin 60^\circ - 6.0 \sin 50^\circ) = 0.1433 + j2.332 \\ &= 2.336 \angle 86.48^\circ \end{aligned}$$

Hence,

$$\vec{M}_b = \frac{6.0 \angle 50^\circ}{2.336 \angle 86.48^\circ} 20 \angle 180^\circ = \frac{6.0 \times 20}{2.336} \angle (50^\circ + 180^\circ - 86.48^\circ) = 51 \angle 143.5^\circ \text{ g}$$

The balancing mass should be located at

$$-\vec{M}_b = 51 \angle 323.5^\circ \text{ g}$$

Note: This angle is measured from the same body reference as for the trial mass.

32.4.3 Dynamic (Two-Plane) Balancing

Instead of an unbalanced disk, consider an elongated rotating object supported at two bearings, as shown in Figure 32.13. In this case, in general, there may not be an equivalent single unbalance force at a single plane normal to the shaft axis. To show this, recall that a system of forces may be represented by a single force at a specified location and a couple (two parallel forces that are equal and opposite). If this single force (resultant force) is zero, we are left with only a couple. The couple cannot be balanced by a single force.

All the unbalance forces at all the planes along the shaft axis can be represented by an equivalent single unbalance force at a specified plane and a couple. If this equivalent force is zero, then to balance the couple we will need two equal and opposite forces at two different planes.

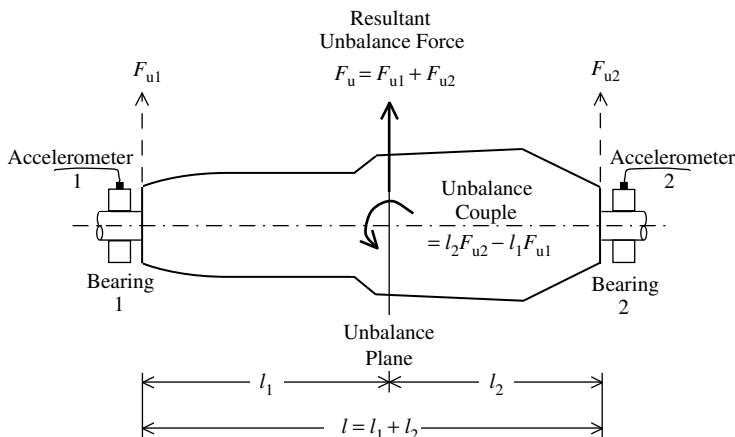

FIGURE 32.13 A dynamic (two-plane) balancing problem.

On the other hand, if the couple is zero, then a single force in the opposite direction at the same plane of the resultant unbalance force will result in complete balancing. However, this unbalance plane may not be reachable, even if it is known, for the purpose of adding the balancing mass.

In the present (two-plane) balancing problem, the balancing masses are added at the two bearing planes so that both the resultant unbalance force and couple are balanced, in general. It is clear from Figure 32.13 that even a sole unbalance mass \bar{M}_b at a single unbalance plane may be represented by two unbalance masses \bar{M}_{b1} and \bar{M}_{b2} at the bearing planes 1 and 2. Likewise, in the presence of an unbalance couple, we can simply add two equal and opposite forces at the planes 1 and 2 so that its couple is equal to the unbalance couple. Hence, a general unbalance can be represented by the two unbalance masses \bar{M}_{b1} and \bar{M}_{b2} at planes 1 and 2, as shown in Figure 32.13. As for the single-plane balancing problem, the resultant unbalance forces at the two bearings (which would be measured by the accelerometers at 1 and 2) are

$$\bar{V}_{u1} = \bar{A}_{11}\bar{M}_{b1} + \bar{A}_{12}\bar{M}_{b2} \quad (32.39)$$

$$\bar{V}_{u2} = \bar{A}_{21}\bar{M}_{b1} + \bar{A}_{22}\bar{M}_{b2} \quad (32.40)$$

Suppose that a trial mass of \bar{M}_{t1} (at a known location with respect to the body reference line) was added at plane 1. The resulting unbalance forces at the two bearings are

$$\bar{V}_{r11} = \bar{A}_{11}(\bar{M}_{b1} + \bar{M}_{t1}) + \bar{A}_{12}\bar{M}_{b2} \quad (32.41)$$

$$\bar{V}_{r21} = \bar{A}_{21}(\bar{M}_{b1} + \bar{M}_{t1}) + \bar{A}_{22}\bar{M}_{b2} \quad (32.42)$$

Next, suppose that a trial mass of \bar{M}_{t2} (at a known location with respect to the body reference line) was added at plane 2, after removing \bar{M}_{t1} . The resulting unbalance forces at the two bearings are

$$\bar{V}_{r12} = \bar{A}_{11}\bar{M}_{b1} + \bar{A}_{12}(\bar{M}_{b2} + \bar{M}_{t2}) \quad (32.43)$$

$$\bar{V}_{r22} = \bar{A}_{21}\bar{M}_{b1} + \bar{A}_{22}(\bar{M}_{b2} + \bar{M}_{t2}) \quad (32.44)$$

The following subtractions of equations are now made.

Equation 32.41 minus Equation 32.39:

$$\bar{V}_{r11} - \bar{V}_{u1} = \bar{A}_{11}\bar{M}_{t1} \quad \text{or} \quad \bar{A}_{11} = \frac{\bar{V}_{r11} - \bar{V}_{u1}}{\bar{M}_{t1}} \quad (32.45)$$

Equation 32.42 minus Equation 32.40:

$$\bar{V}_{r21} - \bar{V}_{u2} = \bar{A}_{21}\bar{M}_{t1} \quad \text{or} \quad \bar{A}_{21} = \frac{\bar{V}_{r21} - \bar{V}_{u2}}{\bar{M}_{t1}} \quad (32.46)$$

Equation 32.43 minus Equation 32.39:

$$\bar{V}_{r12} - \bar{V}_{u1} = \bar{A}_{12}\bar{M}_{t2} \quad \text{or} \quad \bar{A}_{12} = \frac{\bar{V}_{r12} - \bar{V}_{u1}}{\bar{M}_{t2}} \quad (32.47)$$

Equation 32.44 minus Equation 32.40:

$$\bar{V}_{r22} - \bar{V}_{u2} = \bar{A}_{22}\bar{M}_{t2} \quad \text{or} \quad \bar{A}_{22} = \frac{\bar{V}_{r22} - \bar{V}_{u2}}{\bar{M}_{t2}} \quad (32.48)$$

Hence, generally

$$\bar{A}_{ij} = \frac{\bar{V}_{rij} - \bar{V}_{ui}}{\bar{M}_{tj}} \quad (32.49)$$

These parameters A_{ij} are called *influence coefficients*.

Next, in Equation 32.39 and Equation 32.40 eliminate \bar{M}_{b2} and \bar{M}_{b1} separately to determine the other. Thus,

$$\bar{A}_{22} \bar{V}_{u1} - \bar{A}_{12} \bar{V}_{u2} = (\bar{A}_{22} \bar{A}_{11} - \bar{A}_{12} \bar{A}_{21}) \bar{M}_{b1}$$

$$\bar{A}_{21} \bar{V}_{u1} - \bar{A}_{11} \bar{V}_{u2} = (\bar{A}_{21} \bar{A}_{12} - \bar{A}_{11} \bar{A}_{22}) \bar{M}_{b2}$$

or

$$\bar{M}_{b1} = \frac{\bar{A}_{22} \bar{V}_{u1} - \bar{A}_{12} \bar{V}_{u2}}{(\bar{A}_{22} \bar{A}_{11} - \bar{A}_{12} \bar{A}_{21})} \quad (32.50)$$

$$\bar{M}_{b2} = \frac{\bar{A}_{21} \bar{V}_{u1} - \bar{A}_{11} \bar{V}_{u2}}{(\bar{A}_{21} \bar{A}_{12} - \bar{A}_{11} \bar{A}_{22})} \quad (32.51)$$

Substitute Equation 32.45 to Equation 32.48 into Equation 32.50 and Equation 32.51 to determine \bar{M}_{b1} and \bar{M}_{b2} . Balancing masses that should be added are $-\bar{M}_{b1}$ and $-\bar{M}_{b2}$ in planes 1 and 2, respectively.

The single-plane and two-plane balancing approaches are summarized in Box 32.3.

Example 32.4

Suppose that the following measurements are obtained.

Without trial mass:

Accelerometer at 1: amplitude = 10.0; phase lead = 55°.

Accelerometer at 2: amplitude = 7.0; phase lead = 120°

With trial mass 20 g at location 270° of plane 1:

Accelerometer at 1: amplitude = 7.0; phase lead = 120°

Accelerometer at 2: amplitude = 5.0; phase lead = 225°

With trial mass 25 g at location 180° of plane 2:

Accelerometer at 1: amplitude = 6.0; phase lead = 120°

Accelerometer at 2: amplitude = 12.0; phase lead = 170°

Determine the magnitude and orientation of the necessary balancing masses in planes 1 and 2 in order to completely balance (dynamic) the system.

Solution

In the phasor notation, we can represent the given data as follows:

$$\bar{V}_{u1} = 10.0 \angle 55^\circ; \quad \bar{V}_{u2} = 7.0 \angle 120^\circ$$

$$\bar{V}_{r11} = 7.0 \angle 120^\circ; \quad \bar{V}_{r21} = 5.0 \angle 225^\circ$$

$$\bar{V}_{r12} = 6.0 \angle 120^\circ; \quad \bar{V}_{r22} = 12.0 \angle 170^\circ$$

$$\bar{M}_{t1} = 20 \angle 270^\circ \text{ g}; \quad \bar{M}_{t2} = 25 \angle 180^\circ \text{ g}$$

From Equation 32.45 to Equation 32.48, we have

$$\bar{A}_{11} = \frac{7.0 \angle 120^\circ - 10.0 \angle 55^\circ}{20 \angle 270^\circ}; \quad \bar{A}_{21} = \frac{5.0 \angle 225^\circ - 7.0 \angle 120^\circ}{20 \angle 270^\circ}$$

$$\bar{A}_{12} = \frac{6.0 \angle 120^\circ - 10.0 \angle 55^\circ}{25 \angle 180^\circ}; \quad \bar{A}_{22} = \frac{12.0 \angle 170^\circ - 7.0 \angle 120^\circ}{25 \angle 180^\circ}$$

These phasors are computed as below:

$$\begin{aligned} \bar{A}_{11} &= \frac{(7.0 \cos 120^\circ - 10 \cos 55^\circ) + j(7 \sin 120^\circ - 10 \sin 55^\circ)}{20 \angle 270^\circ} = \frac{-9.235 - j2.129}{20 \angle 270^\circ} = \frac{9.477 \angle 193^\circ}{20 \angle 270^\circ} \\ &= 0.474 \angle -77^\circ \end{aligned}$$

Box 32.3

BALANCING OF ROTATING COMPONENTS

Static or single-plane balancing (balances a single equivalent dynamic force)

Experimental approach:

1. With respect to a body reference line of accelerometer signal at bearing, measure magnitude (V) and phase (ϕ):
 - (a) Without trial mass: (V_u, ϕ_1) or $\bar{V}_u = V_u \angle \phi_1$
 - (b) With trial mass M_t : (V_r, ϕ_2) or $\bar{V}_r = V_r \angle \phi_2$.
2. Compute balancing mass M_b and its location with respect to M_t .
3. Remove M_t and add M_b at determined location.

Computation approach 1:

$$V_w = [V_u^2 + V_r^2 - 2V_u V_w \cos(\phi_2 - \phi_1)]^{1/2}$$

$$\phi_b = \cos^{-1} \left[\frac{V_u^2 + V_w^2 - V_r^2}{2V_u V_w} \right] \text{ and } M_b = \frac{V_u}{V_w} M_t$$

Locate M_b at ϕ_b from M_t .

Computation approach 2:

Unbalance mass phasor

$$\bar{M}_b = \frac{\bar{V}_u}{(\bar{V}_r - \bar{V}_u)} \bar{M}_t$$

where $\bar{M}_t = M_t \angle \theta_t$ (trial mass phasor).

Locate balancing mass at $-\bar{M}_b$.

Dynamic or two-plane balancing (balances an equivalent dynamic force and a couple)

Experimental approach:

1. Measure \bar{V}_{ui} at bearings $i = 1, 2$, with a trial mass.
2. Measure \bar{V}_{rij} at bearings $i = 1, 2$, with only one trial mass \bar{M}_{tj} at $j = 1, 2$.
3. Compute unbalance mass phasor \bar{M}_{bi} in planes $i = 1, 2$.
4. Remove trial mass and place balancing masses $-\bar{M}_{bi}$ in planes $i = 1, 2$.

Computations:

Influence coefficients: $\bar{A}_{ij} = (\bar{V}_{rij} - \bar{V}_{ui})/\bar{M}_{tj}$

Unbalance mass phasors:

$$\bar{M}_{b1} = \frac{\bar{A}_{22}\bar{V}_{u1} - \bar{A}_{12}\bar{V}_{u2}}{(\bar{A}_{22}\bar{A}_{11} - \bar{A}_{12}\bar{A}_{21})} \quad \text{and} \quad \bar{M}_{b2} = \frac{\bar{A}_{21}\bar{V}_{u1} - \bar{A}_{11}\bar{V}_{u2}}{(\bar{A}_{21}\bar{A}_{12} - \bar{A}_{11}\bar{A}_{22})}$$

$$\begin{aligned} \bar{A}_{21} &= \frac{(5 \cos 225^\circ - 7 \cos 120^\circ) + j(5 \sin 225^\circ - 7 \sin 120^\circ)}{20 \angle 270^\circ} = \frac{-7.036 - j9.6}{20 \angle 270^\circ} = \frac{11.9 \angle 234^\circ}{20 \angle 270^\circ} \\ &= 0.595 \angle -36^\circ \end{aligned}$$

$$\begin{aligned} \bar{A}_{12} &= \frac{(6 \cos 120^\circ - 10 \cos 55^\circ) + j(6 \sin 120^\circ - 10 \sin 55^\circ)}{25 \angle 180^\circ} = \frac{-8.736 - j3.0}{25 \angle 180^\circ} = \frac{9.237 \angle 199^\circ}{25 \angle 180^\circ} \\ &= 0.369 \angle 19^\circ \end{aligned}$$

$$\begin{aligned}\bar{A}_{22} &= \frac{(12 \cos 170^\circ - 7 \cos 120^\circ) + j(12 \sin 170^\circ - 7 \sin 120^\circ)}{25 \angle 180^\circ} = \frac{-8.318 - j4.0}{25 \angle 180^\circ} = \frac{9.23 \angle 205.7^\circ}{25 \angle 180^\circ} \\ &= 0.369 \angle 25.7^\circ\end{aligned}$$

Next, the denominators of the balancing mass phasors (in Equation 32.50 and Equation 32.51) are computed as

$$\begin{aligned}\bar{A}_{22}\bar{A}_{11} - \bar{A}_{12}\bar{A}_{21} &= (0.369 \angle 25.7^\circ \times 0.474 \angle -77^\circ) - (0.369 \angle 19^\circ \times 0.595 \angle -36^\circ) \\ &= 0.1749 \angle -51.3^\circ - 0.2196 \angle -17^\circ \\ &= (0.1749 \cos 51.3^\circ - 0.2196 \cos 17^\circ) - j(0.1749 \sin 51.3^\circ - 0.2196 \sin 17^\circ) \\ &= -0.1 - j0.0723 = 0.1234 \angle 216^\circ\end{aligned}$$

and, hence

$$-(\bar{A}_{22}\bar{A}_{11} - \bar{A}_{12}\bar{A}_{21}) = 0.1234 \angle 36^\circ$$

Finally, the balancing mass phasors are computed using Equation 32.50 and Equation 32.51 as

$$\begin{aligned}\bar{M}_{b1} &= \frac{0.369 \angle 25.7^\circ \times 10 \angle 55^\circ - 0.369 \angle 19^\circ \times 7.0 \angle 120^\circ}{0.1234 \angle 216^\circ} = \frac{3.69 \angle 80.7^\circ - 2.583 \angle 139^\circ}{0.1234 \angle 216^\circ} \\ &= \frac{(3.69 \cos 80.7^\circ - 2.583 \cos 139^\circ) + j(3.69 \sin 80.7^\circ - 2.583 \sin 139^\circ)}{0.1234 \angle 216^\circ} = \frac{2.546 + j1.947}{0.1234 \angle 216^\circ} \\ &= \frac{3.205 \angle 37.4^\circ}{0.1234 \angle 216^\circ} = 26 \angle -178.6^\circ \\ \bar{M}_{b2} &= \frac{0.595 \angle -36^\circ \times 10 \angle 55^\circ - 0.474 \angle -77^\circ \times 7.0 \angle 120^\circ}{0.1234 \angle 36^\circ} = \frac{5.95 \angle 19^\circ - 3.318 \angle 43^\circ}{0.1234 \angle 36^\circ} \\ &= \frac{(5.95 \cos 19^\circ - 3.318 \cos 43^\circ) - j(5.95 \sin 19^\circ - 3.318 \sin 43^\circ)}{0.1234 \angle 36^\circ} = \frac{3.2 + j0.326}{0.1234 \angle 36^\circ} \\ &= \frac{1.043 \angle 5.8^\circ}{0.1234 \angle 36^\circ} = 8.45 \angle -30.0^\circ\end{aligned}$$

Finally, we have

$$-\bar{M}_{b1} = 26 \angle 1.4^\circ \text{ g}; \quad -\bar{M}_{b2} = 8.45 \angle 150^\circ \text{ g}$$

32.4.4 Experimental Procedure of Balancing

The experimental procedure for determining the balancing masses and locations for a rotating system should be clear from the analytical developments and examples given above. The basic steps are:

1. Determine the magnitude and the phase angle of accelerometer signals at the bearings with and without trial masses at the bearing planes.
2. Using this data, compute the necessary balancing masses (magnitude and location) at the bearing planes.
3. Place the balancing masses.
4. Check whether the system is balanced. If not, repeat the balancing cycle.

A laboratory experimental setup for two-plane balancing is shown schematically in [Figure 32.14](#). A view of the system is shown in [Figure 32.15](#). The two disks rigidly mounted on the shaft are driven by a DC motor. The drive speed of the motor is adjusted by the manual speed controller. The (two) shaft

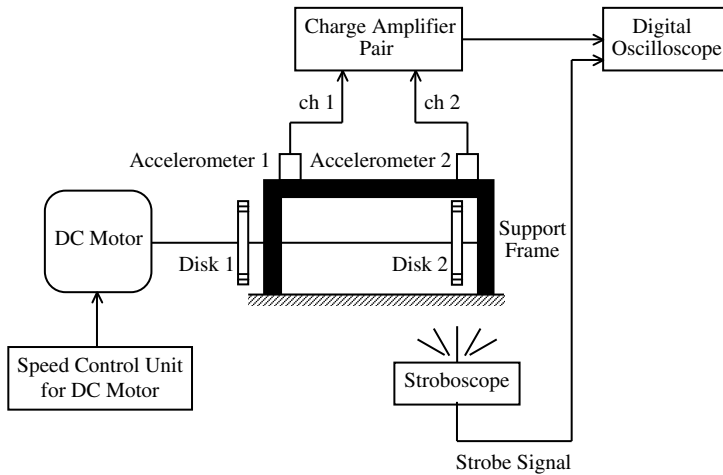

FIGURE 32.14 Schematic arrangement of a rotor balancing experiment.

bearings are located very close to the disks, as shown in Figure 32.14. Two accelerometers are mounted on the top of the bearing housing so that the resulting vertical accelerations can be measured. The accelerometer signals are conditioned using the two-channel charge amplifier and read and displayed through two channels of the digital oscilloscope. The output of the stroboscope (tachometer) is used as the reference signal with respect to the phase angles of the accelerometer signals that are measured.

In Figure 32.15, the items of equipment are seen from left to right. The first item is the two-channel digital oscilloscope. The manual speed controller with control knob for the DC motor follows. Next is the pair of charge amplifiers for the accelerometers. The strobe-light unit (strobe-tacho) is placed on top of the common housing of the charge amplifier pair. The two-disk rotor system with the drive motor is shown as the last item to the right. Also, note the two accelerometers (seen as small vertical projections) mounted on the bearing frame of the shaft directly above the two bearings.

Because this reference always has to be fixed prior to reading the oscilloscope data, the strobe-tacho is synchronized with the disk rotation. This is achieved as follows (note that all the readings are taken with

FIGURE 32.15 A view of the experimental setup for two-plane balancing at the University of British Columbia.

the same rotating speed, which is adjusted by the manual speed controller): First, make a physical mark (e.g., a black spot in a white background) on one of the disks. Aim the strobe flash at this disk. As the motor speed is adjusted to the required fixed value, the strobe flash is synchronized such that the mark on the disk “appears” stationary at the same location (e.g., at the uppermost location of the circle of rotation). This ensures not only that the strobe frequency is equal to the rotating speed of the disk, but also that the same phase angle reference is used for all readings of accelerometer signals.

The two disks have slots at locations whose radius is known, and whose angular positions in relation to a body reference line (a radius representing the 0° reference line) are clearly marked. Known masses (typically, bolts and nuts of known mass) can be securely mounted in these slots. Readings obtained through the oscilloscope are:

1. Amplitude of each accelerometer signal
2. Phase lead of the accelerometer signal with respect to the synchronized and reference-fixed strobe signal (note: a phase lag should be represented by a negative sign in the data)

The measurements taken and the computations made in the experimental procedure should be clear from Example 32.4.

32.5 Balancing of Reciprocating Machines

A reciprocating mechanism has a slider that moves rectilinearly back and forth along some guideway. A piston-cylinder device is a good example. Often, reciprocating machines contain rotatory components in addition to the reciprocating mechanisms. The purpose is to either convert a reciprocating motion to a rotary motion (as in the case of an automobile engine), or to convert a rotary motion to a reciprocating motion (as in the opto-slider mechanism of a photocopier). Irrespective of the reciprocating machine employed, it is important to remove the vibratory excitations that arise in order to realize the standard design goals of smooth operation, accuracy, low noise, reliability, mechanical integrity, and extended service life. Naturally, in view of their rotational asymmetry, reciprocating mechanisms with rotary components are more prone to unbalance than purely rotary components. Removing the “source of vibration” by proper balancing of the machine would be especially applicable in this situation.

32.5.1 Single-Cylinder Engine

A practical example of a reciprocating machine with integral rotary motion is the internal combustion (IC) engine of an automobile. A single-cylinder engine is sketched in Figure 32.16. Observe the nomenclature of the components. The reciprocating motion of the piston is transmitted through the connecting rod and crank into a rotatory motion of the crankshaft. The crank, as sketched in Figure 32.16, has a counterbalance mass, the purpose of which is to balance the rotary force (centrifugal).

FIGURE 32.16 A single-cylinder reciprocating engine.

We will ignore this in our analysis because the goal is to determine the unbalance forces and ways to balance them.

Clearly, both the connecting rod and the crank have distributed mass and moment of inertia. To simplify the analysis, we approximate as follows:

1. Represent the crank mass by an equivalent lumped mass at the crank pin (equivalence may be based on either centrifugal force or kinetic energy).
2. Represent the mass of the connecting rod by two lumped masses, one at the crank pin and the other at the cross head (piston pin).

The piston itself has a significant mass, which is also lumped at the crosshead. Hence, the equivalent system has a crank and a connecting rod, both of which are considered massless, with a lumped mass m_c at the crank pin and another lumped mass m_p at the piston pin (crosshead).

Furthermore, under normal operation, the crankshaft rotates at a constant angular speed (ω). Note that this steady speed is realized not by natural dynamics of the system, but rather by proper speed control (a topic which is beyond the scope of the present discussion).

It is a simple matter to balance the lumped mass m_c at the crank pin. Simply place a counter-mass m_c at the same radius in the radially opposite location (or a mass in inverse proportion to the radial distance from the crankshaft, but remaining in the radially opposite direction). This explains the presence of the counter-mass in the crank shown in Figure 32.16. Once complete balancing of the rotating inertia (m_c) is thus achieved, we still need to completely eliminate the effect of the vibration source on the crankshaft. To achieve this, we must compensate for the forces and moments on the crankshaft that result from:

1. The reciprocating motion of the lumped mass m_p
2. Time-varying combustion (gas) pressure in the cylinder

Both types of forces act on the piston in the direction of its reciprocating (rectilinear) motion. Hence, their influence on the crankshaft can be analyzed in the same way, except that the combustion pressure is much more difficult to determine.

The above discussion justifies the use of the simplified model shown in Figure 32.17 for analyzing the balancing of a reciprocating machine. The characteristics of this model are as follows:

1. A light crank OC of radius r rotates at constant angular speed ω about O, which is the origin of the x - y coordinate frame.
2. A light connecting rod CP of length l is connected to the connecting rod at C and to the piston at P with frictionless pins. Since the rod is light and the joints are frictionless, the force f_c supported by it will act along its length. (Assume that the force f_c in the connecting rod is compressive, for the purpose of the sign convention). Connecting rod makes an angle ϕ with OP (the negative x axis).
3. A lumped mass m_p is present at the piston. A force f acts at P in the negative x direction. This may be interpreted as either the force due to the gas pressure in the cylinder or the inertia force $m_p a$ where a is the acceleration m_p in the positive x direction. These two cases of forcing are considered separately.
4. A lateral force f_l acts on the piston by the cylinder wall, in the positive y direction.

Again, note that the lumped mass m_c at C is not included in the model of Figure 32.17 because it is assumed to be completely balanced by a counter-mass in the crank. Furthermore, the lumped mass m_p includes both the mass of the piston and also part of the inertia of the connecting rod.

There are no external forces at C. Furthermore, the only external forces at P are f and f_l , where f is interpreted as either the inertia force in m_p or the gas force on the piston. Hence, there should be

FIGURE 32.17 The model used to analyze balancing of a reciprocating engine.

equal and opposite forces at the crankshaft O, as shown in Figure 32.17, to support the forces acting at P. Now, let us determine f_l .

Equilibrium at P gives

$$f = f_c \cos \phi$$

$$f_l = f_c \sin \phi$$

Hence,

$$f_l = f \tan \phi \quad (32.52)$$

This lateral force f_l acting at both O and P, albeit in the opposite directions, forms a couple $\tau = xf_l$ or, in view of Equation 32.52:

$$\tau = xf \tan \phi \quad (32.53)$$

This couple acts as a torque on the crankshaft. It follows that, once the rotating inertia m_c at the crank is completely balanced by a counterweight, the load at the crankshaft is due only to the piston load f and it consists of:

1. A force f in the direction of the piston motion (x)
2. A torque $\tau = xf \tan \phi$ in the direction of rotation of the crankshaft (z)

As discussed below, the means of removing f at the crankshaft will also remove τ to some extent. Hence, we will discuss only the approach of balancing f .

32.5.2 Balancing the Inertia Load of the Piston

First, consider the inertia force f due to m_p . Here,

$$f = m_p a \quad (32.54)$$

where a is the acceleration \ddot{x} , with the coordinate x locating the position P of the piston (in other words $OP = x$). We notice from Figure 32.17 that

$$x = r \cos \omega t + l \cos \phi \quad (32.55)$$

However,

$$r \sin \omega t = l \sin \phi \quad (32.56)$$

Hence,

$$\cos \phi = \left[1 - \left(\frac{r}{l} \right)^2 \sin^2 \omega t \right]^{1/2} \quad (32.57)$$

which can be expanded up to the first term of Taylor series as

$$\cos \phi \cong 1 - \frac{1}{2} \left(\frac{r}{l} \right)^2 \sin^2 \omega t \quad (32.58)$$

This approximation is valid because l is usually several times larger than r and, hence, $(r/l)^2$ is much small than unity. Next, in view of

$$\sin^2 \omega t = \frac{1}{2} [1 - \cos 2\omega t] \quad (32.59)$$

we have

$$\cos \phi \cong 1 - \frac{1}{4} \left(\frac{r}{l} \right)^2 [1 - \cos 2\omega t] \quad (32.60)$$

Substitute Equation 32.60 into Equation 32.55. We get, approximately

$$x = r \cos \omega t + \frac{l}{4} \left(\frac{r}{l} \right)^2 \cos 2\omega t + l - \frac{l}{4} \left(\frac{r}{l} \right)^2 \quad (32.61)$$

Differentiate Equation 32.61 twice with respect to t to get the acceleration

$$a = \ddot{x} = -r\omega^2 \cos \omega t - l \left(\frac{r}{l} \right)^2 \omega^2 \cos 2\omega t \quad (32.62)$$

Hence, from Equation 32.54, the inertia force at the piston (and its reaction at the crankshaft) is

$$f = -m_p r \omega^2 \cos \omega t - m_p l \left(\frac{r}{l} \right)^2 \omega^2 \cos 2\omega t \quad (32.63)$$

It follows that the inertia load of the reciprocating piston exerts a vibratory force on the crankshaft which has a *primary component* of frequency ω and a smaller *secondary component* of frequency 2ω , where ω is the angular speed of the crank. The primary component has the same form as that created by a rotating lumped mass at the crank pin. However, unlike the case of a rotating mass, this vibrating force acts only in the x direction (there is no $\sin \omega t$ component in the y direction) and, hence, cannot be balanced by a rotating counter-mass. Similarly, the secondary component cannot be balanced by a counter-mass rotating at double the speed. To eliminate f , we use multiple cylinders whose connecting rods and cranks are connected to the crankshaft with their rotations properly phased (delayed), thus canceling out the effects of f .

32.5.3 Multicylinder Engines

A single-cylinder engine generates a primary component and a secondary component of vibration load at the crankshaft, and they act in the direction of piston motion (x). Because there is no complementary orthogonal component (y), it is inherently unbalanced and cannot be balanced using a rotating mass. It can be balanced, however, by using several piston-cylinder units with their cranks properly phased along the crankshaft. This method of balancing multicylinder reciprocating engines is addressed now.

Consider a single cylinder whose piston inertia generates a force f at the crankshaft in the x direction given by

$$f = f_p \cos \omega t + f_s \cos 2\omega t \quad (32.64)$$

Note that the primary and secondary forcing amplitudes f_p and f_s , respectively, are given by Equation 32.63. Suppose that there is a series of cylinders in parallel, arranged along the crankshaft, and the crank of cylinder i makes an angle α_i with the crank of cylinder 1 in the direction of rotation, as schematically shown in Figure 32.18(a). Hence, force f_i on the crankshaft (in the x direction, shown as vertical in Figure 32.18) due to cylinder i is

$$f_i = f_p \cos(\omega t + \alpha_i) + f_s \cos(2\omega t + 2\alpha_i) \quad \text{for } i = 1, 2, \dots, \text{ with } \alpha_1 = 0 \quad (32.65)$$

Not only do the cranks need to be properly phased, but the cylinders should also be properly spaced along the crankshaft to obtain the necessary balance. Consider two examples.

32.5.3.1 Two-Cylinder Engine

Consider the two-cylinder case, as shown schematically in Figure 32.18(b) where the two cranks are in radially opposite orientations (i.e., 180° out of phase). In this case, $\alpha_2 = \pi$. Hence,

$$f_1 = f_p \cos \omega t + f_s \cos 2\omega t \quad (32.66)$$

$$f_2 = f_p \cos(\omega t + \pi) + f_s \cos(2\omega t + 2\pi) = -f_p \cos \omega t + f_s \cos 2\omega t \quad (32.67)$$

It follows that the primary force components cancel out. However, they form a couple $z_0 f_p \cos \omega t$ where z_0 is the spacing of the cylinders. This causes a bending moment on the crankshaft, and it will not vanish

FIGURE 32.18 (a) Crank arrangement of a multicylinder engine; (b) two-cylinder engine; (c) six-cylinder engine (balanced).

unless the two cylinders are located at the same point along the crankshaft. Furthermore, the secondary components are equal and additive to $2f_s \cos 2\omega t$. This resultant component acts at the midpoint of the crankshaft segment between the two cylinders. There is no couple due to the secondary components.

32.5.3.2 Six-Cylinder Engine

Consider the six-cylinder arrangement shown schematically in Figure 32.18(c). Here, the cranks are arranged such that $\alpha_2 = \alpha_5 = 2\pi/3$, $\alpha_3 = \alpha_4 = 4\pi/3$, and $\alpha_1 = \alpha_6 = 0$. Furthermore, the cylinders are equally spaced, with spacing z_0 . In this case, we have

$$f_1 = f_6 = f_p \cos \omega t + f_s \cos 2\omega t \quad (\text{i})$$

$$f_2 = f_5 = f_p \cos(\omega t + 2\pi/3) + f_s \cos(2\omega t + 4\pi/3) \quad (\text{ii})$$

$$f_3 = f_4 = f_p \cos(\omega t + 4\pi/3) + f_s \cos(2\omega t + 8\pi/3) \quad (\text{iii})$$

Now, we use the fact that

$$\cos \theta + \cos\left(\theta + \frac{2\pi}{3}\right) + \cos\left(\theta + \frac{4\pi}{3}\right) = 0 \quad (\text{iv})$$

which may be proved either by straightforward trigonometric expansion or by using geometric interpretation (i.e., three sides of an equilateral triangle, the sum of whose components in any

direction vanishes). The relation iv holds for any θ , including $\theta = \omega t$ and $\theta = 2\omega t$. Furthermore,

$$\cos(2\omega t + 8\pi/3) = \cos\left(2\omega t + \frac{2\pi}{3}\right)$$

Thus, from Equation i to Equation iii, we can conclude that

$$f_1 + f_2 + f_3 + f_4 + f_5 + f_6 = 0 \quad (32.68)$$

This means that the lateral forces on the crankshaft that are exerted by the six cylinders will completely balance. Furthermore, by taking moments about the location of crank 1 of the crankshaft, we have

$$\begin{aligned} (z_0 + 4z_0) \left[f_p \cos\left(\omega t + \frac{2\pi}{3}\right) + f_s \cos\left(2\omega t + \frac{4\pi}{3}\right) \right] \\ + (2z_0 + 3z_0) \left[f_p \cos\left(\omega t + \frac{4\pi}{3}\right) + f_s \cos\left(2\omega t + \frac{8\pi}{3}\right) \right] \\ + 5z_0 [f_p \cos \omega t + f_s \cos 2\omega t] \end{aligned} \quad (v)$$

which also vanishes in view of relation iv. Hence, the set of six forces is in complete equilibrium and, as a result, there will be neither a reaction force nor a bending moment on the bearings of the crankshaft from these forces.

In addition, it can be shown that the torques $x_i f_i \tan \phi_i$ on the crankshaft due to this set of inertial forces f_i will add to zero, where x_i is the distance from the crankshaft to the piston of the i th cylinder and ϕ_i is the angle ϕ of the connecting rod of the i th cylinder. Hence, this six-cylinder configuration is in complete balance with respect to the inertial load.

Example 32.5

An eight-cylinder in-line engine (with identical cylinders that are placed in parallel along a line) has its cranks arranged according to the phasing angles 0, 180, 90, 270, 270, 90, 180, and 0° on the crankshaft. The cranks (cylinders) are equally spaced, with spacing z_0 . Show that this engine is balanced with respect to primary and secondary components of reaction forces and bending moments of inertial loading on the bearings of the crankshaft.

Solution

The sum of the reaction forces on the crankshaft are

$$\begin{aligned} 2 \left[f_p \cos \omega t + f_s \cos 2\omega t + f_p \cos(\omega t + \pi) + f_s \cos(2\omega t + 2\pi) + f_p \cos\left(\omega t + \frac{\pi}{2}\right) + f_s \cos(2\omega t + \pi) \right. \\ \left. + f_p \cos\left(\omega t + \frac{3\pi}{2}\right) + f_s \cos(2\omega t + 3\pi) \right] = 2 \left[f_p \cos \omega t - f_p \cos \omega t - f_p \sin \omega t + f_p \sin \omega t \right. \\ \left. + f_s \cos 2\omega t + f_s \cos 2\omega t - f_s \cos 2\omega t - f_s \cos 2\omega t \right] = 0 \end{aligned}$$

Hence, both primary forces and secondary forces are balanced. The moment of the reaction forces about the crank 1 location of the crankshaft is

$$\begin{aligned} (z_0 + 6z_0) [f_p \cos(\omega t + \pi) + f_s \cos(2\omega t + 2\pi)] + (2z_0 + 5z_0) \left[f_p \cos\left(\omega t + \frac{\pi}{2}\right) + f_s \cos(2\omega t + \pi) \right] \\ + (3z_0 + 4z_0) \left[f_p \cos\left(\omega t + \frac{3\pi}{2}\right) + f_s \cos(2\omega t + 3\pi) \right] + 7z_0 [f_p \cos \omega t + f_s \cos 2\omega t] \\ = 7z_0 [-f_p \cos \omega t + f_s \cos 2\omega t - f_p \sin \omega t - f_s \cos 2\omega t + f_p \sin \omega t - f_s \cos 2\omega t + f_p \cos \omega t + f_s \cos 2\omega t] = 0 \end{aligned}$$

Hence, both primary bending moments and secondary bending moments are balanced. Therefore, the engine is completely balanced.

The formulas applicable for balancing reciprocating machines are summarized in Box 32.4.

Box 32.4

BALANCING OF RECIPROCATING MACHINES

Single cylinder engine:

Inertia force at piston (and its reaction on crankshaft)

$$f = -m_p r \omega^2 \cos \omega t - m_p l \left(\frac{r}{l} \right)^2 \omega^2 \cos 2\omega t = f_p \cos \omega t + f_s \cos 2\omega t$$

where

ω = rotating speed of crank

m_p = equivalent lumped mass at piston

r = crank radius

l = length of connecting rod

f_p = amplitude of the primary unbalance force (frequency ω)

f_s = amplitude of the secondary unbalance force (frequency 2ω)

Multicylinder engine:

Net unbalance reaction force on crankshaft = $\sum_{i=1}^n f_i$

Net unbalance moment on crankshaft = $\sum_{i=1}^n z_i f_i$

where

$$f_i = f_p \cos(\omega t + \alpha_i) + f_s \cos(2\omega t + 2\alpha_i)$$

α_i = angular position of the crank of i th cylinder, with respect to a body (rotating) reference (i.e., crank phasing angle)

z_i = position of the i th crank along the crankshaft, measured from a reference point on the shaft

n = number of cylinders (assumed identical)

Note: For a completely balanced engine, both the net unbalance force and the net unbalance moment should vanish.

Finally, it should be noted that, in the configuration considered above, the cylinders are placed in parallel along the crankshaft. These are termed in-line engines. Their resulting forces f_i act in parallel along the shaft. In other configurations such as V6 and V8, the cylinders are placed symmetrically around the shaft. In this case, the cylinders (and their inertial forces, which act on the crankshaft) are not parallel. Here, a complete force balance may be achieved without having to phase the cranks. Furthermore, the bending moments of the forces can be reduced by placing the cylinders at nearly the same location along the crankshaft. Complete balancing of the combustion/pressure forces is also possible by such an arrangement.

32.5.4 Combustion/Pressure Load

In the balancing approach presented above, the force f on the piston represents the inertia force due to the equivalent reciprocating mass. Its effect on the crankshaft is an equal reaction force f in the lateral direction (x) and a torque $\pi = x f \tan \phi$ about the shaft axis (z). The balancing approach is to use a series of cylinders so that their reaction forces f_i on the crankshaft from an equilibrium set so that no net reaction or bending moment is transmitted to the bearings of the shaft. The torques τ_i also can be balanced by the same approach, which is the case, for example, in the six-cylinder engine.

Another important force that acts along the direction of piston reciprocation is the drive force due to gas pressure in the cylinder (e.g., created by combustion of the fuel–air mixture of an internal combustion engine). As above, this force may be analyzed by denoting it as f . However, several important observations should be made first:

1. The combustion force f is not sinusoidal of frequency ω . It is reasonably periodic but the shape is complex and depends on the firing/fuel-injection cycle and the associated combustion process.
2. The reaction forces f_i on the crankshaft, which are generated from cylinders i , should be balanced to avoid the transmission of reaction forces and bending moments to the shaft bearings (and hence, to the supporting frame — the vehicle). However, the torques τ_i in this case are in fact the drive torques. Obviously, they are the desired output of the engine and should not be balanced, unlike the inertia torques.

Therefore, although the analysis completed for balancing the inertia forces cannot be directly used here, we can employ similar approaches to the use of multiple cylinders for reducing the gas-force reactions. This is a rather difficult problem given the complexity of the combustion process itself. In practice, much of the leftover effects of the ignition cycle are suppressed by properly designed engine mounts. Experimental investigations have indicated that in a properly balanced engine unit, much of the vibration transmitted through the engine mounts is caused by the engine firing cycle (internal combustion) rather than the reciprocating inertia (sinusoidal components of frequency ω and 2ω). Hence, active mounts, where stiffness can be varied according to the frequency of excitation, are being considered to reduce engine vibrations in the entire range of operating speeds (e.g. 500 to 2500 rpm).

32.6 Whirling of Shafts

In the previous two sections, we studied the vibration excitations caused on rotating shafts and their bearings due to some form of mass eccentricity. Methods of balancing these systems to eliminate the undesirable effects were also presented. One limitation of the given analysis is the assumptions that the rotating shaft is rigid and, thus, does not deflect from its axis of rotation due to the unbalanced excitations. In practice, however, rotating shafts are made lighter than the components they carry (rotors, disks, gears, etc.) and will undergo some deflection due to the unbalanced loading. As a result, the shaft will bow out and this will further increase the mass eccentricity and associated unbalanced excitations and gyroscopic forces of the rotating elements (disks, rotors, etc.). The nature of damping of rotating machinery (which is rather complex and incorporates effects of rotation at bearings, structural deflections, and lateral speeds) will further affect the dynamic behavior of the shaft under these conditions. In this context, the topic of whirling of rotating shafts becomes relevant.

Consider a shaft that is driven at a constant angular speed ω (e.g., by using a motor or some other actuator). The central axis of the shaft (passing through its bearings) will bow out. The deflected axis itself will rotate, and this rotation is termed *whirling* or *whipping*. The whirling speed is not necessarily equal to the drive speed ω (at which the shaft rotates about its axis with respect to a fixed frame). However, when the whirling speed is equal to ω , the condition is called *synchronous whirl*, and the associated deflection of the shaft can be quite excessive and damaging.

To develop an analytical basis for whirling, consider a light shaft supported on two bearings carrying a disk of mass m in between the bearings, as shown in Figure 32.19(a). Note that C is the point on the disk at which it is mounted on the shaft. Originally, in the neutral configuration when the shaft is not driven ($\omega = 0$), the point C coincides with point O on the axis joining the two bearings. If the shaft were rigid, then the points C and O would continue to coincide during motion. The mass center (centroid or center of gravity for constant g) of the disk is denoted as G in Figure 32.19. During motion, C will move away from O due to the shaft deflection. The whirling speed (speed of rotation of the shaft axis) is the speed of rotation of the radial line OC with respect to a fixed reference. Denoting the angle of OC with respect to a fixed reference as θ , the whirling speed is $\dot{\theta}$. This is explained in Figure 32.19(b) where an end view of the

FIGURE 32.19 (a) A whirling shaft carrying a disk with mass eccentricity; (b) end view of the disk and whirling shaft.

disk is given under deflected conditions. The constant drive speed ω of the shaft is the speed of the shaft spin with respect to a fixed reference, and is the speed of rotation of the radial line CG with respect to the fixed horizontal line shown in Figure 32.19(b). Hence, the angle of shaft spin is ωt , as measured with respect to this line. The angle of whirl, θ , is also measured from the direction of this fixed line, as shown.

32.6.1 Equations of Motion

Under practical conditions, the disk moves entirely in a single plane. Hence, its complete set of equations of motion consists of two equations for translatory (planar) motion of the centroid (with lumped mass m), and one equation for rotational motion about the fixed bearing axis. The latter equation depends on the motor torque that drives the shaft at constant speed ω , and is not of interest in the present context. Thus, we will limit our development to the two translatory equations of motion. The equations may be written either in a Cartesian coordinate system (x, y) or a polar coordinate system (r, θ) . Here, we will use the polar coordinate system.

Consider a coordinate frame (\mathbf{i}, \mathbf{j}) that is fixed to the disk with its \mathbf{i} axis lying along OC as shown in Figure 32.19(b). Note that the angular speed of this frame is $\dot{\theta}$ (about the \mathbf{k} axis that is orthogonal to \mathbf{i} and \mathbf{j}). Hence, as is well known, we have

$$\frac{d\mathbf{i}}{dt} = \dot{\theta}\mathbf{j} \quad \text{and} \quad \frac{d\mathbf{j}}{dt} = -\dot{\theta}\mathbf{i} \quad (32.69)$$

The position vector of the mass point G from O is

$$\mathbf{OG} = \mathbf{r}_G = \mathbf{OC} + \mathbf{CG} = r\mathbf{i} + e \cos(\omega t - \theta)\mathbf{i} + e \sin(\omega t - \theta)\mathbf{j} \quad (32.70)$$

The velocity vector \mathbf{v}_G of the mass point G can be obtained simply by differentiating Equation 32.70 with the use of Equation 32.69. However, this can be simplified because ω is constant. Here, line CG has a velocity $e\omega$ that is perpendicular to it about C. This can be resolved along the axes \mathbf{i} and \mathbf{j} . Hence, the velocity of G relative to C is

$$\mathbf{v}_{G/C} = -e\omega \sin(\omega t - \theta)\mathbf{i} + e\omega \cos(\omega t - \theta)\mathbf{j}$$

However, the velocity of point C is

$$\mathbf{v}_C = \frac{d}{dt} r\mathbf{i} = \dot{r}\mathbf{i} + r\frac{d\mathbf{i}}{dt} = \dot{r}\mathbf{i} + r\dot{\theta}\mathbf{j}$$

Hence, the velocity of G, which is given by $\mathbf{v}_G = \mathbf{v}_C + \mathbf{v}_{G/C}$, can be expressed as

$$\mathbf{v}_G = \dot{r}\mathbf{i} + r\dot{\theta}\mathbf{j} - e\omega \sin(\omega t - \theta)\mathbf{i} + e\omega \cos(\omega t - \theta)\mathbf{j} \quad (32.71)$$

Similarly, the acceleration of C is

$$\mathbf{a}_C = \frac{d}{dt} \mathbf{v}_C = \frac{d}{dt} [\dot{r}\mathbf{i} + r\dot{\theta}\mathbf{j}] = \ddot{r}\mathbf{i} + \dot{r}\dot{\theta}\mathbf{j} + \dot{r}\dot{\theta}\mathbf{j} + r\ddot{\theta}\mathbf{j} - r\dot{\theta}^2\mathbf{i} = (\ddot{r} - r\dot{\theta}^2)\mathbf{i} + (r\ddot{\theta} + 2\dot{r}\dot{\theta})\mathbf{j}$$

Also, since line CG rotates at constant angular speed ω about C, the point G has only a radial (centrifugal) acceleration $e\omega^2$ along GC. This can be resolved along \mathbf{i} and \mathbf{j} as before. Hence, the acceleration of G relative to C is

$$\mathbf{a}_{G/C} = -e\omega^2 \cos(\omega t - \theta)\mathbf{i} - e\omega^2 \sin(\omega t - \theta)\mathbf{j}$$

It follows that the acceleration of point G, given by $\mathbf{a}_G = \mathbf{a}_C + \mathbf{a}_{G/C}$, may be expressed as

$$\mathbf{a}_G = (\ddot{r} - r\dot{\theta}^2)\mathbf{i} + (r\ddot{\theta} + 2\dot{r}\dot{\theta})\mathbf{j} - e\omega^2 \cos(\omega t - \theta)\mathbf{i} - e\omega^2 \sin(\omega t - \theta)\mathbf{j} \quad (32.72)$$

The forces acting on the disk are as follows:

Restraining elastic force due to lateral deflection of the shaft = $-kr\mathbf{i}$

Viscous damping force (proportional to the velocity of C) = $-b\dot{r}\mathbf{i} - br\dot{\theta}\mathbf{j}$

In addition, there is a frictional resistance at the bearing, which is proportional to the reaction and, hence, the shaft deflection is r and also depends on the spin speed ω . The following approximate model may be used:

$$\text{Bearing friction force} = -b_f r \omega \mathbf{j}$$

Here,

k = lateral deflection stiffness of the shaft at the location of the disk

b = viscous damping constant for lateral motion of the shaft

b_f = bearing frictional coefficient

The overall force acting on the disk is

$$\mathbf{f} = -b\dot{r}\mathbf{i} - (br\dot{\theta} + b_f r \omega)\mathbf{j} \quad (32.73)$$

The equation of rectilinear motion

$$\mathbf{f} = m\mathbf{a}_G \quad (32.74)$$

on using Equation 32.72 and Equation 32.73, reduces to the following pair in the \mathbf{i} and \mathbf{j} directions:

$$-kr - b\dot{r} = m[\ddot{r} - r\dot{\theta}^2 - e\omega^2 \cos(\omega t - \theta)] \quad (32.75)$$

$$-br\dot{\theta} - b_f r \omega = m[r\ddot{\theta} + 2\dot{r}\dot{\theta} - e\omega^2 \sin(\omega t - \theta)] \quad (32.76)$$

These equations may be expressed as

$$\ddot{r} + 2\zeta_v \omega_n \dot{r} + (\omega_n^2 - \dot{\theta}^2)r = e\omega^2 \cos(\omega t - \theta) \quad (32.77)$$

$$r\ddot{\theta} + 2(\zeta_v \omega_n r + \dot{r})\dot{\theta} + 2\zeta_f \omega_n \omega r = e\omega^2 \sin(\omega t - \theta) \quad (32.78)$$

where the undamped natural frequency of lateral vibration is

$$\omega_n = \sqrt{\frac{k}{m}} \quad (32.79)$$

and

ζ_v = viscous damping ratio of lateral motion

ζ_f = frictional damping ratio of the bearings

Equation 32.77 and Equation 32.78, which govern the whirling motion of the shaft-disk system, are a pair of coupled nonlinear equations, with excitations (depending on ω) that are coupled with a motion variable (θ). Hence, a general solution would be rather complex. A relatively simple solution is possible, however, under steady-state whirling.

32.6.2 Steady-State Whirling

Under steady-state conditions, the whirling speed $\dot{\theta}$ is constant at $\dot{\theta} = \omega_w$, hence, $\ddot{\theta} = 0$. Also, the lateral deflection of the shaft is constant, hence, $\dot{r} = \ddot{r} = 0$. Therefore, Equation 32.77 and Equation 32.78 become

$$(\omega_n^2 - \omega_w^2)r = e\omega^2 \cos(\omega t - \theta) \quad (32.80)$$

$$2\zeta_v \omega_n \omega_w r + 2\zeta_f \omega_n \omega r = e\omega^2 \sin(\omega t - \theta) \quad (32.81)$$

In Equation 32.80 and Equation 32.81, the left-hand side is independent of t . Hence, the right-hand side should also be independent of t . For this, we must have

$$\theta = \omega t - \phi \quad (32.82)$$

where ϕ is interpreted as the phase lag of whirl with respect to the shaft spin (ω), and should be clear from Figure 32.19(b). It follows from Equation 32.82 that, for steady-state whirl, the whirling speed $\dot{\theta} = \omega_w$ is

$$\omega_w = \omega \quad (32.83)$$

This condition is called synchronous whirl because the whirl speed (ω_w) is equal to the shaft spin speed (ω). It follows that under steady-state conditions, we should have the state of synchronous whirl. The equations governing steady-state whirl are

$$(\omega_n^2 - \omega^2)r = e\omega^2 \cos \phi \quad (32.84)$$

$$2\zeta \omega_n \omega r = e\omega^2 \sin \phi \quad (32.85)$$

along with Equation 32.82 and, hence, Equation 32.83. Here, $\zeta = \zeta_v + \zeta_f$ is the overall damping ratio of the system. Note that the phase angle ϕ and the shaft deflection r are determined from Equation 32.84 and Equation 32.85. In particular, squaring these two equations and adding to eliminate ϕ , we obtain

$$r = \frac{e\omega^2}{\sqrt{(\omega_n^2 - \omega^2)^2 + (2\zeta \omega_n \omega)^2}} \quad (32.86)$$

which is of the form of magnitude of the frequency transfer function of a simple oscillator with an acceleration excitation. Divide Equation 32.85 by Equation 32.84 to get the phase angle:

$$\phi = \tan^{-1} \frac{2\zeta \omega_n \omega}{(\omega_n^2 - \omega^2)} \quad (32.87)$$

Using simple calculus (differentiate the square and equate to zero), we can show that the maximum deflection occurs at the critical spin speed ω_c given by

$$\omega_c = \frac{\omega_n}{\sqrt{1 - 2\zeta^2}} \quad (32.88)$$

This *critical speed* corresponds to a resonance. For light damping, we have approximately $\omega_c = \omega_n$. Hence, critical speed for low damping is equal to the undamped natural frequency of bending vibration of the shaft-rotor unit. The corresponding shaft deflection is (see Equation 32.86)

$$r_c = \frac{e}{2\zeta} \quad (32.89)$$

which is also a good approximation of r at critical speed, with light damping. From Equation 32.84 and Equation 32.85, we can see that, at critical speed (with low damping), $\sin \phi = 1$ and $\cos \phi = 0$, which gives $\phi = \pi/2$. Also, note from Equation 32.86 that the steady-state shaft deflection is almost zero at low speeds and approaches e at very high speeds. However, Equation 32.87 shows that, for small ω , $\tan \phi$ is positive and small. We can see from Equation 32.85 that $\sin \phi$ is positive. This means ϕ itself is small for small ω . For large ω , we can see from Equation 32.86 that r approaches e . Thus, we can see from

Equation 32.87 that $\tan \phi$ is small and negative, whereas Equation 32.85 shows that $\sin \phi$ is positive. Hence, ϕ approaches π for large ω .

It is seen from Equation 32.89 that, at critical speed, the shaft deflection increases with mass eccentricity and decreases with damping. This indicates that the approaches for reducing the damaging effects of whirling are:

1. Eliminate or reduce the mass eccentricity through proper construction practices and balancing.
2. Increase damping.
3. Increase shaft stiffness.
4. Avoid operation near critical speed.

There will be limitations to the use of these approaches, particularly making the shaft stiffer. Note also that our analysis did not include the mass distribution of the shaft. A Bernoulli–Euler type beam analysis has to be incorporated for a more accurate analysis of whirling for shafts whose mass cannot be accurately represented by a single parameter that is lumped at the location of the rotor. Formulas related to whirling of shafts are summarized in Box 32.5.

Example 32.6

The fan of a ventilation system has a normal operating speed of 3600 rpm. The blade set of the fan weighs 20 kg and is mounted in the mid-span of a relatively light shaft that is supported on lubricated bearings at its two ends. The bending stiffness of the shaft at the location of the fan is 4.0×10^6 N/m. Equivalent damping ratio that acts on the possible whirling motion of the shaft is 0.05. Owing to fabrication error, the centroid of the fan has an eccentricity of 1.0 cm from the neutral axis of rotation of the shaft:

1. Determine the critical speed of the fan system and the corresponding shaft deflection at the location of the fan at steady state.
2. What is the steady-state shaft deflection at the fan during normal operation?

The fan was subsequently balanced using a mass of 5 kg. The centroid eccentricity was reduced to 2 mm by this means. What is the shaft deflection at the fan during normal operation now? Comment on the improvement that has been realized.

Solution

1. The system is lightly damped. Hence, the critical speed is given by the undamped natural frequency; thus

$$\omega_c \cong \omega_n = \sqrt{\frac{k}{m}} = \sqrt{\frac{4 \times 10^6}{20}} \text{ rad/sec} = 447.2 \text{ rad/sec}$$

The corresponding shaft deflection is

$$r_c = \frac{e}{2\zeta} = \frac{1.0}{2 \times 0.05} \text{ cm} = 10.0 \text{ cm}$$

2. Operating speed $\omega = (3600/60) \times 2\pi \text{ rad/sec} = 377 \text{ rad/sec}$. Using Equation 32.86, the corresponding shaft deflection, at steady state, is

$$r = \frac{1.0 \times (377)^2}{[(447.2^2 - 377^2)^2 + (2 \times 0.05 \times 447.2 \times 377)^2]^{1/2}} \text{ cm} = 2.36 \text{ cm}$$

After balancing, the new eccentricity $e = 0.2 \text{ cm}$.

The new natural frequency (undamped) is

$$\omega_n = \sqrt{\frac{4 \times 10^6}{25}} \text{ rad/sec} = 400 \text{ rad/sec}$$

Box 32.5

WHIRLING OF SHAFTS

Whirling: A shaft spinning at speed ω about its axis, may bend due to flexure. The bent (bowed out) axis will rotate at speed ω_w . This is called whirling.

Equations of motion:

$$\ddot{r} + 2\zeta_v \omega_n \dot{r} + (\omega_n^2 - \dot{\theta}^2)r = e\omega^2 \cos(\omega t - \theta)$$

$$r\ddot{\theta} + 2(\zeta_v \omega_n r + \dot{r})\dot{\theta} + 2\zeta_f \omega_n \omega r = e\omega^2 \sin(\omega t - \theta)$$

where (r, θ) are polar coordinates of shaft deflection at the mounting point of lumped mass.

e = eccentricity of the lumped mass from the spin axis of shaft

$\dot{\theta} = \omega_w$ = whirling speed

ω = spin speed of shaft

$\omega_n = \sqrt{k/m}$ = natural frequency of bending vibration of shaft

k = bending stiffness of shaft at lumped mass

m = lumped mass

ζ_v = damping ratio of bending motion of shaft

ζ_f = damping ratio of shaft bearings

Steady-state whirling (synchronous whirl):

Here, whirling speed ($\dot{\theta}$ or ω_w) is constant and equals the shaft spin speed ω (i.e., $\omega_w = \omega$ for steady-state whirling).

Shaft deflection at lumped mass

$$r = \frac{e\omega^2}{[(\omega_n^2 - \omega^2)^2 + (2\zeta\omega_n\omega)^2]^{1/2}}$$

Phase angle between shaft deflection (r) and mass eccentricity (e)

$$\phi = \tan^{-1} \frac{2\zeta\omega_n\omega}{(\omega_n^2 - \omega^2)}$$

where $\zeta = \zeta_v + \zeta_f$

Note: For small spin speeds ω , we have small r and ϕ . For large ω , we have $r \cong e$ and $\phi \cong \pi$

Critical speed:

$$\begin{aligned} \text{Spin speed } \omega &= \frac{\omega_n}{\sqrt{1 - 2\zeta^2}} \omega_n \text{ for small } \zeta \\ \phi &= \pi/2 \end{aligned}$$

The corresponding shaft deflection during steady-state operation is

$$r = \frac{0.2 \times (377)^2}{[(400^2 - 377^2)^2 + (2 \times 0.05 \times 400 \times 377)^2]^{1/2}} \text{ cm} = 1.216 \text{ cm}$$

Note that, even though the eccentricity has been reduced by a factor of five by balancing, the operating deflection of the shaft has been reduced only by a factor of less than two. The main reason for this is that the operating speed is close to the critical speed. Methods of improving the performance include changing the operating speed, using a smaller mass to balance the fan, using more damping, and making

the shaft stiffer. However, some of these methods may not be feasible. Operating speed is determined by the task requirements. A location may not be available that is sufficiently distant to place a balancing mass that is appropriately small. Increased damping will increase heat generating, cause bearing problems, and will also reduce the operating speed. Replacement or stiffening of the shaft may require too much modification to the system and add cost. A preferable alternative would be to balance the fan by removing some mass. This will move the critical frequency (natural frequency) away from the operating speed rather than closer to it, while reducing the mass eccentricity at the same time. For example, suppose that a mass of 3 kg is removed from the fan, which results in an eccentricity of 2.0 mm. The new natural/critical frequency is

$$\sqrt{\frac{4 \times 10^6}{17}} \text{ rad/sec} = 485.1 \text{ rad/sec}$$

The corresponding shaft deflection during steady operation is

$$r = \frac{0.2 \times (377)^2}{[(485.1^2 - 377^2)^2 + (2 \times 0.05 \times 485.1 \times 377)^2]^{1/2}} \text{ cm} = 0.3 \text{ cm}$$

In this case, the deflection has been reduced by a factor of eight.

32.6.3 Self-Excited Vibrations

Equation 32.77 and Equation 32.78, which represent the general whirling motion of a shaft, are nonlinear and coupled. In these equations, the motion variables (r and θ) occur as (nonlinear) products of the excitation (ω). Such systems are termed self-excited. Note that, in general (before reaching the steady state) the response variables r and θ will exhibit vibratory characteristics in view of the presence of the excitation functions $\cos(\omega t - \theta)$ and $\sin(\omega t - \theta)$. Hence, a whirling shaft may exhibit self-excited vibrations. Because the excitation forces directly depend on the motion itself, it is possible that a continuous energy flow into the system could occur. This will result in a steady growth of the motion amplitudes and represents an *unstable* behavior.

A simple example of self-excited vibration is provided by a pendulum whose length is time variable. Although the system is stable when the length is fixed, it can become unstable under conditions of variable length. Practical examples of self-excited vibrations with possible exhibition of instability include the flutter of aircraft wings due to coupled aerodynamic forces, wind-induced vibrations of bridges and tall structures, galloping of ice-covered transmission lines due to air flow-induced vibrations, and chattering of machine tools due to friction-related excitation forces. Proper design and control methods, as discussed in this chapter, are important in suppressing self-excited vibrations.

32.7 Design through Modal Testing

Experimental modal analysis (EMA) involves extracting modal parameters (natural frequencies, modal damping ratios, mode shapes) of a mechanical system through testing (notably, through excitation-response data) and then developing a dynamic model of the system (mass, stiffness, and damping matrices) on that basis. The techniques of EMA are useful in modeling and model validation (i.e., verification of the accuracy of an existing model that was obtained, for example, through analytical modeling). In addition to these uses, EMA is also a versatile tool for design development. In the context of “design for vibration,” EMA may be employed in the design and design modification of mechanical systems with the goal of achieving desired performance under vibrating conditions. This section will introduce this approach.

In applying EMA for design development of a mechanical system, three general approaches are employed:

1. Component modification
2. Modal response specification
3. Substructuring

The method of component modification allows us to modify (i.e., add, remove, or vary) physical parameters (inertia, stiffness, damping) in a mechanical system, and to determine the resulting effect on the modal response (natural frequencies, damping ratios, and mode shapes) of the system. The method of modal response specification provides the capability to establish the best changes, from the design viewpoint, in system parameters (inertia, stiffness, damping values, and associated directions) in order to realize a specified change in the modal response. In the techniques of substructuring, two or more subsystem models are combined using proper components of interfacing (interconnection), and the overall model of the integrated system is determined. Some of the subsystems used in this approach could be of analytical or computational origin (e.g., finite element models). It should be clear how these methods could be used in the design development of a mechanical system for proper vibration performance. The first method is essentially a trial and error technique of incremental design. Here, some appropriate parameters are changed and the resulting modal behavior is determined. If the resulting performance is not satisfactory, further changes are made in discrete steps until an acceptable performance (with regard to natural frequencies, response magnification factors, etc.) is achieved. The second method is clearly a direct design approach, where the design specifications are first developed in terms of modal characteristics, and then the design procedure will generate the size and type of the physical parameters to meet the specifications. In the third method, a suitable set of subsystems is first designed to meet performance characteristics of each subsystem. Then, these subsystems are linked through suitable mechanical interfacing components, and the performance of the overall system is determined to verify acceptance. In this manner, a complex system may be designed through the systematic design of its subsystems.

32.7.1 Component Modification

The method of component modification involves changing a mass, stiffness, or damping element in the system and determining the corresponding dynamic response, particularly the natural frequencies, modal damping ratios, and mode shapes. This is relatively straightforward because a single modal analysis or modal test (EMA) will give the required information. Because single step of component modification might not be acceptable as an appropriate design (e.g., a natural frequency might be too close to a significant frequency component of a vibration excitation), a number of modifications may be necessary. For such incremental procedures, modal analysis would be more convenient and cost effective than EMA because, in the latter case, physical modification and retesting would be needed, whereas the former involves the same computational steps as before, but with a new set of parameter values.

For example, consider an aluminum I beam that has a number of important modes of vibration, including bending and torsional modes. Figure 32.20(a) shows the fourth mode shape of vibration at natural frequency 678.4 Hz. The dotted line in Figure 32.20(b) shows the transfer function magnitude when the beam is excited at some location in the vertical direction and the response is measured in the vertical direction, at some other location, where neither of the locations are node points. The curve shows the first six natural frequencies.

Next, a lumped mass is added to the top flange at the shown location. The corresponding transfer function magnitude is shown by the solid curve in Figure 32.20(b). Note that all the natural frequencies have decreased due to the added mass, but the effect is larger for higher modes. Similarly, mode shapes also will change. If the new modes are not satisfactory (e.g., a particular natural frequency has not shifted enough) further modification and evaluation will be required.

Consider a mechanical vibrating system whose free response y is described by

$$\mathbf{M}\ddot{\mathbf{y}} + \mathbf{K}\mathbf{y} = 0 \quad (32.90)$$

Damping has been ignored for simplicity, but the following discussion can also be extended to a damped system (quite directly, for the case of proportional damping). If the mass matrix \mathbf{M} and the stiffness matrix \mathbf{K} are modified by $\delta\mathbf{M}$ and $\delta\mathbf{K}$, respectively, the corresponding response (as well as the natural frequencies and mode shapes) will be different from that of the original system. To illustrate, let the

FIGURE 32.20 An example of component modification: (a) the shape of Mode 4 prior to modification; (b) transfer function magnitude before and after modification.

modal matrix (the matrix whose columns are the independent mode shape vectors of the original system) be Ψ . Then, using the modal transformation

$$\mathbf{y} = \Psi \mathbf{q} \quad (32.91)$$

Equation 32.90 can be expressed in the canonical form, with modal generalized coordinates \mathbf{q} , as

$$\bar{\mathbf{M}} \ddot{\mathbf{q}} + \bar{\mathbf{K}} \mathbf{q} = 0 \quad (32.92)$$

where

$$\Psi^T \mathbf{M} \Psi = \bar{\mathbf{M}} = \text{diag}[M_1, M_2, \dots, M_n] \quad (32.93)$$

$$\Psi^T \mathbf{K} \Psi = \bar{\mathbf{K}} = \text{diag}[K_1, K_2, \dots, K_n] \quad (32.94)$$

If the same transformation (Equation 32.91) is used for the modified system

$$(\mathbf{M} + \delta \mathbf{M}) \ddot{\mathbf{y}} + (\mathbf{K} + \delta \mathbf{K}) \mathbf{y} = 0 \quad (32.95)$$

we obtain

$$(\bar{\mathbf{M}} + \mathbf{\Psi}^T \delta \mathbf{M} \mathbf{\Psi}) \ddot{\mathbf{q}} + (\bar{\mathbf{K}} + \mathbf{\Psi}^T \delta \mathbf{K} \mathbf{\Psi}) \mathbf{q} = 0 \quad (32.96)$$

Since both $\mathbf{\Psi}^T \delta \mathbf{M} \mathbf{\Psi}$ and $\mathbf{\Psi}^T \delta \mathbf{K} \mathbf{\Psi}$ are not diagonal matrices in general, $\mathbf{\Psi}$ would not remain the modal matrix for the modified system. Furthermore, the original natural frequencies $\omega_i = \sqrt{K_i/M_i}$ will change due to the component modification. For the special case of proportional modifications ($\delta \mathbf{M}$ proportional to \mathbf{M} and $\delta \mathbf{K}$ proportional to \mathbf{K}), the mode shapes will not change. However, in general, the natural frequencies will change.

The reverse problem is the modal response specification. Here, a required set of modal parameters (ω_{ir} and ψ_{ir}) is specified and the necessary changes $\delta \mathbf{M}$ and $\delta \mathbf{K}$ to meet the specifications must be determined. Note that the solution is not unique and is more difficult than the direct problem. In this case, a sensitivity analysis may initially be performed to determine the directions and magnitudes of the modal shift for a particular physical parameter shift. Then, the necessary magnitudes of physical shift to achieve the specified modal shift are estimated on that basis. The corresponding modifications are made and the modified system is analyzed/tested to check whether it is within specification. If not, further cycles of modification should be performed.

Example 32.7

As an example of component modification, consider the familiar problem of a two-DoF system, as shown in Figure 32.21. The squared nondimensional natural frequencies $r_i^2 = (\omega_i/\omega_0)^2$ of the systems are given by

$$r_1^2, r_2^2 = \frac{1}{2\alpha} \times \{\alpha + \beta + \alpha\beta\} \left\{ 1 \pm \sqrt{1 - \frac{4\alpha\beta}{(\alpha + \beta + \alpha\beta)^2}} \right\}$$

where $\omega_0 = \sqrt{k/m}$. We also showed that the mode shapes, as given by the ratio of the displacement of mass 2 to that of mass 1 at a natural frequency, are

$$\left(\frac{\psi_2}{\psi_1} \right)_i = \frac{1 + \beta - r_i^2}{\beta} \quad \text{for mode } i$$

Consider a system with $\alpha = 0.5$ and $\beta = 0.5$. By direct computation, we can show that $r_1 = 0.71$ and $r_2 = 1.41$. Estimate the modification of β (the relative stiffness of the second spring) that would be necessary to shift the system natural frequencies to approximately $r_1 = 0.8$ and $r_2 = 2.0$. Check the corresponding shift in mode shapes.

Solution

For $\alpha = 0.5$ and $\beta = 0.5$, direct substitution yields $r_1 = 0.71$ and $r_2 = 1.41$ with $(\psi_2/\psi_1)_1 = 2.0$ and $(\psi_2/\psi_1)_2 = -1.0$. Now, consider an incremental change in β by 0.1. Then, $\beta = 0.6$. The corresponding natural frequencies are computed as

$$r_i^2 = \frac{1}{2 \times 0.5} \{0.5 + 0.6 + 0.5 \times 0.6\} \left\{ 1 \mp \left[1 - \frac{4 \times 0.5 \times 0.6}{(0.5 + 0.6 + 0.5 \times 0.6)^2} \right]^{1/2} \right\} = 0.528, 2.272$$

Hence,

$$r_1, r_2 = 0.727, 1.507$$

This step may be interpreted as a way of establishing the sensitivity of the system to the particular component modification. Clearly, the problem of modification is not linear. However, as a first

FIGURE 32.21 A two-degree-of-freedom example.

approximation, assume a linear variation of r_i^2 with β , and make modifications according to

$$\frac{\delta\beta}{\delta\beta_0} = \frac{\delta r_i^2}{\delta r_{i0}^2} \quad (32.97)$$

where the subscript 0 refers to the initial trial variation ($\delta\beta_0 = 0.1$). Equation 32.97 is intuitively satisfying given the nature of the physical problem and the fact that, for a single-DoF problem, squared frequency varies with k_0 . Then, we have

For mode 1:

$$\frac{\delta\beta}{0.1} = \frac{0.8^2 - 0.71^2}{0.727^2 - 0.71^2} = 5.634$$

or

$$\delta\beta = 0.56$$

For mode 2:

$$\frac{\delta\beta}{0.1} = \frac{2^2 - 1.41^2}{1.507^2 - 1.41^2} = 7.09$$

or

$$\delta\beta = 0.709$$

Therefore, we use $\delta\beta = 0.71$, which is the larger of the two. This corresponds to

$$\beta = 0.5 + 0.71 = 1.21$$

The natural frequencies are computed as usual:

$$r_1^2, r_2^2 = \frac{1}{2 \times 0.5} \{0.5 + 1.21 + 0.5 \times 1.21\} \left\{ 1 \mp \left[1 - \frac{4 \times 0.5 \times 1.21}{(0.5 + 1.21 + 0.5 \times 1.21)^2} \right]^{1/2} \right\} = 0.60, 4.03$$

or

$$r_1, r_2 = 0.78, 2.01$$

In view of the nonlinearity of the problem, this shift in frequencies is satisfactory. The corresponding mode shapes are

$$\left(\frac{\psi_2}{\psi_1} \right)_1 = \frac{(1 + 1.21) - 0.6}{1.21} = 1.33$$

$$\left(\frac{\psi_2}{\psi_1} \right)_2 = \frac{(1 + 1.21) - 4.03}{1.21} = -1.50$$

It follows that, as the stiffness of the second spring is increased, the motions of the two masses become closer in mode 1. Furthermore, in mode 2, the node point becomes closer to mass 1. Note the limitation of this particular component modification. As $\beta \rightarrow \infty$, the two masses become rigidly linked giving a frequency ratio of $r_1 = \sqrt{k/(m + \alpha m)}/\sqrt{k/m} = 1/\sqrt{1 + \alpha} = 1/\sqrt{1.5} = 0.816$, with $r_2 \rightarrow \infty$. Hence, it is unreasonable to expect a frequency ratio that is closer to this value of r_1 by a change in β alone.

32.7.2 Substructuring

For large and complex mechanical systems with many components, the approach of substructuring can make the process of “design for vibration” more convenient and systematic. In this approach, the system is first divided into a convenient set of subsystems that are more amenable to testing and analysis. The subsystems are separately modeled and designed through the approaches of modal analysis and testing, along with any other convenient approaches (e.g., finite element technique). Note that the performance

of the overall system depends on the interface conditions that link the subsystems, as well as the characteristics of the individual subsystems. Hence, it is not possible to translate the design specifications for the overall system into those for the subsystems without taking the interface conditions into account. The overall system is *assembled* from the designed subsystems by using *compatibility* requirements at the assembly locations together with dynamic equations of the interconnecting components such as spring–mass–damper units or rigid linkages. If the assembled system does not meet the design specifications, then modifications should be made to one or more of the subsystems and interfacing (assembly) linkages, and the procedure should be repeated. Thus, the main steps of using the approach of substructuring for vibration design of a complex system are as follows:

1. Divide the mechanical system into convenient subsystems (substructuring) and represent the interconnection points of subsystems by forces/moments.
2. Develop models for the subsystems through analysis, modal testing, and other standard procedures.
3. Design the subsystems so that their performance is well within the performance specifications provided for the overall system.
4. Establish the interconnecting (assembling) linkages for the subsystems, and obtain dynamic equations for them in terms of the linking forces/moments and motions (displacements/rotations).
5. Establish continuity (force balancing) and compatibility (motion consistency) conditions at the assembly locations.
6. Using matrix methods, eliminate the unknown variables and assemble the overall system.
7. Analyze (or test) the overall system to determine its vibration performance. If satisfactory, stop. If not, make modifications to the systems or assembly conditions and repeat step 4 to step 7.

As a simple example, consider two single-DoF systems that are interconnected by a spring linkage, as shown in Figure 32.22. The two subsystems may be represented by

$$\begin{bmatrix} m_1 & 0 \\ 0 & m_2 \end{bmatrix} \ddot{\mathbf{y}} + \begin{bmatrix} k_1 & 0 \\ 0 & k_2 \end{bmatrix} \mathbf{y} = 0$$

and the corresponding natural frequencies are

$$\omega_{s1} = \sqrt{k_1/m_1} \quad \text{and} \quad \omega_{s2} = \sqrt{k_2/m_2}$$

The overall interconnected system is given by

$$\begin{bmatrix} m_1 & 0 \\ 0 & m_2 \end{bmatrix} \ddot{\mathbf{y}} + \begin{bmatrix} k_1 + k_c & -k_c \\ -k_c & k_2 + k_c \end{bmatrix} \mathbf{y} = 0$$

FIGURE 32.22 An example of substructuring.

Its natural frequencies are obtained by solving the equation

$$\det \begin{bmatrix} k_1 + k_c - \omega^2 m_1 & -k_c \\ -k_c & k_2 + k_c - \omega^2 m_2 \end{bmatrix} = 0$$

or

$$(k_1 + k_c - \omega^2 m_1)(k_2 + k_c - \omega^2 m_2) - k_c^2 = 0$$

which simplifies to

$$\omega^4 - \left[\frac{k_1 + k_c}{m_1} + \frac{k_2 + k_c}{m_2} \right] \omega^2 + \frac{k_1 k_2 + k_c(k_1 + k_2)}{m_1 m_2} = 0$$

The sum of the roots is

$$\omega_1^2 + \omega_2^2 = \frac{k_1 + k_c}{m_1} + \frac{k_2 + k_c}{m_2} > \omega_{s1}^2 + \omega_{s2}^2$$

The product of the roots is

$$\omega_1^2 \omega_2^2 = \frac{k_1 k_2 + k_c(k_1 + k_2)}{m_1 m_2} > \omega_{s1}^2 \omega_{s2}^2$$

This does not mean that both frequencies will increase due to the interconnection. Note that the limit on the lower frequency, as $k_c \rightarrow \infty$, is given by that of a single-DoF system with mass $m_1 + m_2$ and stiffness $k_1 + k_2$, which is, $\sqrt{(k_1 + k_2)/(m_1 + m_2)}$. This value can be larger or smaller than the natural frequency of a subsystem depending on the relative values of the parameters. Hence, even for this system, exact satisfaction of a set of design natural frequencies would be somewhat challenging because these frequencies depend on the interconnection as well as the subsystems.

Substructuring is a design development technique where complex designs can be accomplished through parallel and separate development of several subsystems and interconnections. Through this procedure, dynamic interactions among subsystems can be estimated and potential problems can be detected, which will allow redesigning of the subsystems or interfacing linkages prior to building the over prototype. Design approaches using EMA that may be used in vibration problems are summarized in Box 32.6.

32.8 Passive Control of Vibration

The techniques discussed in this chapter for reduction of the effects of mechanical vibration fall into the categories of vibration isolation and design for vibration. The third category, vibration control, is addressed now. Characteristic of vibration control is the use of a sensing device to detect the level of vibration in a system, and an actuation (forcing) device to apply a forcing function to the system to counteract the effects of vibration. In some such devices, the sensing and forcing functions are implicit and integrated together.

Vibration control may be subdivided into the following two broad categories:

1. Passive control
2. Active control

Passive control of vibration employs passive controllers. By definition, passive devices do not require external power for their operation. The two passive controllers of vibration discussed in the present section are vibration absorbers (or dynamic absorbers or Frahm absorbers, named after H. Frahm, who first employed the technique for controlling ship oscillations) and dampers. In both types of devices, sensing is implicit and control is achieved through a force generated by the device from its response to the vibration excitation. A dynamic absorber is a mass–spring-type mechanism with little or no damping,

Box 32.6

TEST-BASED DESIGN APPROACHES FOR VIBRATION

1. Component modification:

Modify a component (mass, spring, damper) and determine modal parameters (natural frequencies, damping ratios, mode shapes).

- Can determine sensitivity to component changes.
- Can check whether a particular change is satisfactory.

2. Modal response specification:

Specify a desired modal response (natural frequencies, damping ratios, mode shapes) and determine the “best” component changes (mass, spring, damper) that will realize the modal specs.

- Can be accomplished by first performing a sensitivity study (as in item 1).

3. Substructuring:

- (i) Design subsystems to meet specs (analytically, experimentally, or by a mixed approach).
- (ii) Establish interconnections between subsystems, and obtain continuity (force balance) and compatibility (motion consistency) at assembly locations.
- (iii) Assemble the overall system by eliminating unknown variables at interconnections.
- (iv) Analyze or test the overall system. If satisfactory, stop. Otherwise, make changes to the subsystems or interconnections, and repeat the above steps.

which can “absorb” the vibration excitation through energy transfer into it, thereby reducing the vibrations of the primary system. The energy received by the absorber will be slowly dissipated due to its own damping. A damper is a purely dissipative device which, unlike a dynamic absorber, directly dissipates the energy received from the system rather than storing it. Hence, it is a more wasteful device, which also may exhibit problems related to wear and thermal effects. However, it has advantages over an absorber, having, for example, a wider frequency of operation.

32.8.1 Undamped Vibration Absorber

A dynamic vibration absorber (or a dynamic absorber, vibration absorber, or Frahm absorber) is a simple mass–spring oscillator with very low damping. An absorber that is tuned to a frequency of vibration of a mechanical system and is able to receive a significant portion of the vibration energy from the primary system at that frequency. In effect, the resulting vibration of the absorber applies an oscillatory force opposing the vibration excitation of the primary system and thereby virtually cancels the effect. In theory, the vibration of the system can be completely removed while the absorber itself undergoes vibratory motion. Since damping is quite low in practical vibration absorbers, we will first consider the case of an undamped absorber.

A vibration absorber may be used for vibration control in two common types of situations, as shown in [Figure 32.23](#). Here, the primary system whose vibration needs to be controlled is modeled as an

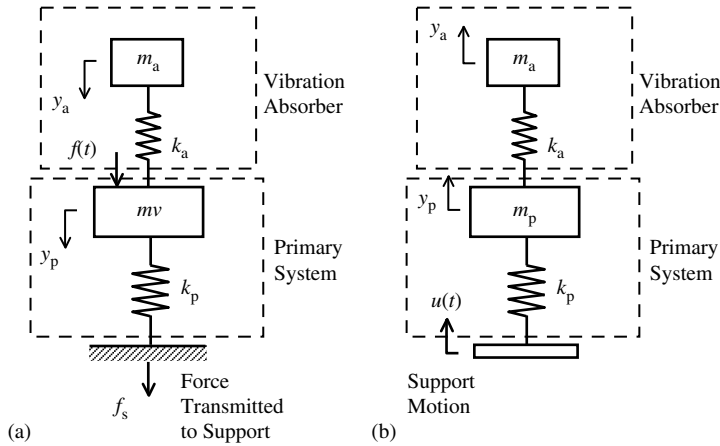

FIGURE 32.23 Two types of applications of a vibration absorber: (a) reduction of the response to forcing excitation (or reducing the force transmitted to support structure); (b) reduction of the response to support motion.

undamped, single-DoF mass–spring system (denoted by the subscript p). An undamped vibration absorber is also a single-DoF mass–spring system (denoted by the subscript a). In the application shown in Figure 32.23(a), the objective of the absorber is to reduce the vibratory response y_p of the primary system as a result of a vibration excitation $f(t)$. The force f_s that is transmitted to the support structure due to the vibratory response of the system is given by

$$f_s = k_p y_p \quad (32.98)$$

Therefore, the objective of reducing y_p may also be interpreted as one of reducing this transmitted vibratory force (a goal of vibration isolation). In the second type of application, represented in Figure 32.23(b), the primary system is excited by a vibratory support motion and the objective of the absorber is to reduce the resulting vibratory motions y_p of the primary system. Note that, in both classes of application, the purpose is to reduce the vibratory responses. Hence, static loads (e.g., gravity) are not considered in the analysis.

Table 32.1 shows the development of the equations of motion for the two systems shown in Figure 32.23. Because we are interested mainly in the control of oscillatory responses to oscillatory excitations, the frequency-domain model is particularly useful. Note from Table 32.1 that the transfer function f_s/f of System a is simply k times the transfer function y_p/f , and is in fact identical to the transfer function y_p/u of System b. The two problems are essentially identical and, thus, we need only address only one of them.

Before investigating the common transfer function for the two types of problems, let us look closely at the frequency-domain equations for the system shown in Figure 32.23(a). We have

$$(k_p + k_a - \omega^2 m_p) y_p - k_a y_a = f \quad (32.99)$$

$$(k_a - \omega^2 m_a) y_a = k_a y_p \quad (32.100)$$

along with Equation 32.98. Here, m_p and k_p are the mass and the stiffness of the primary system, m_a and k_a are the mass and the stiffness of the absorber, f is the excitation amplitude, ω is the excitation frequency, y_p is the primary mass response, and y_a is the absorber response. Now note from Equation 32.100 that if $\omega = \sqrt{k_a/m_a}$ then $y_p = 0$. This means that if the absorber is tuned so that its natural frequency is equal to the excitation frequency (drive frequency), the primary system will not (ideally) undergo any vibratory motion, and is perfectly controlled. The reason for this should be clear from Equation 32.99 which, when $y_p = 0$ is substituted, gives $k_a y_a = -f$. In other words, a tuned absorber applies to the primary system a spring force that is exactly equal and opposite to the excitation force, thereby neutralizing the effect. The absorber mass moves, albeit 180° out of phase with the excitation.

TABLE 32.1 Equations for the Two Types of Absorber Applications

	Absorber Application for the Reduction of Response to a:	
	Forcing Excitation	Support Motion
Time-domain equations	$m_p \ddot{y}_p = -k_p y_p - k_a (y_p - y_a) + f(t)$ $m_a \ddot{y}_a = k_a (y_p - y_a)$	$m_p \ddot{y}_p = k_p (u(t) - y_p) - k_a (y_p - y_a)$ $m_a \ddot{y}_a = k_a (y_p - y_a)$
Frequency-domain equations	$(-\omega^2 m_p + k_p + k_a) y_p = k_a y_a + f$ $(-\omega^2 m_a + k_a) y_a = k_a y_p$	$(-\omega^2 m_p + k_p + k_a) y_p = k_a y_a + k_p u$ $(-\omega^2 m_a + k_a) y_a = k_a y_p$
Matrix form	$\begin{bmatrix} k_p + k_a - \omega^2 m_p & -k_a \\ -k_a & k_a - \omega^2 m_a \end{bmatrix} \begin{bmatrix} y_p \\ y_a \end{bmatrix} = \begin{bmatrix} f \\ 0 \end{bmatrix}$	$\begin{bmatrix} k_p + k_a - \omega^2 m_p & -k_a \\ -k_a & k_a - \omega^2 m_a \end{bmatrix} \begin{bmatrix} y_p \\ y_a \end{bmatrix} = k_p \begin{bmatrix} u \\ 0 \end{bmatrix}$
Transfer-function matrix form	$\begin{bmatrix} y_p \\ y_a \end{bmatrix} = \frac{1}{\Delta} \begin{bmatrix} k_a - \omega^2 m_a & k_a \\ k_a & k_p k_a - \omega^2 m_p \end{bmatrix} \begin{bmatrix} f \\ 0 \end{bmatrix}$	$\begin{bmatrix} y_p \\ y_a \end{bmatrix} = \frac{k}{\Delta} \begin{bmatrix} k_a - \omega^2 m_a & k_a \\ k_a & k_p k_a - \omega^2 m_p \end{bmatrix} \begin{bmatrix} u \\ 0 \end{bmatrix}$
Vibration-control transfer function	$\frac{f_s}{f} = \frac{k_p y_p}{f} = \frac{k_p}{\Delta} (k_a - \omega^2 m_a)$	$\frac{y_p}{u} = \frac{k_p}{\Delta} (k_a - \omega^2 m_a)$
Characteristic polynomial	$\Delta = (k_p + k_a - \omega^2 m_p)(k_a - \omega^2 m_a) - k_a^2$ $= m_p m_a \omega^4 - [k_a(m_p + m_a) + k_p m_a] \omega^2 + k_p k_a$	

The frequency of these motions will be ω (the same as that of the excitation) and the amplitude is proportional to that of the excitation (f) and inversely proportional to the stiffness of the absorber spring. It follows that a vibration absorber “absorbs” vibration energy from the primary system. Furthermore, note from Equation 32.98 that with a tuned absorber the vibration force transmitted to the support structure is (ideally) zero as well. All this information is observed without any mathematical manipulation of the equations of motion.

Note that we are dealing with vibratory excitations and responses. Therefore, static loading (such as gravity and spring preloads) is not considered (we investigate responses with respect to the static equilibrium configuration of the system). In summary, we are now able to state the characteristics of a vibration absorber (undamped) as follows:

1. It is effective only for a single excitation frequency (i.e., a sinusoidal excitation).
2. For the best effect, it should be “tuned” such that its natural frequency $\sqrt{k_a/m_a}$ is equal to the excitation frequency.
3. In the case of forcing vibration excitation, a tuned absorber can (ideally) make the vibratory response of the primary system and the vibratory force transmitted to the support structure zero.
4. In the case of a vibratory support motion, a tuned absorber can make the resulting response of the primary system zero.
5. It functions by acquiring vibration energy from the primary system and storing it (as kinetic energy of the mass or potential energy of the spring) rather than by directly dissipating the energy.
6. It functions by applying a vibration force to the primary system that is equal and opposite to the excitation force, thereby neutralizing the excitation.
7. The amplitude of motion of the vibration absorber is proportional to the excitation amplitude and is inversely proportional to the absorber stiffness. The frequency of the absorber motion is the same as the excitation frequency.

Now, consider the transfer function (f_s/f or y_p/u) of an undamped vibration absorber, as given in Table 32.1. We have

$$G(\omega) = \frac{k_p(k_a - \omega^2 m_a)}{m_p m_a \omega^4 - [k_a(m_p + m_a) + k_p m_a] \omega^2 + k_p k_a} \quad (32.101)$$

It is convenient to use a nondimensional form in analyzing this frequency-transfer function. To that end, we define the following nondimensional parameters and frequency variable:

Fractional mass of the absorber $\mu = m_a/m_p$

Nondimensional natural frequency of the absorber $\alpha = \omega_a/\omega_p$

Nondimensional excitation (drive) frequency $r = \omega/\omega_p$

where

$\omega_a = \sqrt{k_a/m_a}$ = natural frequency of the absorber

$\omega_p = \sqrt{k_p/m_p}$ = natural frequency of the primary system

It is straightforward to divide the numerator and the denominator by $k_p k_a$ and then carry out simple algebraic manipulations to express the transfer function of Equation 32.101 in the nondimensional form as

$$G(r) = \frac{\alpha^2 - r^2}{r^4 - [\alpha^2(1 + \mu) + 1]r^2 + \alpha^2} \quad (32.102)$$

For this undamped system, there is no difference between the resonant frequencies (where the magnitude of the transfer function peaks) and the natural frequencies (roots of the characteristic equation that correspond to the “natural” or free time response oscillations). These are obtained by solving the equation

$$r^4 - [\alpha^2(1 + \mu) + 1]r^2 + \alpha^2 = 0 \quad (32.103)$$

which gives

$$r_1^2, r_2^2 = \frac{1}{2} [\alpha^2(1 + \mu) + 1] \mp \frac{1}{2} \sqrt{[\alpha^2(1 + \mu) + 1]^2 - 4\alpha^2} \quad (32.104)$$

These are squared frequencies, both of which are positive as clear from Equation 32.104. The actual, nondimensional natural frequencies are their square roots. The magnitude of the transfer function becomes infinite at either of these two natural/resonant frequencies. Furthermore, it is clear from Equation 32.102 that the transfer function magnitude becomes zero at $r = \alpha$, where the excitation frequency (ω) is equal to the natural frequency of the absorber (ω_a) as noted above. In the present undamped case, the transfer function $G(r)$ is real but it can be either positive or negative. The magnitude is thus the absolute value of $G(r)$, which is positive. The magnitude plot given in Figure 32.24 shows the resonant and control characteristics of a system with an undamped vibration absorber. Originally, the primary system had a resonance at $r = 1$ (i.e., $\omega = \omega_p$). When the absorber, which also has a resonance at $r = 1$, is added, the original resonance becomes an *antiresonance* with a zero response. Here, however, two new resonances are created, one at $r = 0.854$ and the other at $r = 1.171$, which are on either side of the tuned frequency ($r = 1$) of the absorber.

Owing to these two resonances, the effective region of the absorber is limited to a narrow frequency band centering its tuned frequency. Specifically, the absorber is not effective unless $|G| < 1$. The effective frequency band of a vibration absorber may be determined using this condition.

Example 32.8

A high-precision, yet high-power positioning system uses a hydraulic actuator and a valve. The pressurized oil to this hydraulic servo system is provided by a gear-type rotary pump. The pump and the positioning system are mounted on the same workbench. The mass of the pump is 25 kg. The normal operating speed of the pump is 3600 rpm. During operation, it was observed that the pump exhibits a vertical resonance at this speed and it affects the accuracy of the position servo system. To control the vibrations of the pump at its operating speed, a vibration absorber of mass 1.25 kg tuned to the normal operating speed of the pump is attached, as shown schematically in Figure 32.25. Because the speed of the pump normally fluctuates during operation, we must determine the speed range within which the vibration absorber is effective. What are the new resonant frequencies of the system? (Neglect damping.)

FIGURE 32.24 The effect of an undamped vibration absorber on the vibration response of a primary system.

FIGURE 32.25 A hydraulic positioning system with a gear pump.

Solution

For this problem, the fractional mass $\mu = 1.25/25.0 = 0.05$. Since the absorber is tuned to the resonant frequency of the pump, $\alpha = 1.0$. From Equation 32.103, the characteristic equation of the modified system becomes

$$r^4 - 2.05r^2 + 1 = 0$$

which has roots $r_1 = 0.854$ and $r_2 = 1.171$. It follows that the new resonances are at 0.854×3600 and 1.171×3600 rpm. These are 3074.4 and 4215.6 rpm, which should be avoided. From Equation 32.102, the system transfer function is

$$G(r) = \frac{1 - r^2}{(r^4 - 2.05r^2 + 1)}$$

The effective frequency band of the absorber corresponds to $|G(r)| < 1.0$. Since a sign reversal of $G(r)$ occurs at $r = 1$, we need to solve both

$$\frac{1 - r^2}{(r^4 - 2.05r^2 + 1)} = 1 \quad \text{and} \quad -1$$

The first equation gives the roots $r = 0$ and 1.025. The second equation gives the roots $r = 0.977$ and 1.45.

Hence, the effective frequency band corresponds to $\Delta r = [0.977, 1.025]$. In terms of the operating speed of the pump, we have an effective band of 3517.2 to 3690 rpm. Thus, a speed fluctuation of about ± 80 rpm is acceptable.

Finally, recall that the presence of the absorber generates two new resonances on either side of the resonance of the original system (to which the absorber is normally tuned). It is also clear from Equation 32.104 that these two resonances become farther and farther apart as the fractional mass μ of the vibration absorber is increased.

32.8.2 Damped Vibration Absorber

Damping is not the primary means by which vibration control is achieved in a vibration absorber. As noted above, the absorber acquires vibration energy from the primary system (and in turn, exerts a force on the system that is equal and opposite to the vibration excitation), thereby suppressing the vibratory motion. The energy received by the absorber has to be dissipated gradually and, hence, some damping should be present in the absorber. Furthermore, the two resonances that are created by adding the absorber have an infinite magnitude in the absence of damping. Hence, damping has the added benefit of lowering these resonant peaks.

The analysis of a vibratory system with a damped absorber is similar to but somewhat more complex than, that involving an undamped absorber. Furthermore, an extra design parameter — the damping ratio of the absorber — enters into the scene. Consider the model shown in Figure 32.26. Another version of application of a damped absorber, which corresponds to Figure 32.23(b), may also be presented. However, because the two types of application have the same transfer function, it is sufficient to consider Figure 32.26 alone.

FIGURE 32.26 Primary system with a damped vibration absorber.

Again, the transfer function of vibration control may be taken as either y_a/f or f_s/f , the latter being simply k_p times the former. Although we will consider the dimensionless case of f_s/f , the results are equally valid for y_p/f , except that the responses must be converted from force to displacement by dividing by k_p .

There is no need to derive the transfer function anew for the damped system. Simply replace k_a in Equation 32.101 by the complex stiffness $k_a + j\omega b_a$, which incorporates the viscous damping constant b_a and the excitation frequency ω . Hence, the transfer function of the damped system is

$$G(\omega) = \frac{k_p(k_a + j\omega b_a - \omega^2 m_a)}{m_p m_a \omega^4 - [(k_a + j\omega b_a)(m_p + m_a) + k_p m_a] \omega^2 + k_p(k_a + j\omega b_a)} \quad (32.105)$$

With the parameters defined as before, the nondimensional form of this transfer function is obtained by dividing throughout by $k_p k_a$ and then substituting the appropriate parameters. In particular, we use the fact that

$$\frac{b_a}{k_a} = \frac{2b_a}{2\sqrt{k_a m_a}} \sqrt{\frac{m_a}{k_a}} = \frac{2\zeta_a}{\omega_a} = \frac{2\zeta_a}{\omega_p} \frac{\omega_p}{\omega_a} = \frac{2\zeta_a}{\alpha \omega_p} \quad (32.106)$$

where the damping ratio ζ_a of the absorber is given by

$$\zeta_a = \frac{b_a}{2\sqrt{k_a m_a}} \quad (32.107)$$

as usual. Then, we follow the same procedure that used to derive Equation 32.102 from Equation 32.101 to get

$$G(r) = \frac{\alpha^2 - r^2 + 2j\zeta_a \alpha r}{r^4 - [(\alpha^2 + 2j\zeta_a \alpha r)(1 + \mu) + 1]r^2 + (\alpha^2 + 2j\zeta_a \alpha r)} \quad (32.108)$$

Note that this result is equivalent to simply replacing α^2 by $\alpha^2 + 2j\zeta_a \alpha r$ in Equation 32.102.

It is important to note that the undamped natural frequencies are obtained by solving the characteristics equation with $\zeta_a = 0$. These are the same as before and given by the square roots of Equation 32.104. The damped natural frequencies are obtained by first setting $jr = \lambda$ (hence, $r^2 = -\lambda^2$ and $r^4 = \lambda^4$) and then solving the resulting characteristics equation (see the denominator of Equation 32.108).

$$\lambda^4 + 2\zeta_a \alpha (1 + \mu) \lambda^3 + (\alpha^2 + \alpha^2 \mu + 1) \lambda^2 + 2\zeta_a \alpha \lambda + \alpha^2 = 0 \quad (32.109)$$

and then taking the imaginary parts of the roots of λ . These depend on ζ_a and are different from those obtained from Equation 32.104. The resonant frequencies correspond to the r values where the magnitude of $G(r)$ will peak. Generally, these are not the same as the undamped or damped natural frequencies. However, for low damping (small ζ_a compared with 1), these three types of system characteristics frequencies are almost identical.

The magnitude of the transfer function (Equation 32.108) is plotted in Figure 32.27 for the case $\mu = 1.0$ and $\alpha = 1.0$, as in Figure 32.24, but for damping ratios $\zeta_a = 0.01, 0.1$, and 0.5 . Note that the curve for $\zeta_a = 0.01$ is very close to that in Figure 32.24 for the undamped case. When ζ_a is large, as shown in the case of $\zeta_a = 0.5$, the two masses m_p and m_a tend to become locked together and appear to behave like a single mass. Then, the system tends to act like a single-DoF one, and the primary system is modified only in its mass (which increases). Consequently, only one resonant frequency is produced, which is smaller than that of the original primary system. Furthermore, as expected in this high-damping case, the effect of a vibration absorber is no longer present.

All three curves in Figure 32.27 pass through the two common points A and B, as shown. This is true for all curves corresponding to all values of ζ_a , and particularly for the extreme cases of $\zeta_a = 0$ and $\zeta_a \rightarrow \infty$. Hence, these points can be determined as the points of intersection of the transfer function magnitude curves for the limiting cases $\zeta_a = 0$ and $\zeta_a \rightarrow \infty$.

FIGURE 32.27 Vibration amplification (transfer function magnitude) curves for damped vibration absorbers (absorber mass $\mu = 0.1$, absorber resonant frequency $\alpha = 1.0$).

Equation 32.102 gives $G(r)$ for $\zeta_a = 0$. Next, from Equation 32.108, we note that, as $\zeta_a \rightarrow \infty$, all the terms not containing ζ_a can be neglected. Hence,

$$G(r) = \frac{2j\zeta_a\alpha r}{-2j\zeta_a\alpha r(1 + \mu)r^2 + 2j\zeta_a\alpha r}$$

Cancel the common term and we get (for $r \neq 0$)

$$G(r) = \frac{1}{1 - (1 + \mu)r^2} \quad \text{for } \zeta_a \rightarrow \infty \quad (32.110)$$

Note that this is the normalized transfer function of a single-DoF system of natural frequency $1/\sqrt{1 + \mu}$. This result confirms the fact that as $\zeta_a \rightarrow \infty$, the two masses m_p and m_a become locked together and act as a single mass $(m_p + m_a)$ supported on a spring of stiffness k_p . Its natural frequency is $\sqrt{k_p/(m_p + m_a)}$ which, when normalized with respect to $\sqrt{k_p/m_p}$, becomes

$$\sqrt{\frac{k_p}{(m_p + m_a)} \frac{m_p}{k_p}} = \sqrt{\frac{m_p}{(m_p + m_a)}} = \frac{1}{\sqrt{1 + \mu}}$$

In determining the points of intersection between the functions (see Equation 32.102 and Equation 32.110), we should first note that at the first point of intersection (A), the function in Equation 32.102 is negative and positive in Equation 32.110, while the reverse is true for the second point of intersection (B). For either point, this means that the sign of one of the functions should be reversed before equating them. Thus,

$$\frac{\alpha^2 - r^2}{r^4 - [\alpha^2(1 + \mu) + 1]r^2 + \alpha^2} = -\frac{1}{1 - (1 + \mu)r^2}$$

which gives

$$(2 + \mu)r^4 - 2[\alpha^2(1 + \mu) + 1]r^2 + 2\alpha^2 = 0 \quad (32.111)$$

This is the equation whose roots (e.g., r_1 and r_2) give the points A and B. Then, we have the sum of the squared roots equal to the negative coefficient of r^2 in the quadratic (in r^2) Equation 32.111. Thus,

$$r_1^2 + r_2^2 = \frac{2[\alpha^2(1 + \mu) + 1]}{(2 + \mu)} \quad (32.112)$$

In addition, the product of the squared roots is equal to the constant term in the quadratic (r^2) in Equation 32.111. Hence,

$$r_1^2 r_2^2 = \frac{2\alpha^2}{(2 + \mu)} \quad (32.113)$$

32.8.2.1 Optimal Absorber Design

It has been pointed out (primarily by J.P. Den Hartog) that an optimal absorber design should not only have equal response magnitudes at the common points of intersection (i.e., equal ordinates of points A and B in Figure 32.27), but also that the resonances should occur at these points to achieve some balance and uniformity in the response amplification in the region surrounding the tuned frequency of the absorber. It is expected that these (intuitive) design conditions would give relations between the parameters α , μ , and ζ_a , corresponding to an optimal absorber.

Consider the first requirement of equal transfer function magnitudes at A and B. As noted earlier, because these two points do not depend on ζ_a , we use Equation 32.110 to satisfy the requirement. Thus, keeping in mind the sign reversal of the transfer function between A and B (i.e., as the transfer function passes through the resonance), we have

$$\frac{1}{1 - (1 + \mu)r_1^2} = -\frac{1}{1 - (1 + \mu)r_2^2}$$

which gives

$$r_1^2 + r_2^2 = \frac{2}{1 + \mu} \quad (32.114)$$

Substituting this result (for equal ordinates) in the intersection-point condition (see Equation 32.112), we have

$$\frac{2}{1 + \mu} = \frac{2[\alpha^2(1 + \mu) + 1]}{(2 + \mu)}$$

On simplification, we get the simple result

$$\alpha = \frac{1}{1 + \mu} \quad (32.115)$$

Next, we turn to the task of achieving peak magnitudes of the transfer function at the points of intersection (A and B). Generally, when one point peaks the other does not. As reported by Den Hartog, with straightforward but lengthy analysis, we obtain

$$\zeta_a^2 = \frac{\mu[3 - \sqrt{\mu(\mu + 2)}]}{8(1 + \mu)^3} \quad (32.116)$$

for peak at the first intersection point, and

$$\zeta_a^2 = \frac{\mu[3 + \sqrt{\mu(\mu + 2)}]}{8(1 + \mu)^3} \quad (32.117)$$

for peak at the second intersection point.

So, for design purposes, a balance is obtained by taking the average value of the results of Equation 32.116 and Equation 32.117 as

$$\zeta_a^2 = \frac{3\mu}{8(1+\mu)^3} \quad (32.118)$$

Thus, Equation 32.115 and Equation 32.118 correspond to an optimal vibration absorber. In addition, practical requirements and limitations need to be addressed in any design procedure. In particular, since μ is considerably less than unity (i.e., absorber mass is a small fraction of the primary mass), the absorber mass should undergo relatively large amplitudes at the operating frequency in order to receive the energy of the primary system. The absorber spring must be designed accordingly, while meeting the tuning frequency conditions that determine the ratio m_a/k_a .

Example 32.9

The air compressor of a wind tunnel weighs 48 kg and normally operates at 2400 rpm. The first major resonance of the compressor unit occurs at 2640 rpm, with severe vibration amplitudes that are quite dangerous. Design a vibration absorber (damped) for installation on the mounting base of the compressor. What are the vibration amplifications of the compressor unit at the new resonances of the modified system? Compare these with the vibration amplitude of the original system in normal operation.

Solution

As usual, we will tune the absorber to the normal operating speed (2400 rpm). Then, we have the nondimensional resonant frequency of the absorber:

$$\alpha = \frac{\omega_a}{\omega_p} = \frac{2400}{2640} = \frac{12}{13}$$

Now, for an optimal absorber, from Equation 32.115

$$\mu = \frac{1}{\alpha} - 1 = \frac{13}{12} - 1 = \frac{1}{12}$$

Hence, the absorber mass

$$m_a = 48 \times \frac{1}{12} \text{ kg} = 4.0 \text{ kg}$$

Then, from Equation 32.118, the damping ratio of the absorber is

$$\zeta_a = \left[\frac{3/12}{8(1+1/12)^3} \right]^{1/2} = 0.157$$

Now,

$$\omega_a = \sqrt{\frac{k_a}{m_a}} = \sqrt{\frac{k_a}{4.0}} = \frac{2400}{60} \times 2\pi \text{ rad/sec} = 88\pi \text{ rad/sec}$$

Hence,

$$k_a = (88\pi)^2 \times 4.0 \text{ N/m} = 2.527 \times 10^5 \text{ N/m}$$

Also,

$$\zeta_a = \frac{1}{2} \frac{b_a}{\sqrt{m_a k_a}}$$

Then, we have

$$b_a = 2 \times 0.157 \sqrt{4.0 \times 2.527 \times 10^5} \text{ N sec/m} = 315.7 \text{ N sec/m}$$

This gives us the damped absorber. Now, let us check its performance. We know that, in theory, the vibration amplitude at the operating speed should be almost zero now. However, two resonances are created around the operating point. Since damping is small, we use the undamped characteristic Equation 32.103 to compute these resonances:

$$r^4 - \left[\frac{12^2}{13^2} \left(1 + \frac{1}{12} \right) + 1 \right] r^2 + \frac{12^2}{13^2} = 0$$

which gives

$$r^4 - \frac{25}{13} r^2 + \frac{12^2}{13^2} = 0$$

The roots of r^2 are 0.692 and 1.231. The (positive) roots of r are 0.832 and 1.109.

These correspond to compressor speeds of (multiply r by 2640 rpm) 2196 and 2929 rpm. Although they are approximately at -10% and $+20\%$ of the operating speed, the first resonance will be encountered during startup and shutdown conditions. To determine the corresponding vibration amplifications (force/force), use Equation 32.108 which, when the undamped characteristic equation is substituted into the denominator, becomes

$$G(r) = \frac{\alpha^2 - r^2 + 2j\zeta_a \alpha r}{[-2j\zeta_a \alpha r(1 + \mu)r^2 + 2j\zeta_a \alpha r]} = \frac{1 - j(\alpha^2 - r^2)/(2\zeta_a \alpha r)}{1 - (1 + \mu)r^2} \quad (32.119)$$

Substitute the resonant frequencies $r_1 = 0.832$ and $r_2 = 1.109$. We get $|G(r_1)| = 4.223$ and $|G(r_2)| = 4.634$.

Without the absorber, we approximate the system by a simple undamped oscillator with transfer function

$$G_p(r) = \frac{1}{1 - r^2}$$

The corresponding vibration amplification at the operating speed is

$$|G_p(r_0)| = \frac{1}{|1 - 12^2/13^2|} = 6.76$$

It is observed that after adding the absorber, the resonant vibrations are smaller than even the operating vibrations of the original system. Hence, the design is satisfactory. Note that we used the force/force transfer functions. To get the displacement/force transfer functions we divide by k_p . However, we have

$$\sqrt{\frac{k_p}{m_p}} = \frac{2640}{60} \times 2\pi \text{ rad/sec} = 88\pi \text{ rad/sec}$$

Hence,

$$k_p = (88\pi)^2 \times 48 \text{ N/m} = 3.67 \times 10^6 \text{ N/m} = 3.67 \times 10^3 \text{ N/mm}$$

Thus, the amplitude of operating vibrations of the original system is

$$\frac{6.76}{3.67 \times 10^3} \text{ mm/N} = 1.84 \times 10^{-3} \text{ mm/N}$$

The amplitudes of the resonant vibrations of the modified system are

$$\frac{4.223}{3.67 \times 10^3} \quad \text{and} \quad \frac{4.634}{3.67 \times 10^3} \text{ mm/N or } 1.15 \times 10^{-3} \text{ and } 1.26 \times 10^{-3} \text{ mm/N}$$

Vibration absorbers are simple and passive devices, which are commonly used in the control of narrowband vibrations (limited to a very small interval of frequencies). Applications are found in vibration suppression of transmission wires (e.g., a stockbridge damper, which simply consists of a piece of cable carrying two masses at its ends), consumer appliances, automobile engines, and industrial machinery. It should be noted that the concepts presented for a rectilinear vibration absorber may be directly extended to a rotary vibration absorber. Figure 32.28 provides a schematic representation of a rotary vibration absorber. This model corresponds to vibration force excitations (compare with Figure 32.23(a)). The case of rotational support-motion excitations (see Figure 32.23(b)), which has essentially the same transfer function, may also be addressed. Approaches of vibration control are summarized in Box 32.7.

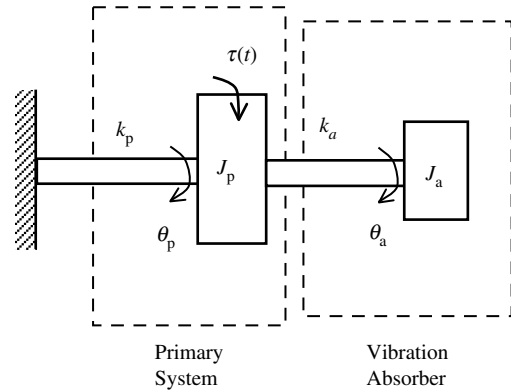

FIGURE 32.28 The application of a rotary vibration absorber.

32.8.3 Vibration Dampers

As discussed above, vibration absorbers are simple and effective passive devices, which are used in vibration control. They have the added advantage of being primarily nondissipative. The main disadvantage of a vibration absorber is that it is only effective over a very narrow band of frequencies enclosing its resonant frequency (tuned frequency). When passive vibration control over a wide band of frequencies is required, a damper would be a preferable choice.

Vibration dampers are dissipative devices. They control vibration through direct dissipation of the vibration energy of the primary (vibrating) system. As a result, however, there will be substantial heat generation, and associated thermal problems and component wear. Consequently, methods of cooling (e.g., use of a fan, coolant circulation, and thermal conduction blocks) may be required in some special situations.

Consider a vibrating system modeled as an undamped single-DoF mass–spring system (simple oscillator). The magnitude of the excitation-response transfer function will have a resonance with a theoretically infinite magnitude in this case. Operation in the immediate neighborhood of such a resonance would be destructive. Adding a simple viscous damper, as shown in Figure 32.29(a), will correct the situation. The equation of motion (about the static equilibrium position) is

$$m\ddot{y} + b\dot{y} + ky = f(t) \quad (32.120)$$

with the dynamic force that is transmitted through the support base (f_s) given by

$$f_s = ky + b\dot{y} \quad (32.121)$$

Hence, the transfer function between the forcing excitation f and the vibration response y is

$$\frac{y}{f} = \frac{1}{k - \omega^2 m + j\omega b} \quad (32.122)$$

and that between the forcing excitation and the force transmitted to the support structure is

$$\frac{f_s}{f} = \frac{k + j\omega b}{k - \omega^2 m + j\omega b} \quad (32.123)$$

Using the nondimensional frequency variable $r = \omega/\omega_n$ where $\omega_n = \sqrt{k/m}$ is the undamped natural frequency of the system and the damping ratio $\zeta = b/(2\sqrt{km})$, we can express Equation 32.122 and

Box 32.7

VIBRATION CONTROL

Passive control (no external power):

1. Dampers
 - A dissipative approach (thermal problems, degradation)
 - Useful over a wide frequency band
2. Vibration absorbers (dynamic absorbers, Frahm absorbers)
 - Absorbs energy from vibrating system and applies counteracting force
 - Useful over a very narrow frequency band (near the tuned frequency)
 - Absorber executes large motions

Undamped absorber design:

$$\text{Transfer function of system with absorber} = \frac{\alpha^2 - r^2}{r^4 - [\alpha^2(1 + \mu) + 1]r^2 + \alpha^2}$$

where

μ = absorber mass/primary system mass

α = absorber natural frequency/primary system natural frequency

r = excitation frequency/primary system natural frequency

The most effective operating frequency $r_{\text{op}} = \alpha$.

Avoid the two resonances.

Optimal damped absorber design:

Mass ratio

$$\mu = \frac{1}{\alpha} - 1$$

Damping ratio

$$\zeta_a = \frac{3\mu}{8(1 + \mu)^3}$$

Active control (needs external power):

1. Measure vibration response using sensors/transducers.
2. Apply control forces to vibrating system through actuators, according to a suitable control algorithm.

Equation 32.123 in the form

$$\frac{y}{f} = \frac{1}{k(1 - r^2 + 2j\zeta r)} \quad (32.124)$$

$$\frac{f_s}{f} = \frac{1 + 2j\zeta r}{(1 - r^2 + 2j\zeta r)} \quad (32.125)$$

When vibration control of the primary system is desired, we use the transfer function in Equation 32.124. However, when force transmissibility is the primary consideration, we use Equation 32.125.

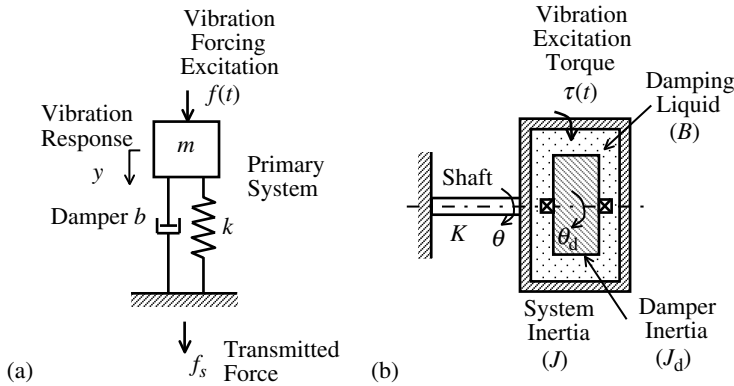

FIGURE 32.29 (a) A system with a linear viscous damper; (b) a rotary system with a Houdaille damper.

Furthermore, it is convenient to use the transfer function in Equation 32.124 in the nondimensional form:

$$\frac{ky}{f} = G(r) = \frac{1}{(1 - r^2 + 2j\zeta r)} \quad (32.126)$$

The magnitude of this transfer function is plotted in Figure 32.30 for several values of damping ratio. Note that the addition of significant levels of damping considerably lowers the resonant peak and flattens the overall response. This example illustrates the broadband nature of the effect of a damper. However, unlike a vibration absorber, it is not possible with a simple damper to bring the vibration levels to a theoretical zero. However, a damper is able to bring the response uniformly close to the static value (unity in Figure 32.30).

FIGURE 32.30 Frequency response of a system containing a linear damper.

Another common application of damper is connecting it through a free inertia element. For a rotational system, such an arrangement is known as the Houdaille damper, and is modeled as in Figure 32.30(b). The equations of motion are

$$J\ddot{\theta} + B(\dot{\theta} - \dot{\theta}_d) + K\theta = \tau(t) \quad (32.127)$$

$$J_d\ddot{\theta}_d + B(\dot{\theta}_d - \dot{\theta}) = 0 \quad (32.128)$$

In this case, the transfer function between the vibratory excitation torque τ and the response angle θ is given by

$$\frac{\theta}{\tau} = \frac{B + J_d j\omega}{KB - B(J + J_d)\omega^2 - J_d J j\omega^3 + K J_d j\omega} \quad (32.129)$$

Again, we use the normalized form of $K\theta/\tau$. Then, we obtain

$$\frac{K\theta}{\tau} = G(r) = \frac{2\zeta + jr\mu}{2\zeta[1 - (1 + \mu)r^2] + jr\mu(1 - r^2)} \quad (32.130)$$

where $r = \omega/\omega_n$, $\zeta = B/(2\sqrt{KJ})$, $\mu = J_d/J$, and $\omega_n = \sqrt{K/J}$.

Note the two extreme cases. When $\zeta = 0$, the system becomes the original undamped system, as expected. When $\zeta \rightarrow \infty$, the system becomes an undamped simple oscillator, but with a lower natural frequency of $r = 1/\sqrt{1 + \mu}$, instead of $r = 1$ that was present in the original system. This is to be expected because as $\zeta \rightarrow \infty$, the two inertia elements become locked together and act as a single combined inertia $J + J_d$. Clearly, in these two extreme systems, the effect of damping is not present. Optimal damping occurs somewhere in between, as is clear from the curves of response magnitude shown in Figure 32.31 for the case of $\mu = 0.2$.

Proper selection of the nature and values of damping is crucial for the effective use of a damper in vibration control. Damping in physical systems is known to be nonlinear and frequency dependent, as well as time-variant and dependent on the environment (e.g., temperature). Various models are available for different types of damping, but these are only approximate representations. In practice, such considerations as the type of damper used, the nature of the system, the specific application, and the

FIGURE 32.31 Response curves for a rotary system with Houdaille damper of inertia ratio $\mu = 0.2$.

speed of operation, determine which particular model (linear viscous, hysteric, Coulomb, Stribeck, quadratic aerodynamic, etc.) is suitable. In addition to the simple linear theory of viscous damper, specific properties of physical damping should be taken into consideration in practical designs.

32.9 Active Control of Vibration

Passive control of vibration is relatively simple and straightforward. Although it is robust, reliable, and economical, it has its limitations. Note that the control force that is generated in a passive device depends entirely on the natural dynamics. Once the device is designed (i.e., after the parameter values for mass, damping constant, stiffness, location, etc. are chosen), it is not possible to adjust the control forces that are naturally generated in real time. Furthermore, in a passive device there is no supply of power from an external source. Hence, even the magnitude of the control forces cannot be changed from their natural values. Since a passive device senses the response of the system as an integral process of the overall dynamics of the system, it is not always possible to directly target the control action at particular responses (e.g., particular modes). This can result in incomplete control, particularly in complex and high-order (e.g., distributed-parameter) systems. These shortcomings of passive control can be overcome using active control. Here, the system responses are directly sensed using sensor-transducer devices, and control actions of specific desired values are applied to desired locations/modes of the system.

32.9.1 Active Control System

Figure 32.32 presents a schematic diagram of an active control system. The mechanical dynamic system whose vibrations need to be controlled is the *plant* or *process*. The controller is the device that generates the signal (or command) according to some scheme (or control law) and controls vibrations of the plant. The plant and the controller are the two essential components of a *control system*. Usually, the plant must

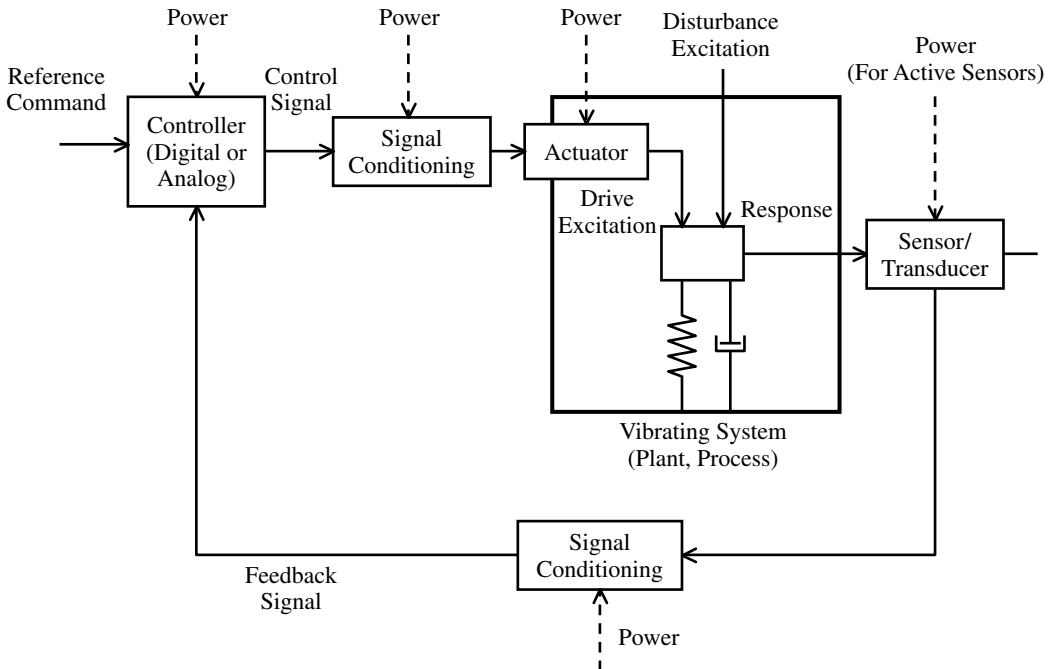

FIGURE 32.32 A system for active control of vibration.

be monitored and its response must be measured using sensors providing feedback into the controller. Then, the controller compares the sensed signal with a desired response specified externally, and uses the error to generate a proper control signal. In this manner, we have a feedback control system. In the absence of a sensor and feedback, we have an open-loop control system. In *feed-forward control*, the excitation (i.e., input signal), not the response (i.e., output signal), is measured and used (i.e., fed forward into the controller) for generating the control signal. Both feedback and feedforward schemes may be used in the same control system.

The actuator that receives a control signal and drives the plant may be an integral part of the plant (e.g., the motor that drives the blade of a saw). Alternatively, it may have to be added specifically as an external component for the control actuation (e.g., a piezoelectric or electromagnetic actuator for controlling blade vibrations of a saw). In the former case, in particular, proper signal conditioning is needed to convert the control signal to a form that is compatible with the existing actuator. In the latter case, both the controller and the actuator must be developed in parallel for integration into the plant. In digital control, the controller is a digital processor. The control signal is in digital form and, typically, it has to be converted into the analog form prior to using in the actuator. Hence, digital-to-analog conversion (DAC) is a form of signal conditioning that is useful here. Furthermore, the analog signal that is generated may have to be filtered and amplified to an appropriate level for use in the actuator. It follows that filters and amplifiers are signal conditioning devices, which are useful in vibration control. In *software control*, the control signal is generated by a computer, which functions as the digital controller. In *hardware control*, the control signal is rapidly generated by digital hardware without using software programs. Alternatively, *analog control* may be used where the control signal is generated directly using analog circuitry. In this case, the controller is quite fast and it does not require DAC. Note that the actuator may need high levels of power. Furthermore, the controller and associated signal conditioning will require some power. The need for an external power source for control distinguishes active control from passive control.

In a feedback control system, sensors are used to measure the plant response, which enables the controller to determine whether the plant operates properly. A sensor unit that “senses” the response may automatically convert (transduce) this “measurement” into a suitable form. A piezoelectric accelerometer senses acceleration and converts it into an electric charge, an electromagnetic tachometer senses velocity and converts it into a voltage, and a shaft encoder senses a rotation and converts it into a sequence of voltage pulses. Hence, the terms *sensor* and *transducer* are used interchangeably to denote a sensor-transducer unit. The signal that is generated in this manner may need conditioning before feeding into the controller. For example, the charge signal from a piezoelectric accelerometer has to be converted to a voltage signal of appropriate level using a charge amplifier, and then it has to be digitized using an analog-to-digital converter (ADC) for use in a digital controller. Furthermore, filtering may be needed to remove measurement noise. Hence, signal conditioning is usually needed between the sensor and the controller as well as between the controller and the actuator. External power is required to operate active sensors (e.g., potentiometer) whereas passive sensors (e.g., electromagnetic tachometer) employ self-generation and do not need an external power source. External power may be needed for conditioning the sensor signals. Finally, as indicated in [Figure 32.32](#), a vibrating system may have unknown disturbance excitations, which can make the control problem particularly difficult. Removing such excitations at the source level through proper design or vibration isolation is desirable, as discussed above. However, in the context of control, if these disturbances can be measured or some information about them is available, then they can be compensated for within the controller itself. This is, in fact, the approach of feedforward control.

32.9.2 Control Techniques

The purpose of a vibration controller is to excite (activate) a vibrating system in order to control its vibration response in a desired manner. In the present context of active feedback control, the controller uses measured response signals and compares them with their desired values in its task of determining an

appropriate action. The relationship that generates the control action from a measured response (and a desired value for the response) is called a *control law*. Sometimes, a *compensator* (analog or digital, hardware or software) is employed to improve the system performance or to enhance the controller so that the task of control is easier. However, for our purpose, we may consider a compensator as an integral part of the controller and thus a distinction between the two is not made.

Various control laws, both linear and nonlinear, have been developed for practical applications. Many of them are suitable in vibration control. A comprehensive presentation of all such control laws is outside the scope of this book. We will give several linear control laws that are common and representative of what is available. These techniques are based on a linear representation (linear model) of the vibrating system (plant). Even when the overall operating range of a plant (e.g., robotic manipulator) is nonlinear, it is often possible to linearize the vibration response (e.g., link vibrations and joint vibrations of a robot) about a reference configuration (e.g., robot trajectory). These linear control techniques would be still suitable even though the overall dynamics of the system is nonlinear.

32.9.2.1 State-Space Models

In applying many types of control techniques, it is convenient to represent the vibrating system (plant) by a state-space model. This is simply a set of ordinary first-order differential equations, which could be coupled or nonlinear, and could have time-varying parameters (time-variant models). Here, we limit our discussion to linear and time-invariant state-space models. Such a model is expressed as

$$\dot{\mathbf{x}} = \mathbf{Ax} + \mathbf{Bu} \quad (32.131)$$

$$\mathbf{y} = \mathbf{Cx} + \mathbf{Du} \quad (32.132)$$

where

$\mathbf{x} = [x_1, x_2, \dots, x_n]^T$ = state vector (n th order column)

$\mathbf{u} = [u_1, u_2, \dots, u_r]^T$ = input vector (r th order column)

$\mathbf{y} = [y_1, y_2, \dots, y_m]^T$ = output vector (m th order column)

\mathbf{A} = system matrix ($n \times n$ square)

\mathbf{B} = input gain matrix ($n \times r$)

\mathbf{C} = measurement gain matrix ($m \times n$)

\mathbf{D} = feedforward gain matrix ($m \times r$)

Usually, for vibrating systems, it is possible to make $\mathbf{D} = 0$, and hence we will drop this matrix in the sequel. Furthermore, although a state variable x_i need not have a direct physical meaning, an output variable y_j should have some physical meaning and, in typical situations, should be measurable as well. The input variables are the “control variables” and are used for controlling the system (plant). The output variables are the “controlled variables,” which correspond to the system response and are measured for feedback control.

It can be verified that the eigenvalues of the system matrix \mathbf{A} occur in complex conjugates of the form $-\zeta_i\omega_i \pm j\sqrt{1 - \zeta_i^2}\omega_i$ in the damped oscillatory case, or as $\pm j\omega_i$ in the undamped case, where ω_i is the i th natural frequency of the system and ζ_i is the corresponding damping ratio (of the i th mode). The mathematical verification requires some linear algebra. An intuitive verification can be made since Equation 32.131 is an equivalent model for a system having the traditional mass–spring–damper model

$$\mathbf{M}\ddot{\mathbf{y}} + \mathbf{C}\dot{\mathbf{y}} + \mathbf{K}\mathbf{y} = \mathbf{f}(t) \quad (32.133)$$

where \mathbf{M} = mass matrix, \mathbf{C} = damping matrix, \mathbf{K} = stiffness matrix, $\mathbf{f}(t)$ = forcing input vector, and \mathbf{y} = displacement response vector. Where both models (Equation 32.131 and Equation 32.133), are equivalent they should have the same characteristic equation, which by its roots determines the natural frequencies and modal damping ratios. This is the case because we are simply looking at two different mathematical representations of the same system. Hence, the parameters of its dynamics, such as ω_i and ζ_i , should remain unchanged. In fact, the state-space mode (Equation 32.131) is not unique, and different versions of state vectors and corresponding models are possible. Of course, all of them should have the

same characteristics polynomial (and hence, the same ω_i and ζ_i). One such state-space model may be derived from Equation 32.133 as follows:

Define the state vector as

$$\mathbf{x} = \begin{bmatrix} y \\ \dot{y} \end{bmatrix} \text{ and } \mathbf{u} = \mathbf{f}(t) \quad (32.134)$$

Since (for nonsingular \mathbf{M} , as required), Equation 32.133 may be written as

$$\ddot{\mathbf{y}} = -\mathbf{M}^{-1}\mathbf{K}\mathbf{y} - \mathbf{M}^{-1}\mathbf{C}\dot{\mathbf{y}} + \mathbf{M}^{-1}\mathbf{f}(t) \quad (32.135)$$

we have

$$\dot{\mathbf{x}} = \begin{bmatrix} \mathbf{0} & \mathbf{I} \\ -\mathbf{M}^{-1}\mathbf{K} & -\mathbf{M}^{-1}\mathbf{C} \end{bmatrix} \mathbf{x} + \begin{bmatrix} \mathbf{0} \\ \mathbf{M}^{-1} \end{bmatrix} \mathbf{u} \quad (32.136)$$

This is a state-space model that is equivalent to the conventional model (Equation 32.133), and can be shown to have the same characteristic equation. The development of a state-space model for a vibrating system can be illustrated using an example.

Example 32.10

Consider a machine mounted on a support structure, modeled as in Figure 32.33. Using the excitation forces $f_1(t)$ and $f_2(t)$ as the inputs and the displacements y_1 and y_2 of the masses m_1 and m_2 as the outputs, develop a state-space model for this system.

Solution

Assume that the displacements are measured from the static equilibrium positions of the masses. Hence, the gravity forces do not enter into the formulation. Newton's Second law is applied to the two masses; thus

$$m_1\ddot{y}_1 = f_1 - k_1(y_1 - y_2) - b_1(\dot{y}_1 - \dot{y}_2)$$

$$m_2\ddot{y}_2 = f_2 - k_1(y_2 - y_1) - b_1(\dot{y}_2 - \dot{y}_1) - k_2y_2 - b_2\dot{y}_2$$

The following state variables are defined:

$$x_1 = y_1; \quad x_2 = \dot{y}_1; \quad x_3 = y_2; \quad x_4 = \dot{y}_2$$

Also, the input vector is $\mathbf{u} = [u_1 \ u_2]^T$ and the output vector is $\mathbf{y} = [y_1 \ y_2]^T$. Then, we have

$$\dot{x}_1 = x_2$$

$$m_1\dot{x}_2 = u_1 - k_1(x_1 - x_3) - b_1(x_2 - x_4)$$

$$\dot{x}_3 = x_4$$

$$m_2\dot{x}_4 = u_2 - k_1(x_3 - x_1) - b_1(x_4 - x_2) - k_2x_3 - b_2x_4$$

FIGURE 32.33 A model of a machine mounted on support structure.

Accordingly, the state-space model is given by Equation 32.131 and Equation 32.132 with

$$\mathbf{A} = \begin{bmatrix} 0 & 1 & 0 & 0 \\ -k_1/m_1 & -b_1/m_1 & k_1/m_1 & b_1/m_1 \\ 0 & 0 & 0 & 1 \\ k_1/m_2 & b_1/m_2 & (k_1 + k_2)/m_2 & (b_1 + b_2)/m_2 \end{bmatrix}, \quad \mathbf{B} = \begin{bmatrix} 0 & 0 \\ 1/m_1 & 0 \\ 0 & 0 \\ 0 & 1/m_2 \end{bmatrix},$$

$$\mathbf{C} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix}, \quad \text{and } \mathbf{D} = 0$$

Also, note that the system can be expressed as

$$\begin{bmatrix} m_1 & 0 \\ 0 & m_2 \end{bmatrix} \ddot{\mathbf{y}} + \begin{bmatrix} b_1 & -b_1 \\ -b_1 & (b_1 + b_2) \end{bmatrix} \dot{\mathbf{y}} + \begin{bmatrix} k_1 & -k_1 \\ -k_1 & (k_1 + k_2) \end{bmatrix} \mathbf{y} = \mathbf{f}(t)$$

Its characteristic equation may be expressed as the determinant equation:

$$\det \begin{bmatrix} m_1 s^2 + b_1 s + k_1 & -b_1 s - k_1 \\ -b_1 s - k_1 & m_2 s^2 + (b_1 + b_2)s + (k_1 + k_2) \end{bmatrix} = 0$$

It can be verified through direct expansion of the determinants that this equation is equivalent to the characteristic equation of the matrix \mathbf{A} , as given by $\det(\lambda \mathbf{I} - \mathbf{A}) = 0$, or

$$\det \begin{bmatrix} \lambda & -1 & 0 & 0 \\ k_1/m_1 & \lambda + b_1/m_1 & -k_1/m_1 & -b_1/m_1 \\ 0 & 0 & \lambda & -1 \\ k_1/m_2 & -b_1/m_2 & -(k_1 + k_2)/m_2 & \lambda - (b_1 + b_2)/m_2 \end{bmatrix} = 0$$

Note that, in the present context, x and y represent the vibration response of the plant and the control objective is to reduce these to zero. We will give some common control techniques that can achieve this goal.

32.9.2.2 Position and Velocity Feedback

In this technique, the position and velocity of each DoF is measured and fed into the system with sign reversal (negative feedback) and amplification by a constant gain. Because velocity is the derivative of position and since the gains are constant (i.e., proportional), this method falls into the general category of proportional-plus-derivative (PD or PPD) control. In this approach, it is tacitly assumed that the degrees of freedom are uncoupled. Then, control gains are chosen so that the DoF in the controlled system are nearly uncoupled, thereby justifying the original assumption. To explain this control method, suppose that a DoF of a vibrating system is represented by

$$m\ddot{y} + b\dot{y} + ky = u(t) \quad (32.137)$$

where y is the displacement (position) of the DoF and u is the excitation input that is applied. Now suppose that u is generated according to the (active) control law

$$u = -k_c y - b_c \dot{y} + u_r \quad (32.138)$$

where k_c is the position feedback gain and b_c is the velocity feedback gain. The implication here is that the position y and the velocity \dot{y} are measured and fed into the controller which in turn generates u according to Equation 32.138. Also, u_r is some reference input that is provided externally to the controller.

Then, substituting Equation 32.138 into Equation 32.137, we obtain

$$m\ddot{y} + (b + b_c)\dot{y} + (k + k_c)y = u_r \quad (32.139)$$

The closed-loop system (the controlled system) now behaves according to Equation 32.139. The control gains b_c and k_c can be chosen arbitrarily (subject to the limitations of the physical controller, signal conditioning circuitry, the actuator, etc.) and may even be negative. In particular, by increasing b_c , the damping of the system can be increased. Similarly, by increasing k_c the stiffness (and the natural frequency) of the system can be increased. Even though a passive spring and damper with stiffness k_c and damping constant b_c can accomplish the same task, once the devices are chosen it is not possible to conveniently change their parameters. Furthermore, it will not be possible to make k_c or b_c negative in this case of passive physical devices. The method of PPD control is simple and straightforward, but the assumptions of linear uncoupled DoF place a limitation on its general use.

32.9.2.3 Linear Quadratic Regulator Control

This is an optimal control technique. Consider a vibrating system that is represented by the linear state-space model:

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u} \quad (32.131)$$

Assume that all the states \mathbf{x} are measurable and all the system modes are controllable. Then, we use the constant-gain feedback control law:

$$\mathbf{u} = \mathbf{K}\mathbf{x} \quad (32.140)$$

The choice of parameter values for the feedback gain matrix \mathbf{K} is infinite. Therefore, we can use this freedom to minimize the cost function:

$$J = \frac{1}{2} \int_t^\infty [\mathbf{x}^T \mathbf{Q} \mathbf{x} + \mathbf{u}^T \mathbf{R} \mathbf{u}] d\tau \quad (32.141)$$

This is the time integral of a quadratic function in both state and input variables, and the optimization goal may be interpreted as bringing \mathbf{x} down to zero (regulating \mathbf{x} to 0), but without spending a rather high control effort. Hence, the name linear quadratic regulation (LQR). In addition, \mathbf{Q} and \mathbf{R} are weighting matrices, with the former being at least positive semidefinite and the latter positive definite. Typically, \mathbf{Q} and \mathbf{R} chosen as diagonal matrices with positive diagonal elements whose magnitudes are determined by the degree of relative emphasis that should be given to various elements of \mathbf{x} and \mathbf{u} . It is well known that \mathbf{K} that minimizes the cost function (Equation 32.141) is given by

$$\mathbf{K} = -\mathbf{R}^{-1} \mathbf{B}^T \mathbf{K}_r \quad (32.142)$$

where \mathbf{K}_r is the positive-definite solution of the matrix Riccati algebraic equation

$$\mathbf{K}_r \mathbf{A} + \mathbf{A}^T \mathbf{K}_r - \mathbf{K}_r \mathbf{B} \mathbf{R}^{-1} \mathbf{B}^T \mathbf{K}_r + \mathbf{Q} = 0 \quad (32.143)$$

It is also known that the resulting closed-loop control system is stable. Furthermore, the minimum (optimal) value of the cost function (Equation 32.141) is given by

$$J_m = \frac{1}{2} \mathbf{x}^T \mathbf{K}_r \mathbf{x} \quad (32.144)$$

where \mathbf{x} is the present value of the state vector. Major computational burden of the LQR method is in the solution (Equation 32.143). Other limitations of the technique arise due to the need to measure all the state variables (which may be relaxed to some extent). Although stability of the controlled system is guaranteed, the level of stability that is achieved (i.e., stability margin or the level of modal damping) cannot be directly specified. Further, robustness of the control system in the presence of model errors, unknown disturbances and so on, may be questionable. Besides, the cost function incorporates an integral over an infinite time duration, which does not typically reflect the practical requirement of rapid vibration control.

32.9.2.4 Modal Control

The LQR control technique has the serious limitation of not being able to directly achieve specified levels of modal damping, which may be an important goal in vibration control. The method of modal control that accomplishes this objective is *pole placement*, where poles (eigenvalues) of the controlled system are placed at specified values. Specifically, consider the plant (Equation 32.131) and the feedback control law (Equation 32.140). Then, the closed-loop system is given by

$$\dot{\mathbf{x}} = (\mathbf{A} + \mathbf{BK})\mathbf{x} \quad (32.145)$$

It is well known that if the plant (\mathbf{A} , \mathbf{B}) is controllable, then a control gain matrix \mathbf{K} can be chosen that will arbitrarily place the eigenvalues of the closed-loop system matrix $\mathbf{A} + \mathbf{BK}$. Based on the given assumptions, the modal control technique assigns not only the modal damping but also the damped natural frequencies at specified values. The assumptions given above are quite stringent but they can be relaxed to some degree. However, a shortcoming of this method is the fact that it does not place a restriction on the control effort, for example, as the LQR technique does, in achieving a specified level of modal control.

32.10 Control of Beam Vibrations

Beam is a distributed-parameter system, which in theory has an infinite number of modes of vibration with associated mode shapes and natural frequencies. In this sense, it is an “infinite order” system with infinite DoF. Hence, the computation of modal quantities and associated control inputs can be quite complex. Fortunately, however, just a few modes may be retained in a dynamic model without sacrificing a great deal of accuracy, thereby facilitating simpler control. Some concepts of controlling vibrations in a beam are considered in this section. The present treatment is intended as an illustration of the relevant techniques and is not meant to be exhaustive. These techniques may be extended to other types of continuous system such as beams with different boundary conditions and plates. Because the control techniques that were outlined previously depend on a model, we will first illustrate the procedure of obtaining a state-space model for a beam.

32.10.1 State-Space Model of Beam Dynamics

Consider a Bernoulli–Euler-type beam with Kelvin–Voigt-type internal (material) damping. The beam equation may be expressed as

$$ELv(x, t) + E^*L \frac{\partial v(x, t)}{\partial t} + \rho A(x) \frac{\partial^2 v(x, t)}{\partial t^2} = f(x, t) \quad (32.146)$$

in which L is the partial differential operator given by

$$L = \frac{\partial^2 I(x)}{\partial x^2} \frac{\partial^2}{\partial x^2} \quad (32.147)$$

and

$f(x, t)$ = distributed force excitation per unit length of the beam

$v(x, t)$ = displacement response at location x along the beam at time t

$I(x)$ = second moment of area of the beam cross section about the neutral axis

E = Young’s modulus of the beam material

E^* = Kelvin–Voigt material damping parameter

Note that a general beam with nonuniform characteristics is assumed and, hence, the variations of $I(x)$ and $\rho A(x)$ with x are retained in the formulation.

Using the approach of modal expansion, the response of the beam may be expressed by

$$v(x, t) = \sum_{i=1}^{\infty} Y_i(x) q_i(t) \quad (32.148)$$

where $Y_i(x)$ is the i th mode shape of the beam, which satisfies

$$LY_i(x) = \frac{\rho A(x)}{E} \omega_i^2 Y_i(x) \quad (32.149)$$

and ω_i is the i th undamped natural frequency. The orthogonality condition for this general example of a nonuniform beam is

$$\int_{x=0}^l \rho A Y_i Y_j dx = \begin{cases} 0 & \text{for } i \neq j \\ \alpha_j & \text{for } i = j \end{cases} \quad (32.150)$$

Suppose that the forcing excitation on the beam is a set of r point forces $u_k(t)$ located at $x = l_k$, $k = 1, 2, \dots, r$. Then, we have

$$f(x, t) = \sum_{k=1}^r u_k \delta(x - l_k) \quad (32.151)$$

where $\delta(x - l_i)$ is the *Dirac delta function*. Now, substitute Equation 32.148 and Equation 32.151 into Equation 32.146, use Equation 32.149, multiply throughout by $Y_j(x)$, and integrate over $x[0, l]$, using Equation 32.150. This gives

$$\ddot{q}_j + \gamma_j \dot{q}_j(t) + \omega_j^2 q_j = \frac{1}{\alpha_j} \sum_{k=1}^r u_k Y_j(l_k) \quad \text{for } j = 1, 2, \dots \quad (32.152)$$

where

$$\gamma_j = \frac{E^*}{E} \omega_j^2 \quad (32.153)$$

Now, define the state variables x_j according to

$$x_{2j-1} = \omega_j q_j, \quad x_{2j} = \dot{q}_j \quad \text{for } j = 1, 2, \dots \quad (32.154)$$

Assuming that only the first m modes are retained in the expansion, we then have the state equations

$$\dot{x}_{2j-1} = \omega_j x_{2j}, \quad \dot{x}_{2j} = -\omega_j x_{2j-1} - \gamma_j x_{2j} + \frac{1}{\alpha_j} \sum_{k=1}^r u_k Y_j(l_k) \quad \text{for } j = 1, 2, \dots, m \quad (32.155)$$

This can be put in the matrix-vector form of a state-space model

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u} \quad (32.131)$$

where

$$\mathbf{A} = \begin{bmatrix} 0 & \omega_1 & & & 0 \\ -\omega_1 & -\gamma_1 & & & \\ & & \ddots & & \\ & & & 0 & \omega_m \\ 0 & & & -\omega_m & -\gamma_m \end{bmatrix}_{n \times n} \quad (32.156)$$

and

$$\mathbf{B} = \begin{bmatrix} 0 & & 0 \\ Y_1(l_1)/\alpha_1 & \cdots & Y_1(l_r)/\alpha_1 \\ \vdots & & \vdots \\ 0 & & 0 \\ Y_m(l_1)/\alpha_m & \cdots & Y_m(l_r)/\alpha_m \end{bmatrix}_{n \times r} \quad (32.157)$$

with $n = 2m$, where m is the number of modes retained in the modal expansion. Note that, as the number of modes used in this model increases, both the accuracy and the computational effort that is needed for the control problem increase because of the proportional increase of the system order. At some point, the potential improvement in accuracy by further increasing the model size would be insignificant in comparison with added computational burden. Hence, a balance must be struck in this tradeoff.

32.10.2 Control Problem

The state-space model (Equation 32.131) for the beam dynamics, with matrices (Equation 32.156 and Equation 32.157), is known to be *controllable*. Hence, it is possible to determine a constant-gain feedback controller $\mathbf{u} = \mathbf{K}\mathbf{x}$ that minimizes a quadratic-integral cost function of the form in Equation 32.141. Also, a similar controller can be determined that places the eigenvalues of the system at specified locations thereby achieving not only specified levels of modal damping but also a specified set of natural frequencies. However, there is a practical obstacle to achieving such an active controller. Note that, in the model given in Equation 32.156 and Equation 32.157, the state variables are proportional to the modal variables q_i and their time derivatives \dot{q}_i . They are not directly measurable. However, the displacements and velocities at a set of discrete locations along the beam can usually be measured. Let these locations (s) be denoted by p_1, p_2, \dots, p_s . Thus, in view of the modal expansion (Equation 32.148), the measurements can be expressed as

$$v(p_j, t) = \sum_{i=1}^m Y_i(p_j)q_i(t), \quad \dot{v}(p_j, t) = \sum_{i=1}^m Y_i(p_j)\dot{q}_i(t) \quad \text{for } j = 1, 2, \dots, s \quad (32.158)$$

Now, define the output (measurement) vector \mathbf{y} according to

$$\mathbf{y} = [v(p_1, t), \dot{v}(p_1, t), \dots, v(p_s, t), \dot{v}(p_s, t)]^T \quad (32.159)$$

In view of Equation 32.158 and the definitions of the state variable in Equation 32.154, we can write

$$\mathbf{y} = \mathbf{C}\mathbf{x} \quad (32.160)$$

with

$$\mathbf{C} = \begin{bmatrix} Y_1(p_1)/\omega_1 & 0 & \cdots & Y_m(p_1)/\omega_m & 0 \\ 0 & Y_1(p_1) & \cdots & 0 & Y_m(p_1) \\ \vdots & \vdots & \cdots & \vdots & \vdots \\ Y_1(p_s)/\omega_1 & 0 & \cdots & Y_m(p_s)/\omega_m & 0 \\ 0 & Y_1(p_s) & \cdots & 0 & Y_m(p_s) \end{bmatrix}_{2s \times n} \quad (32.161)$$

Hence, an active controller is possible of the form:

$$\mathbf{u} = \mathbf{H}\mathbf{y} \quad (32.162)$$

which is an output feedback controller. Therefore, in view of Equation 32.160, we have

$$\mathbf{u} = \mathbf{H}\mathbf{C}\mathbf{x} \quad (32.163)$$

This is not the same as complete state feedback $\mathbf{u} = \mathbf{K}\mathbf{x}$ where \mathbf{K} can take any real value (and, hence, the LQR solution in Equation 32.142 and the complete pole placement solution cannot be applied directly). In Equation 32.163, only \mathbf{H} can be arbitrarily chosen, and \mathbf{C} is completely determined according to Equation 32.161. The resulting product $\mathbf{H}\mathbf{C}$ will not usually correspond to either the LQR solution or the complete pole assignment solution. Still, the output feedback controller in Equation 32.162 can provide a satisfactory performance. However, a sufficient number of displacement and velocity sensors (s) have to be used in conjunction with a sufficient number of actuators (r) for active control. This will increase the system complexity and cost. Furthermore, due to added components and their active nature, the reliability of fault-free operation may degrade somewhat. A satisfactory alternative would be to use passive control devices such as dampers and dynamic absorbers, which is illustrated below. Note that in the matrices \mathbf{B} and \mathbf{C} given by Equation 32.157 and Equation 32.161, both the actuator locations l_i and the sensor locations p_j are variable. Hence, there exists an additional design freedom (or optimization parameters) in selecting the sensor and actuator locations in achieving satisfactory control.

32.10.3 Use of Linear Dampers

Now, consider the use of a discrete set of linear dampers for controlling beam vibration. Suppose that r linear dampers with damping constants b_j are placed at locations l_j , $j = 1, 2, \dots, r$ along the beam, as schematically shown in Figure 32.34. The damping forces are given by

$$u_j = -b_j \dot{v}(l_j, t) \quad \text{for } j = 1, 2, \dots, r \quad (32.164)$$

Substituting the truncated modal expansion (m modes)

$$\dot{v}(l_j, t) = \sum_{i=1}^m Y_i(l_j) \dot{q}_i(t) \quad (32.165)$$

we get, in view of Equation 32.154, the passive feedback control action

$$\mathbf{u} = -\mathbf{K}\mathbf{x} \quad (32.166)$$

with

$$\mathbf{K} = \begin{bmatrix} 0 & b_1 Y_1(l_1) & \cdots & 0 & b_1 Y_m(l_1) \\ \vdots & \vdots & \cdots & \vdots & \vdots \\ 0 & b_r Y_1(l_r) & \cdots & 0 & b_r Y_m(l_r) \end{bmatrix}_{r \times n} \quad (32.167)$$

By substituting Equation 32.166 into Equation 32.131, we have the closed-loop system equation

$$\dot{\mathbf{x}} = (\mathbf{A} - \mathbf{F})\mathbf{x} = \mathbf{A}_c \mathbf{x} \quad (32.168)$$

FIGURE 32.34 Use of linear dampers in beam vibration control.

where $\mathbf{F} = \mathbf{BK}$ and is given by

$$\mathbf{F} = \begin{bmatrix} 0 & 0 & \cdots & 0 & 0 \\ 0 & \sum b_i Y_{11}(l_i)/\alpha_1 & \cdots & 0 & \sum b_i Y_{1m}(l_i)/\alpha_1 \\ \vdots & \vdots & \cdots & \vdots & \vdots \\ 0 & 0 & \cdots & 0 & 0 \\ 0 & \sum b_i Y_{m1}(l_i)/\alpha_m & \cdots & 0 & \sum b_i Y_{mm}(l_i)/\alpha_m \end{bmatrix}_{n \times n} \quad (32.169)$$

with

$$Y_{ij}(x) = Y_i(x)Y_j(x) \quad (32.170)$$

In this case, the controller design involves the selection of the damping constants b_i and the damper locations l_j to achieve the required performance. This may be achieved, for example, by seeking to make the eigenvalues of the closed-loop system matrix \mathbf{A}_c reach a set of desired values. This achieves the desired modal damping and natural frequency characteristics. However, given that the structure of the \mathbf{F} matrix is fixed, as seen in Equation 32.169, this is not equivalent to complete state feedback (or complete output feedback). Hence, generally, it is not possible to place the poles of the system at the exact desired locations.

32.10.3.1 Design Example

In realizing a desirable modal response of a beam using a set of linear dampers, one may seek to minimize a cost function of the form

$$J = \text{Re}(\boldsymbol{\lambda} - \boldsymbol{\lambda}_d)^T \mathbf{Q} \text{Re}(\boldsymbol{\lambda} - \boldsymbol{\lambda}_d) + \text{Im}(\boldsymbol{\lambda} - \boldsymbol{\lambda}_d)^T \mathbf{R}(\boldsymbol{\lambda} - \boldsymbol{\lambda}_d) \quad (32.171)$$

where $\boldsymbol{\lambda}$ are the actual eigenvalues of the closed-loop system matrix (\mathbf{A}_c), and $\boldsymbol{\lambda}_d$ are the desired eigenvalues that will give the required modal performance (damping ratios and natural frequencies). “Re” denotes the real part and “Im” denotes the imaginary part. Weighting matrices \mathbf{Q} and \mathbf{R} , which are real and diagonal with positive diagonal elements, should be chosen to relatively weight various eigenvalues. This allows the emphasis of some eigenvalues over others, with real parts and the imaginary parts weighting separately.

Various computational algorithms are available for minimizing the cost function (Equation 32.171). Although the precise details are beyond the scope of this book, we will present an example result. Consider a uniform simply supported 12×5 American Standard beam, with the following pertinent specifications: $E = 2 \times 10^8$ kPa (29×10^6 psi), $\rho A = 47$ kg/m (2.6 lb/in.), length $l = 15.2$ m (600 in.), $I = 9 \times 10^{-5}$ m⁴ (215.8 in.⁴). The internal damping parameter for the j th mode of vibration is given by

$$E^*(\omega_j) = (g_2/\omega_j) + g_2 \quad (32.172)$$

in which ω_j is the j th undamped natural frequency given by

$$\omega_j = (j\pi/l)^2 \sqrt{EI/\rho A} \quad (32.173)$$

The numerical values used for the damping parameters are $g_1 = 88 \times 10^4$ kPa (12.5×10^4 psi) and $g_2 = 3.4 \times 10^4$ kPa s (5×10^3 psi s). For the present problem, $Y_i(x) = \sqrt{2}\sin(j\pi x/l)$ and $\alpha_j = \rho A l$ for all j .

First, ω_j and γ_j are computed using Equation 32.173 and Equation 32.153, respectively, along with Equation 32.172. Next, the open-loop system matrix \mathbf{A} is formed according to Equation 32.156 and its eigenvalues are computed. These are listed in Table 32.2, scaled to the first undamped natural frequency (ω_1). Note that in view of the very low levels of internal material damping of the beam, the actual natural frequencies, as given by the imaginary parts of the eigenvalues, are almost identical to the undamped natural frequencies.

Next, we attempt to place the real parts of the (scaled) eigenvalues all at -0.20 while exercising no constraint on the imaginary parts (i.e., damped natural frequencies) by using: (a) single damper, and

TABLE 32.2 Eigenvalues of the Open-Loop (Uncontrolled) Beam

Mode	Eigenvalue (rad/sec) (Multiply by 26.27)
1	$-0.000126 \pm j1.0$
2	$-0.000776 \pm j4.0$
3	$-0.002765 \pm j9.0$
4	$-0.007453 \pm j16.0$
5	$-0.016741 \pm j25.0$
6	$-0.033.75 \pm j36.0$

(b) two dampers. In the cost function (Equation 32.171), the first three modes are more heavily weighted than the remaining three. Initial values of the damper parameters are $b_1 = b_2 = 0.1$ lbf sec/in. (17.6 N sec/m) and the initial locations $l_1/l = 0.0$ and $l_2/l = 0.5$. At the end of the numerical optimization, using a modified gradient algorithm, the following optimized values were obtained:

1. Single-damper control

$$b_1 = 36.4 \text{ lbf sec/in. } (6.4 \times 10^3 \text{ N sec/m})$$

$$l_1/l = 0.3$$

The corresponding normalized eigenvalues (of the closed-loop system) are given in Table 32.3.

2. Two-damper control

$$b_1 = 22.8 \text{ lbf sec/in. } (4.0 \times 10^3 \text{ N sec/m})$$

$$b_2 = 12.1 \text{ lbf sec/in. } (2.1 \times 10^3 \text{ N sec/m})$$

$$l_1/l = 0.25, \quad l_2/l = 0.43$$

The corresponding normalized eigenvalues are given in Table 32.4.

It would be overly optimistic to expect perfect assignment all real parts at -0.2 . However, note that good levels of damping have been achieved for all modes except for Mode 3 in the single-damper control and Mode 4 in the two-damper control. In any event, because the contribution of the higher modes towards the overall response, is relatively smaller, it is found that the total response (e.g., at point $x = l/12$) is well damped in both cases of control.

Appendix 32A

MATLAB Control Systems Toolbox

32A.1 Introduction

Modeling, analysis, design, data acquisition, and control are important activities within the field of vibration. Computer software tools and environments are available for effectively carrying out, both at the learning level and at the professional application level. Several such environments and tools are commercially available.

MATLAB¹ is an interactive computer environment with a high-level language and tools for scientific and technical computation, modeling and simulation, design, and control of dynamic systems. SIMULINK¹ is a graphical environment for modeling, simulation, and analysis of dynamic systems, and is available as an extension to MATLAB. The Control Systems Toolbox of MATLAB is suitable in the analysis, design, and control of mechanical vibrating systems.

32A.2 MATLAB

MATLAB interactive computer environment is very useful in computational activities in Mechatronics. Computations involving scalars, vectors, and matrices can be carried out and the results can be

graphically displayed and printed. MATLAB toolboxes are available for performing specific tasks in a particular area of study such as control systems, fuzzy logic, neural network, data acquisition, image processing, signal processing, system identification, optimization, model predictive control, robust control, and statistics. User guides, Web-based help, and on-line help from the parent company, MathWorks, Inc., and various other sources. What is given here is a brief introduction to get started in MATLAB for tasks that are particularly related to Control Systems and Mechatronics.

32A.2.1 Computations

Mathematical computations can be done by using the MATLAB command window. Simply type in the computations against the MATLAB prompt “>>” as illustrated next.

32A.2.2 Arithmetic

An example of a simple computation using MATLAB is given below:

```
>> x = 2; y = - 3;
>> z = x^2 - x * y + 4
z =
    14
```

In the first line, we have assigned values 2 and 3 to two variables x and y . In the next line, the value of an algebraic function of these two variables is indicated. Then, MATLAB provides the answer as 14. Note that if you place a “;” at the end of the line, the answer will not be printed/displayed.

Table 32A.1 gives the symbols for common arithmetic operations used in MATLAB. Following example shows the solution of the quadratic equation $ax^2 + bx + c = 0$:

```
>> a = 2; b = 3; c = 4;
>> x = (-b + sqrt(b^2 - 4*a*c))/(2*a)
x =
- 0.7500 + 1.1990i
```

The answer is complex, where i denotes $\sqrt{-1}$. Note that the function `sqrt()` is used, which provides the positive root only. Some useful mathematical functions are given in [Table 32A.2](#).

32A.2.3 Arrays

An array may be specified by giving the start value, increment, and the end value limit. An example is given below.

```
>> x = (0.9:-0.1:0.42)
x =

    0.9000    0.8000    0.7000    0.6000    0.5000
```

TABLE 32A.1 MATLAB Arithmetic Operations	
Symbol	Operation
+	Addition
-	Subtraction
*	Multiplication
/	Division
^	Power

TABLE 32A.2 Useful Mathematical Functions in MATLAB

Function	Description
abs()	Absolute value/magnitude
acos()	Arc-cosine (inverse cosine)
acosh()	Arc-hyperbolic-cosine
asin()	Arc-sine
atan()	Arc-tan
cos()	Cosine
cosh()	Hyperbolic cosine
exp()	Exponential function
imag()	Imaginary part of a complex number
log()	Natural logarithm
log10()	Log to base 10 (common log)
real()	Real part of a complex number
sign()	Signum function
sin()	Sine
sqrt()	Positive square root
tan()	Tan function

Note that MATLAB is case sensitive.

The entire array may be manipulated. For example, all the elements are multiplied by π as below:

```
>> x = x*pi
x =
2.8274 2.5133 2.1991 1.8850 1.5708
```

The second and the fifth elements are obtained by

```
>> x([2 5])
ans =
2.5133 1.5708
```

Next, we form a new array y using x , and then plot the two arrays, as shown in Figure 32A.1:

```
>> y = sin(x);
>> plot(x,y)
```

A polynomial may be represented as an array of its coefficients. For example, the quadratic equation $ax^2 + bx + c = 0$ as given before, with $a = 2$, $b = 3$, and $c = 4$, may be solved using the function “roots” as below:

```
>> p = [2 3 4];
>> roots(p)
ans =
-0.7500 + 1.1990i
-0.7500 - 1.1990i
```

The answer is the same as we obtained before.

32A.2.4 Relational and Logical Operations

Useful relational operations in MATLAB are given in Table 32A.3. Basic logical operations are given in Table 32A.4.

FIGURE 32A.1 A plot using MATLAB.

TABLE 32A.3 Some Relational Operations

Operator	Description
<	Less than
<=	Less than or equal to
>	Greater than
>=	Greater than or equal to
==	Equal to
~=	Not equal to

TABLE 32A.4 Basic Logical Operations

Operator	Description
&	AND
	OR
~	NOT

Consider the following example:

```
>> x = (0:0.25:1)*pi
x =
    0    0.7854    1.5708    2.3562    3.1416
>> cos(x) > 0
ans =
    1     1     1     0     0
>> (cos(x) > 0)&(sin(x) > 0)
ans =
    0     1     1     0     0
```

In this example, first an array is computed. Then the cosine of each element is computed. Next it is checked whether the elements are positive. (A truth value of 1 is sent out if true and a truth value of 0 if false.) Finally, the “AND” operation is used to check whether both corresponding elements of two arrays are positive.

32A.2.5 Linear Algebra

MATLAB can perform various computations with vectors and matrices (see [Appendix 3A](#) and [Appendix 6A](#)). Some basic illustrations are given here.

A vector or a matrix may be specified by assigning values to its elements. Consider the following example:

```
>> b = [ 1.5  -2];
>> A = [2   1;  -1  1];
>> b = b'
b =
    1.5000
   -2.0000
>> x = inv(A) * b
x =
    1.1667
   -0.8333
```

In this example, first a second-order row vector and 2 × 2 matrix are defined. The row vector is transposed to get a column vector. Finally the matrix–vector equation **Ax = b** is solved according to **x = A⁻¹b**. The determinant and the eigenvalues of **A** are determined by

TABLE 32A.5 Some Matrix Operations in MATLAB

Operation	Description
+	Addition
−	Subtraction
*	Multiplication
/	Division
^	Power
'	Transpose

TABLE 32A.6 Useful Matrix Functions in MATLAB

Function	Description
det()	Determinant
inv()	Inverse
eig()	Eigenvalues
[,] = eig()	Eigenvectors and eigenvalues

```
>> det(A)
ans =
    3
>> eig(A)
ans =
    1.5000 + 0.8660i
    1.5000 - 0.8660i
```

Both eigenvectors and eigenvalues of **A** computed as

```
>> [V,P] = eig(A)
V =
    0.7071    0.7071
   -0.3536 + 0.6124i   -0.3536 - 0.6124i
P =
    1.5000 + 0.8660i    0
    0    1.5000 - 0.8660i
```

Here, the symbol **V** is used to denote the matrix of eigenvectors. The symbol **P** is used to denote the diagonal matrix whose diagonal elements are the eigenvalues.

Useful matrix operations in MATLAB are given in Table 32A.5 and several matrix functions are given in Table 32A.6.

32A.2.6 M-Files

The MATLAB commands have to be keyed in on the command window, one by one. When several commands are needed to carry out a task, the required effort can be tedious. Instead, the necessary commands can be placed in a text file, edited as appropriate (using text editor), which MATLAB can use to execute the complete task. Such a file is called an M-file. The file name must have the extension “m” in the form *filename.m*. A toolbox is a collection of such files, for use in a particular application area (e.g., control systems, fuzzy logic). Then, by keying in the M-file name at the MATLAB command prompt, the file will be executed. The necessary data values for executing the file have to be assigned beforehand.

32A.3 Control Systems Toolbox

There are several toolboxes with MATLAB, which can be used to analyze, compute, simulate, and design control problems. Both time-domain representations and frequency-domain representations can be

used. Also, both classical and modern control problems can be handled. The application is illustrated here through several control problems.

32A.3.1 MATLAB Modern Control Examples

Several examples in modern control engineering are given now to illustrate the use of MATLAB in control.

32A.3.1.1 Pole Placement of a Third-Order Plant

A mechanical plant is given by the input–output differential equation $\ddot{x} + \dot{x} = u$, where u is the input and x is the output. Determine a feedback law that will yield approximately a simple oscillator with a damped natural frequency of 1 unit and a damping ratio of $1/\sqrt{2}$.

To solve this problem, first we define the state variables as $x_1 = x$, $x_2 = \dot{x}_1$, and $x_3 = \dot{x}_2$. The corresponding state-space model is

$$\dot{\mathbf{x}} = \begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \\ \dot{x}_3 \end{bmatrix} = \underbrace{\begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & -1 \end{bmatrix}}_{\mathbf{A}} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} + \underbrace{\begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix}}_{\mathbf{B}} u$$

$$y = \underbrace{[1 \quad 0 \quad 0]}_{\mathbf{C}} \mathbf{x}$$

The open-loop poles and zeros are obtained using the following MATLAB commands:

```
>> A = [0 1 0; 0 0 1; 0 0 -1];
>> B = [0; 0; 1];
>> C = [1 0 0];
>> D = [0];
>> sys_open = ss(A,B,C,D);
>> [nat_freq_open,damping_open,poles_open] = damp(sys_open)
>> pzmap(sys_open)
```

The open-loop poles are: $[0 \ 0 \ -1]^T$.

The step response of the open-loop system is obtained using the command:

```
>> step(sys_open)
```

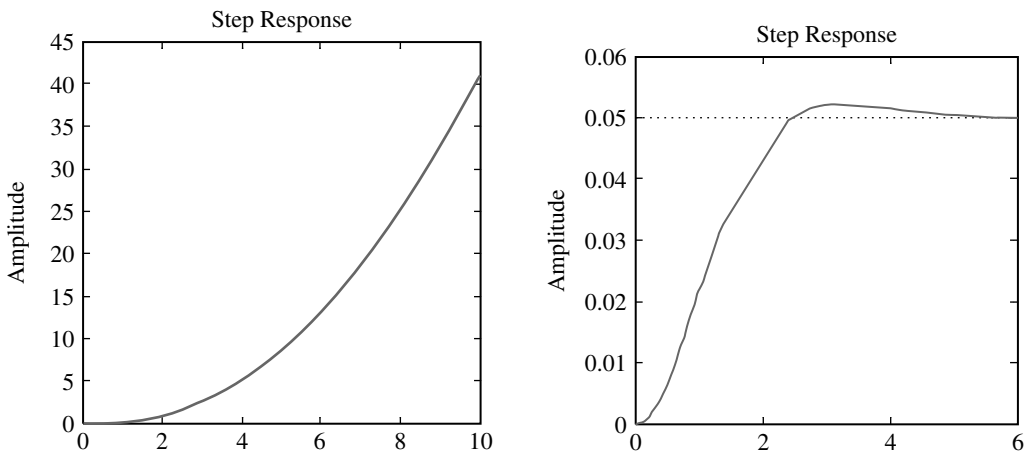

FIGURE 32A.2 (a) Step response of the open-loop system; (b) step response of the third-order system with pole-placement control.

The result is shown in Figure 32A.2(a). Clearly, the system is unstable.

With the desired damped natural frequency $\omega_d = 1$ and damping ratio $\zeta = 1/\sqrt{2}$, we get the undamped natural frequency $\omega_n = \sqrt{2}$ and, hence, $\zeta\omega_n = 1$. It follows that we need to place two poles at $-1 \pm j$. Also the third pole has to be far from these two on the left half plane (LHP); say, at -10 . The corresponding control gain K can be computed using the “place” command in MATLAB:

```
>> p = [-1 + j -1 - j -10];
>> K = place(A,B,p)
place:ndigits = 15
K =
    20.0000    22.0000    11.0000
```

The corresponding step response of the closed-loop system is shown in Figure 32A.2(b).

32A.3.1.2 Linear Quadratic Regulator for a Third-Order Plant

For the third-order plant in the previous example, we design a linear quadratic regulator (LQR), which has a state feedback controller, using MATLAB Control Systems Toolbox. The MATLAB command $K = \text{lqr}(A,B,Q,R)$ computes the optimal gain matrix K such that the state-feedback law $\mathbf{u} = -K\mathbf{x}$ minimizes the quadratic cost function

$$J = \int_0^{\infty} (\mathbf{x}^T \mathbf{Q} \mathbf{x} + \mathbf{u}^T \mathbf{R} \mathbf{u}) dt$$

The weighting matrices \mathbf{Q} and \mathbf{R} are chosen to apply the desired weights to the various states and inputs. The MATLAB commands for designing the controller are

```
>> A = [0 1 0; 0 0 1; 0 0 -1];
>> B = [0; 0; 1];
>> C = [1 0 0];
>> D = [0];
>> Q = [2 0 0; 0 2 0; 0 0 2];
>> R = 2;
>> Klqr = lqr(A,B,Q,R)
>> lqr_closed = ss(A-B*Klqr,B,C,D);
>> step(lqr_closed)
```

The step response of the system with the designed LQR controller is shown in Figure 32A.3.

32A.3.1.3 Modal Analysis Example

Consider the two-DoF mechanical system shown in Figure 32A.4. We now solve the modal analysis problem using MATLAB, for the numerical values

$$\alpha = 0.5, \quad \beta = 0.5, \quad m = 1 \text{ kg}; \quad k = 1 \text{ N/m}$$

For the given mass matrix \mathbf{M} and the stiffness matrix \mathbf{K} , the solution steps for the alternative approach of modal analysis are

1. Determine $\mathbf{M}^{1/2}$ and $\mathbf{M}^{-1/2}$.
2. Solve for the eigenvalues λ and the eigenvectors Φ of $\mathbf{M}^{-1/2} \mathbf{K} \mathbf{M}^{-1/2}$. These eigenvalues are the squares of the natural frequencies of the original system.

FIGURE 32A.3 Step response of the third-order system with LQR control.

FIGURE 32A.4 A two-DoF system.

3. Determine the modal vectors ψ of the original system using the transformation $\psi = M^{-1/2}\phi$.

The program code is given below:

```
%Modal Analysis Example
clear;
m = 1.0;
k = 1.0;
M = [ m 0; 0 m/2 ];
K = [3/2 * k - k/2;
     - k/2 k/2];
M_sqrt = M^0.5;
M_s_inv = inv(M_sqrt);
lemda = eig(M_s_inv * K * M_s_inv);
[U,D] = eig(M_s_inv * K * M_s_inv);
V = M_s_inv * U;
disp('Natural frequencies')
fprintf('omega1 = %10.3f%14.3f\n',sqrt(lemda(2,1)));
fprintf('\n omega2 = %10.3f%14.3f\n',sqrt(lemda(1,1)));
fprintf('\n')
fprintf('\nMode shapes \n')
fprintf('First mode   Second Mode \n')
for i = 1:2
    fprintf('%10.3f%14.3f\n',V(i,2)/V(1,2),V(i,1)/V(1,1));
end
```

The necessary results are obtained as shown below:

```
>> Natural frequencies
omega1 = 1.414
omega2 = 0.707
```

Summary

The matrix perturbation theory for structural dynamic modification and sensitivity analysis is presented in this chapter. The theory covers a broad spectrum of subjects, specifically, matrix perturbation of real modes of complex structures and matrix perturbation of complex modes. The contents include nine sections. Section 33.2 provides the preliminaries to matrix perturbation and sensitivity analysis. Section 33.3 presents the matrix perturbation method including first-order and second-order perturbation. Section 33.4 presents methods for design sensitivity

analysis. In Section 33.5, high-accuracy modal superposition for sensitivity analysis of modes is given. Section 33.6 presents the sensitivity analysis of eigenvectors for free-free structures. In Section 33.7 and Section 33.8, matrix perturbations for repeated modes and closely spaced modes are discussed. In Section 33.9, the matrix perturbation approach for complex modes is presented.

33.1 Introduction

In modern engineering problems, the dynamic design of structures is becoming increasingly important. In order to achieve an optimal design, we repeatedly have to modify the structural parameters and solve the generalized eigenvalue problem. The iterative vibration analysis can be very tedious for large and complex structures. Therefore, it is necessary to seek a fast computation method for sensitivity analysis and reanalysis. The matrix perturbation method is an extremely useful tool for this purpose.

The matrix perturbation method is concerned with how the natural frequencies and modal vectors change if small modifications are imposed on the parameters of structures. Engineering problems often involve many small modifications in the structural parameters, such as material property variations, manufacturing errors, iterative design of structural parameters, design sensitivity analysis, random eigenvalue analysis, robustness analysis of control systems, and so on.

In this chapter, it is assumed that the reader has an undergraduate knowledge in vibration theory (see Chapter 1 to Chapter 5, and Chapter 14) and a working knowledge in the finite element method (see Chapter 9).

The contents of the chapter include the basic preliminaries: vibration equations of the finite element model, eigenvalue problem, modal vectors, orthogonality conditions, modal expansion theorem, and the power series expansion of eigensolutions. The chapter also covers such topics as: the perturbation method for distinct eigenvalues and corresponding eigenvectors; sensitivities of eigenvalues and eigenvectors; the high-accuracy modal superposition method for eigenvector derivatives; eigenvector derivatives for free-free structures; perturbation method for systems with repeated eigenvalues and close eigenvalues; and perturbation method of the complex modes of systems with real unsymmetric matrices.

33.2 Structural Dynamic Modification of Finite Element Model

The finite element method is an important tool to obtain numerical and computational solutions to problems in structural vibration analysis. By applying the finite element method to a structure, a discrete analysis model to idealize the continuum can be obtained. The finite equation of vibrations of a structure in the global coordinate system is

$$\mathbf{M}\ddot{\mathbf{q}} + \mathbf{C}\dot{\mathbf{q}} + \mathbf{K}\mathbf{q} = \mathbf{Q} \quad (33.1)$$

where \mathbf{M} , \mathbf{K} , and \mathbf{C} are the mass, stiffness, and damping matrices, respectively, $\ddot{\mathbf{q}}$, $\dot{\mathbf{q}}$, and \mathbf{q} are the acceleration, velocity, and displacement vectors, respectively, and \mathbf{Q} is the external load vector.

Neglecting the damping force and external load vector, Equation 33.1 becomes

$$\mathbf{M}\ddot{\mathbf{q}} + \mathbf{K}\mathbf{q} = \mathbf{0} \quad (33.2)$$

This is the natural vibration equation for the structure. Its solution (the natural vibration) is harmonic (see Chapter 30), and is given by

$$\mathbf{q} = \mathbf{u} \cos(\omega t - \varphi) \quad (33.3)$$

where \mathbf{u} is modal vector, and ω the natural frequency of the system. Substituting Equation 33.3 into Equation 33.2, the eigenproblem of structural vibration can be obtained as

$$\mathbf{K}\mathbf{u} = \lambda \mathbf{M}\mathbf{u} \quad (33.4)$$

where λ ($\lambda = \omega^2$) denote the eigenvalues of the system.

In structural vibration analysis, the natural frequencies and the corresponding modal vectors can be obtained by solving the eigenproblem (Equation 33.4). The solutions for n eigenvalues and corresponding eigenvectors satisfy

$$\mathbf{K}\mathbf{U} = \mathbf{M}\mathbf{U}\mathbf{\Lambda} \quad (33.5)$$

where \mathbf{U} , which is called the *modal matrix*, is an $(n \times n)$ matrix with its columns equal to the n eigenvectors, and $\mathbf{\Lambda}$ is an $(n \times n)$ diagonal matrix consisting of the corresponding eigenvalues as the diagonal elements; specifically

$$\mathbf{U} = [\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_n] \quad (33.6)$$

$$\mathbf{\Lambda} = \text{diag}(\lambda_i), \quad i = 1, 2, \dots, n \quad (33.7)$$

An important relation for eigenvectors is that of \mathbf{M} orthogonality and \mathbf{K} orthogonality; that is, we have

$$\mathbf{u}_i^T \mathbf{M} \mathbf{u}_j = \delta_{ij} \quad (33.8)$$

$$\mathbf{u}_i^T \mathbf{K} \mathbf{u}_j = \lambda_i \delta_{ij} \quad (33.9)$$

where δ_{ij} is the Kronecker delta. For n eigenpairs, Equation 33.8 and Equation 33.9 can be written as

$$\mathbf{U}^T \mathbf{M} \mathbf{U} = \mathbf{I} \quad (33.10)$$

$$\mathbf{U}^T \mathbf{K} \mathbf{U} = \mathbf{\Lambda} \quad (33.11)$$

Since the modal vectors are independent, an arbitrary displacement vector, \mathbf{u} , can be expressed as a linear combination of \mathbf{u}_i , $i = 1, 2, \dots, n$; that is

$$\mathbf{u} = \sum_{r=1}^n c_r \mathbf{u}_r = \mathbf{U} \mathbf{C} \quad (33.12)$$

where c_r is a constant. Each constant c_r can be determined by

$$c_r = \mathbf{u}_r^T \mathbf{M} \mathbf{u}, \quad r = 1, 2, \dots, n \quad (13.13)$$

This is known as the *expansion theorem*.

Suppose the physical parameter of a given structure is given a small modification. This will cause a small change in the matrices \mathbf{K}_0 and \mathbf{M}_0 ; that is

$$\mathbf{M} = \mathbf{M}_0 + \varepsilon \mathbf{M}_1, \quad \mathbf{K} = \mathbf{K}_0 + \varepsilon \mathbf{K}_1 \quad (33.14)$$

where ε is a small parameter, \mathbf{K}_0 and \mathbf{M}_0 are the original mass and stiffness matrices, respectively, and $\varepsilon \mathbf{M}_1$ and $\varepsilon \mathbf{K}_1$ are the corresponding modifications. It is obvious that if \mathbf{M}_0 and \mathbf{K}_0 are symmetric, the matrices \mathbf{M}_1 and \mathbf{K}_1 are also symmetric.

If $\varepsilon \mathbf{M}_1$ and $\varepsilon \mathbf{K}_1$ are small, the changes of eigenvalues and eigenvectors of the structure are also small. According to the matrix perturbation theory, the eigensolutions of Equation 33.4 can be expressed in the form of a power series in ε ; thus

$$\mathbf{u}_i = \mathbf{u}_{0i} + \varepsilon \mathbf{u}_{1i} + \varepsilon^2 \mathbf{u}_{2i} + \dots \quad (33.15)$$

$$\lambda_i = \lambda_{0i} + \varepsilon \lambda_{1i} + \varepsilon^2 \lambda_{2i} + \dots \quad (33.16)$$

where \mathbf{u}_{0i} and λ_{0i} are the eigensolutions of the original structure, λ_{1i} and λ_{2i} are the first- and the second-order perturbations of the eigenvalues, and \mathbf{u}_{1i} and \mathbf{u}_{2i} are the first- and the second-order perturbation of the eigenvectors.

Since the eigensolutions of the original structure, \mathbf{u}_{0i} and λ_{0i} , are known, only the first- and the second-order perturbations of the eigensolutions are required without solving Equation 33.4.

33.3 Perturbation Method of Vibration Modes

The perturbation methods of vibration modes are well developed (Fox and Kapoor, 1968; Rogers, 1977; Chen and Wada, 1979; Hu, 1987; Chen, 1993). In this section, it is assumed that all eigenvalues of the original structure are distinct.

33.3.1 First-Order Perturbation of Distinct Modes

According to the expansion theorem, the first-order perturbation, \mathbf{u}_{1i} , can be expanded by the modal vectors, \mathbf{u}_{0s} , of the original structure as

$$\mathbf{u}_{1i} = \sum_{s=1}^n c_{1s} \mathbf{u}_{0s} \quad (33.17)$$

where

$$c_{1s} = \frac{1}{\lambda_{0i} - \lambda_{0s}} (\mathbf{u}_{0s}^T \mathbf{K}_1 \mathbf{u}_{0i} - \lambda_{0i} \mathbf{u}_{0s}^T \mathbf{M}_1 \mathbf{u}_{0i}), \quad s \neq i \quad (33.18)$$

$$c_{1i} = -\frac{1}{2} \mathbf{u}_{0i}^T \mathbf{M}_1 \mathbf{u}_{0i} \quad (33.19)$$

The first-order perturbation of the eigenvalues is

$$\lambda_{1i} = \mathbf{u}_{0i}^T \mathbf{K}_1 \mathbf{u}_{0i} - \lambda_{0i} \mathbf{u}_{0i}^T \mathbf{M}_1 \mathbf{u}_{0i} \quad (33.20)$$

33.3.2 Second-Order Perturbation of Distinct Modes

If the parameter modification is fairly large, in order to obtain high computing accuracy, the second-order perturbation must be used. According to the expansion theorem, the second-order perturbation, \mathbf{u}_{2i} , can be expanded by the modal vectors, \mathbf{u}_{0s} , of the original structure as

$$\mathbf{u}_{2i} = \sum_{s=1}^n c_{2s} \mathbf{u}_{0s} \quad (33.21)$$

where

$$c_{2s} = \frac{1}{\lambda_{0i} - \lambda_{0s}} (\mathbf{u}_{0s}^T \mathbf{K}_1 \mathbf{u}_{1i} - \lambda_{0i} \mathbf{u}_{0s}^T \mathbf{M}_1 \mathbf{u}_{1i} - \lambda_{1i} \mathbf{u}_{0s}^T \mathbf{M}_0 \mathbf{u}_{1i} - \lambda_{1i} \mathbf{u}_{0s}^T \mathbf{M}_1 \mathbf{u}_{0i}), \quad s \neq i \quad (33.22)$$

$$c_{2i} = -\frac{1}{2} (\mathbf{u}_{1i}^T \mathbf{M}_0 \mathbf{u}_{1i} + \mathbf{u}_{0i}^T \mathbf{M}_1 \mathbf{u}_{1i} + \mathbf{u}_{1i}^T \mathbf{M}_1 \mathbf{u}_{0i}) \quad (33.23)$$

The second perturbation of the eigenvalues is

$$\lambda_{2i} = \mathbf{u}_{0i}^T \mathbf{K}_1 \mathbf{u}_{1i} - \lambda_{0i} \mathbf{u}_{0i}^T \mathbf{M}_1 \mathbf{u}_{1i} - \lambda_{1i} \mathbf{u}_{0i}^T \mathbf{M}_0 \mathbf{u}_{1i} - \lambda_{1i} \mathbf{u}_{0i}^T \mathbf{M}_1 \mathbf{u}_{0i} \quad (33.24)$$

33.3.3 Numerical Examples

As illustrations of the matrix perturbation method, several numerical examples are given now.

Example 33.1

Consider the five-degree-of-freedom (five-DoF) system shown in [Figure 33.1](#). The physical parameters are given as

$$m_1 = m_2 = m_3 = m_4 = 1.0, \quad m_5 = 0.5, \quad k_1 = k_2 = k_3 = k_4 = k_5 = 1.0$$

FIGURE 33.1 Mass–spring system for Example 33.1.

In order to study the computing accuracy of first- and second-order perturbations, let us assume that the fifth mass undergoes a decrement of 5 to 30%, and the stiffness of the first spring undergoes a decrement of 5 to 30%.

The computed results for the natural frequencies are presented in Table 33.1, in which the initial solutions mean the eigensolutions of the original structure.

6	391.1	393.7	0.66	392.06	0.24	319.35	0.06

As can be seen from the results, if the change of the structural parameter is 15%, the average change of the natural frequencies is 9.0%. Using the first-order perturbation, the average error of the frequencies is reduced to 1.32%.

If the change of the structural parameter is 30%, the average error of the natural frequencies is 18%. Using the first-order perturbation, the average error of natural frequencies is reduced to 1.6%.

The notation used in Table 33.1 and Table 33.2 is as follows:

- A: the exact solutions of the modified structure
- B: the initial solutions of the original structure
- C: percent error
- D: the first-order perturbation solutions
- E: the second-order perturbation solutions
- F: the percent errors of the initial solutions
- G: the percent errors of the first-order perturbation
- H: the percent errors of the second perturbation

Example 33.2

Consider a truss structure (as shown in Figure 33.2) with 20 rods. The cross section area of the second rod is changed from 1.0 to 2.0 cm². The results calculated are listed in Table 33.2.

FIGURE 33.2 Truss structure for Example 33.2.

Example 33.3

Consider a torsional vibration system with five disks, as shown in Figure 33.3. The physical parameters of the system are as follows:

- $I_1 = 10.78 \text{ kg cm sec}^2$
- $I_2 = 82.82 \text{ kg cm sec}^2$
- $I_3 = 14.27 \text{ kg cm sec}^2$
- $I_4 = 29.56 \text{ kg cm sec}^2$
- $I_5 = 21.66 \text{ kg cm sec}^2$
- $K_1 = 10.48 \times 10^4 \text{ kg cm/rad}$
- $K_2 = 34.30 \times 10^4 \text{ kg cm/rad}$
- $K_3 = 24.40 \times 10^4 \text{ kg cm/rad}$
- $K_4 = 40.60 \times 10^4 \text{ kg cm/rad}$

The corresponding constrained system is shown in Figure 33.3b, in which the hung stiffness is $K_5 = 4060 \text{ kg cm/rad}$.

The exact eigensolutions of the constrained system are taken as the initial results. Using matrix

perturbation, the eigensolutions of the free-free system can be obtained. The results are listed in Table 33.3 and Table 33.4.

The notation used in Table 33.3 is as follows:

- ω_0 : exact solution of the natural frequency of the free-free system (l/sec)
- ω'_0 : perturbation solutions of the natural frequency of the free-free system (l/sec)
- ω_x : natural frequency of the constrained system (l/sec)

$\varepsilon\omega_1 = \omega'_0 - \omega_x$ the perturbation of the natural frequency

$$\delta = \frac{|\omega_0 - \omega_x|}{\omega_0} \text{ (%)}$$

$$\delta' = \frac{|\omega_0 - \omega'_0|}{\omega_0} \text{ (%)}$$

The notation used in Table 33.4 is as follows:

- \mathbf{u}_0^i : exact solution of eigenvectors of the free–free system
- $\mathbf{u}_0^{i'}$: perturbation solution of eigenvectors of the free–free system
- \mathbf{u}_x^i : eigenvector of the constrained system
- $\epsilon \mathbf{u}_1^i$: first-order perturbation of eigenvectors

As can be seen from Table 33.3, the natural frequencies of the free–free system are increased by the hung elastic elements. For example, the frequency of the rigid mode is increased to 1.595950 (1/sec), and the frequency of the first elastic mode is increased by 0.8124%. By modifying the eigensolutions with the perturbation method, the frequency of the rigid mode is reduced to 0.079700 (1/sec), which is nearly equal to zero, and all the frequencies of the elastic modes become almost exact solutions. The results in Table 33.4 show that the mode shapes of the free–free system, $\mathbf{u}_0^{i'}$, are close to the exact solution, \mathbf{u}_0^i .

33.4 Design Sensitivity Analysis of Structural Vibration Modes

In the optimization of structural analysis, the design sensitivity analysis of eigenvalues and eigenvectors plays an essential role. The designer can use this information directly in an interactive computer-aided design procedure as a valuable guide. Significant work has been done in this area (Haug et al., 1985; Adelman and Haftka, 1986; Chen and Pan, 1986; Wang, 1991).

33.4.1 Direct Differential Method for Sensitivity Analysis

Design sensitivity analysis of eigenvalues and eigenvectors will reveal how the changes in some design parameters in the system affect the dynamic characteristics of the structure.

Let $\lambda_{i,j}$ and $\mathbf{u}_{i,j}$ denote the sensitivity of the eigenvalue, λ_i , and the eigenvector, \mathbf{u}_i , respectively, with respect to the design variables b_j ($j = 1, 2, \dots, L$), and let \mathbf{K}_j and \mathbf{M}_j denote the derivative of the stiffness and mass matrices, respectively, with respect to b_j . The design sensitivity of the eigenvalue is

$$\lambda_{i,j} = \mathbf{u}_i^T (\mathbf{K}_j - \lambda_i \mathbf{M}_j) \mathbf{u}_i \quad (33.25)$$

The sensitivity of the eigenvector, $\mathbf{u}_{i,j}$, can be expressed as the following series:

$$\mathbf{u}_{i,j} = \sum_{s=1}^n c_{ijs} \mathbf{u}_s \quad (33.26)$$

where

$$c_{ijs} = \frac{1}{\lambda_i - \lambda_s} \mathbf{u}_s^T (\mathbf{K}_j - \lambda_i \mathbf{M}_j) \mathbf{u}_i, \quad i \neq s, \quad i, s = 1, 2, \dots, n, \quad i \neq s \quad (33.27)$$

$$c_{iji} = -\frac{1}{2} \mathbf{u}_i^T \mathbf{M}_j \mathbf{u}_i \quad (33.28)$$

33.4.2 Perturbation Sensitivity Analysis

Let $\Delta \mathbf{K}$ and $\Delta \mathbf{M}$ denote the increments of the stiffness and the mass matrices resulting from an incremental change of the design variable, Δb_j , and let $\Delta \lambda_i$ and $\Delta \mathbf{u}_i$ denote the corresponding perturbations of the eigenvalue and eigenvector, respectively. The direct differential method of design sensitivity analysis of vibration modes can now be put into perturbation form, approximately as

$$\lambda_{i,j} = \frac{\Delta \lambda_i}{\Delta b_j} \quad (33.29)$$

$$\mathbf{u}_{i,j} = \frac{\Delta \mathbf{u}_i}{\Delta b_j} \quad (33.30)$$

where $\Delta\lambda_i$ and $\Delta\mathbf{u}_i$ can be evaluated by the perturbation formulas presented in this chapter. In practical analysis, the design variables could be the cross-sectional area of the truss members, bending moment of inertia, equivalent torsional moment of inertia of a beam, the thickness of a plate, or other variable. In some complex structures, a mass, m_r , may be placed at a node point and moving in the direction of the r th DoF, or an elastic support with spring stiffness, K_r , may be placed at a certain node point. It is also possible that an elastic connector of stiffness, K_j , might exist between two components. They can also be considered as design variables. In finite element analysis, $\Delta\mathbf{K}$ and $\Delta\mathbf{M}$ are known to be the sum of the element increments, $\Delta\mathbf{K}^e$ and $\Delta\mathbf{M}^e$; thus

$$\Delta\mathbf{K} = \sum_e \Delta\mathbf{K}^e \quad (33.31)$$

$$\Delta\mathbf{M} = \sum_e \Delta\mathbf{M}^e \quad (33.32)$$

Hence, the sensitivity formulas of vibration modes as given above can be transformed into the finite element perturbation form (Chen and Pan, 1986)

$$\lambda_{i,j} = \frac{1}{\Delta b_j} \sum_e \bar{\mathbf{u}}_i^T (\Delta\mathbf{K}^e - \lambda_i \Delta\mathbf{M}^e) \bar{\mathbf{u}}_i \quad (33.33)$$

and

$$\mathbf{u}_{i,j} = \frac{1}{\Delta b_j} \sum_e \left(\sum_{\substack{s=1 \\ s \neq i}}^n \frac{1}{\lambda_i - \lambda_s} \bar{\mathbf{u}}_s^T (\Delta\mathbf{K}^e - \lambda_i \Delta\mathbf{M}^e) \bar{\mathbf{u}}_i \mathbf{u}_s - \frac{1}{2} \bar{\mathbf{u}}_i^T \Delta\mathbf{M}^e \bar{\mathbf{u}}_i \mathbf{u}_i \right) \quad (33.34)$$

In these formulas, the overbar signifies that the eigenvector concerned contains only the components needed for the e th finite element. It is important to observe that, in Equation 33.33 and Equation 33.34, calculations are done on the element basis, and as a result, the calculations are greatly simplified.

Using the shorthand notations

$$\lambda_{i,j}^e = \frac{1}{\Delta b_j} \bar{\mathbf{u}}_i^T \Delta\mathbf{K}^e - \lambda_i \Delta\mathbf{M}^e \bar{\mathbf{u}}_i \quad (33.35)$$

$$\mathbf{u}_{i,j}^e = \frac{1}{\Delta b_j} \left(\sum_{\substack{s=1 \\ s \neq i}}^n \frac{1}{\lambda_i - \lambda_s} \bar{\mathbf{u}}_s^T \Delta\mathbf{K}^e - \lambda_i \Delta\mathbf{M}^e \bar{\mathbf{u}}_i \mathbf{u}_s - \frac{1}{2} \bar{\mathbf{u}}_i^T \Delta\mathbf{M}^e \bar{\mathbf{u}}_i \mathbf{u}_i \right) \quad (33.36)$$

Equation 33.33 and Equation 33.34 can be written as

$$\lambda_{i,j} = \sum_e \lambda_{i,j}^e \quad (33.37)$$

and

$$\mathbf{u}_{i,j} = \sum_e \mathbf{u}_{i,j}^e \quad (33.38)$$

where $\lambda_{i,j}^e$ and $\mathbf{u}_{i,j}^e$ are the design sensitivity of the e th element for the eigenvalue λ_i and the eigenvector \mathbf{u}_i , respectively. Let us consider the following important cases.

For a concentrated mass, m_r , placed at a node point and moved in the direction of the r th DoF, Equation 33.33 and Equation 33.34 become

$$\lambda_{i,r} = \frac{\Delta\lambda_i}{\Delta m_r} = -\lambda_i u_{ir}^2 \quad (33.39)$$

and

$$\mathbf{u}_{i,r} = \frac{\Delta \mathbf{u}_i}{\Delta m_r} = \sum_{\substack{s=1 \\ s \neq i}}^n \frac{-\lambda_i}{\lambda_i - \kappa_s} u_{sr} u_{ir} \mathbf{u}_s - \frac{1}{2} u_{ir}^2 \mathbf{u}_i \quad (33.40)$$

where u_{ir} is the r th element of the i th eigenvector \mathbf{u}_i .

For an elastic connector with stiffness K_j between the r th and the l th DoF of two components, Equation 33.33 and Equation 33.34 become

$$\lambda_{i,j} = \frac{\Delta \lambda_i}{\Delta k_j} = (u_{ir} - u_{il})^2 \quad (33.41)$$

and

$$\mathbf{u}_{i,j} = \frac{\Delta \mathbf{u}_i}{\Delta k_j} = \sum_{\substack{s=1 \\ s \neq i}}^n \frac{1}{\lambda_i - \lambda_s} (u_{sr} u_{ir} - u_{sl} u_{ir} - u_{sr} u_{il} + u_{sl} u_{il}) \mathbf{u}_s \quad (33.42)$$

For an elastic support with spring stiffness K_r placed in the direction of the r th DoF, Equations 33.33 and Equation 33.34 become

$$\lambda_{i,r} = \frac{\Delta \lambda_i}{\Delta k_r} = u_{ir}^2 \quad (33.43)$$

and

$$\mathbf{u}_{i,r} = \frac{\Delta \mathbf{u}_i}{\Delta k_r} = \sum_{\substack{s=1 \\ s \neq i}}^n \frac{1}{\lambda_i - \lambda_s} u_{sr} u_{ir} \mathbf{u}_s \quad (33.44)$$

33.4.3 Numerical Example

The design sensitivity analysis of an automotive chassis is presented here as an illustration of the method.

Example 33.4

The finite element model of an automobile chassis consists of 39 beam elements involving 30 nodal points and 180 DoF (Figure 33.4).

The design variables for the sensitivity analysis of eigenvalues in this example are the equivalent torsional moment of inertia, J , and the bending moment of inertia, I_y , of the beam element of

FIGURE 33.4 Finite element model of the automotive chassis for Example 33.4.

	$\lambda_{4I_y}^e$	22.4	22.4	15.7	15.7	11.8	11.8	10.9	10.9

the structure. Results for the sensitivity of eigenvalues with respect to J and I_y are given in Table 33.5, in which NE denotes the number of the element. Only the highest eight values are given, and they are listed in descending order.

From Table 33.5, it is seen that for this particular chassis, the sensitivities of the first natural frequency, $\lambda_{1I_y}^e$, are much smaller than λ_{1J}^e . This indicates that there is very little effect of the change of bending moment of inertia, I_y , of the beams on the vibration of the chassis at its first natural frequency. Thus, we can conclude that the first mode is a torsional mode. Similarly, the results indicate that the third mode is also a torsional mode. On the other hand, the second and the fourth modes are recognized to be bending modes. This information is very useful to the designer when deciding on a change in the design. For example, if he wants to increase the first torsional frequency, the efficient way is for him to increase the equivalent torsional moments of inertia of beam elements 15, 11, 19, 24, 6, and so on.

It should be noted that only the first low-frequency modes are available and can be used as basis vectors of eigenvector derivatives in Equation 33.26. However, modal truncation induces errors, and the errors become significant if more high-frequency modes are truncated. An improvement to truncated modal superposition representation of eigenvector derivatives is presented in the next section.

33.4.4 Concluding Remarks

As can be seen from the numerical examples given above, the matrix perturbation method is an extremely useful tool for fast reanalysis of a modified structure. It is widely used in a range of structural modifications, such as the modification of various types of elements, local modification of structures, sensitivity analysis of vibration modes, and so on. Therefore, matrix perturbation plays an important role in dynamic analysis and optimization of structures.

33.5 High-Accuracy Modal Superposition for Sensitivity Analysis of Modes

The modal superposition method is often used to compute the derivatives of modal vectors. Because of the cost of generating computer solutions for a dynamic analysis, it is impractical to obtain all modes.

Therefore, only the first L low-frequency modes are computed and are used as basis vectors of eigenvector derivatives. However, as noted above, modal truncation induces errors, which can be significant if more high-frequency modes are truncated. An explicit method to improve the truncated modal superposition representation of eigenvector derivatives is presented (Wang, 1991), in which a residual static mode is used to approximate the contribution due to unavailable high-frequency modes (method one).

In this section a more accurate modal superposition method (method two; Chen, 1993a; Liu and Chen, 1994a) than method one is given. In this method, the contribution of the truncated modes to the eigenvector derivatives is expressed exactly, as a convergent series that can be evaluated by a simple iterative procedure.

33.5.1 Method One

The modal sensitivity can be expressed as

$$u_{i,j} = \sum_{s=1}^N c_s u_s = \sum_{j=1}^L c_j \mathbf{u}_j + \mathbf{S}_R \quad (33.45)$$

where

$$\mathbf{S}_R = \sum_{j=L+1}^N c_j \mathbf{u}_j \quad (33.46)$$

Since $\lambda_i \ll \lambda_{L+1}$, Equation 33.46 can be approximated as

$$\mathbf{S}_R \approx \mathbf{S}_{RA} = \bar{\mathbf{H}}_0 - \bar{\mathbf{W}}_0 \quad (33.47)$$

where

$$\bar{\mathbf{H}}_0 = \mathbf{K}^{-1}(-\mathbf{K}_j + \lambda_{i,j} \mathbf{M} + \lambda_i \mathbf{M}_j) \quad (33.48)$$

$$\bar{\mathbf{W}}_0 = \sum_{j=1}^L \frac{1}{\lambda_j} \mathbf{u}_j^T (-\mathbf{K}_j + \lambda_{i,j} \mathbf{M} + \lambda_i \mathbf{M}_j) \mathbf{u}_j \quad (33.49)$$

33.5.2 Method Two

The contribution of $u_{i,j}$, \mathbf{S}_R due to truncated high-frequencies modes is as follows:

$$\mathbf{S}_R = \sum_{j=0}^{\infty} \lambda_i^j (\mathbf{H}_j - \mathbf{W}_j) \quad (33.50)$$

where

$$\mathbf{W}_j = \mathbf{U}_L \mathbf{\Lambda}_L^{-j-1} \mathbf{U}_L^T (-\mathbf{K}_j + \lambda_{i,j} \mathbf{M} + \lambda_i \mathbf{M}_j) \quad (33.51)$$

$$\mathbf{U}_L = [\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_L] \quad (33.52)$$

\mathbf{H}_j can be obtained with the following iterative procedure:

$$\left. \begin{aligned} \mathbf{H}_0 &= \mathbf{K}^{-1}(-\mathbf{K}_j + \mathbf{K}_{i,j} \mathbf{M} + \lambda_i \mathbf{M}_j) \\ \mathbf{F}'_{j-1} &= \mathbf{M} \mathbf{H}_{j-1}, \quad j \geq 1 \\ \mathbf{H}_j &= \mathbf{K}^{-1} \mathbf{F}'_{j-1} \end{aligned} \right\} \quad (33.53)$$

Define $\mathbf{S}_R(k)$ as

$$\mathbf{S}_R(k) = \sum_{j=0}^k \lambda_i^j (\mathbf{H}_j - \mathbf{W}_j) \quad (33.54)$$

Using this definition, the given iterative process can be terminated if the following inequality

$$\|\mathbf{S}_R(k) - \mathbf{S}_R(k-1)\|_2 \leq \varepsilon \quad (33.55)$$

is satisfied, where ε is a specified accuracy requirement.

It should be noted that, if only the first term in the series (Equation 33.50) is retained with all the other terms neglected, then method two is reduced to method one. In addition, the series (Equation 33.50) can be used to estimate the errors induced by the modal truncation.

33.6 Sensitivity of Eigenvectors for Free-Free Structures

As can be seen from Equation 33.48 and Equation 33.53, both method one and method two fail to deal with the free-free structures with rigid-body modes because they involve the inversion of the stiffness matrix. However, we can transform the eigenproblem with a singular stiffness matrix into its equivalent eigenproblem with a nonsingular stiffness matrix, in the sense that these two eigenproblems have the same derivatives of eigenvalues and eigenvectors (Liu and Chen, 1994b).

Consider the eigenvalue problem

$$\bar{\mathbf{K}}\bar{\mathbf{u}}_i = \bar{\lambda}_i \bar{\mathbf{M}}\bar{\mathbf{u}}_i \quad (33.56)$$

where

$$\bar{\mathbf{K}} \equiv \mathbf{K} - \mu \mathbf{M} \quad (33.57)$$

Here, μ is a nonzero scalar parameter and $\bar{\mathbf{K}}$ is nonsingular if $\mu \neq \lambda_i$ ($i = 1, 2, \dots, n$)

It can be shown that

$$\bar{\lambda}_i = \lambda_i - \mu \quad (33.58)$$

$$\bar{\mathbf{u}}_i = \mathbf{u}_i, \quad i = 1, 2, \dots, N \quad (33.59)$$

and

$$\frac{d\bar{\lambda}_i}{db} = \frac{d\lambda_i}{db} \quad (33.60)$$

$$\frac{d\bar{\mathbf{u}}_i}{db} = \frac{d\mathbf{u}_i}{db} \quad (33.61)$$

The derivatives $d\mathbf{u}_i/db$ can be obtained from the derivatives $d\bar{\mathbf{u}}_i/db$ of the eigenproblem of Equation 33.56, in which $\bar{\mathbf{K}}$ is nonsingular. In this context, both method one and method two, discussed in Section 33.5.1 and Section 33.5.2, can be applied to deal with the free-free structures with rigid-body modes.

To achieve a faster average convergent speed for all the first m eigenvector derivatives, μ can be determined as

$$\begin{cases} \mu = \frac{\left(\sum_{j=1}^m \lambda_j\right)}{m}, & j = 1, 2, \dots, m \\ \mu \neq \lambda_j, \end{cases} \quad (33.62)$$

33.7 Matrix Perturbation Theory for Repeated Modes

33.7.1 Basic Equations

In this section, let us consider the case of repeated eigenvalues, namely, $\lambda_{0i} = \lambda_{0i+1} = \dots = \lambda_{0i+m-1}$. The system is known as a *degenerate system*. In engineering, many complex and large structures, such as airplanes, rockets, tall towers, bridges, and ocean platforms, often have multiple or cluster eigenvalues. The matrix perturbation for the repeated modes is presented in Haug, et al. (1980), Chen and Pan (1986), Hu (1987), Mills-Curran (1988), Ojalvo (1988), Dailey (1989), Lim et al. (1989) and Shaw and Jayasuriya (1992).

Assume that $\lambda_0 = \lambda_{01} = \lambda_{02} = \dots = \lambda_{0m}$; that is, λ_0 is a repeated eigenvalue with multiplicity equal to m , and $\mathbf{u}_{01}, \mathbf{u}_{02}, \dots, \mathbf{u}_{0m}$ are the eigenvectors associated with λ_0 . Then, a linear combination of \mathbf{u}_{0j} ($j = 1, 2, \dots, m$), denoted as \mathbf{U}_0 , will also be the eigenvector associated with λ_0 :

$$\mathbf{U}_0 = \mathbf{U}_{0m}\boldsymbol{\alpha} \quad (33.63)$$

where

$$\mathbf{U}_{0m} = [\mathbf{u}_{01}, \mathbf{u}_{02}, \dots, \mathbf{u}_{0m}] \quad (33.64)$$

$$\boldsymbol{\alpha}^T \boldsymbol{\alpha} = \mathbf{I} \quad (33.65)$$

and

$$\boldsymbol{\alpha} = [\alpha_1, \alpha_2, \dots, \alpha_m]^T \quad (33.66)$$

Note that $\boldsymbol{\alpha}$ is a constant matrix to be determined.

According to the matrix perturbation method, the eigenvalues and eigenvectors of the structure with repeated eigenvalues for the perturbed structure can be expressed as

$$\boldsymbol{\Lambda}_m = \boldsymbol{\Lambda}_0 + \varepsilon \boldsymbol{\Lambda}_1 \quad (33.67)$$

$$\mathbf{U}_m = \mathbf{U}_{0m}\boldsymbol{\alpha} + \varepsilon(\mathbf{U}_0\mathbf{C}_m + \mathbf{U}_A\mathbf{C}_A) = \mathbf{U}_{0m}\boldsymbol{\alpha} + \varepsilon(\mathbf{U}_{0m}\boldsymbol{\alpha}\mathbf{C}_m + \mathbf{U}_A\mathbf{C}_A) \quad (33.68)$$

where \mathbf{U}_A is the $n \times (n - m)$ modal matrix containing all the eigenvectors except \mathbf{U}_{0m} , $\boldsymbol{\Lambda}_m$ is the $m \times m$ eigenvalue diagonal matrix of the perturbed structure, $\boldsymbol{\Lambda}_1$ is the $m \times m$ diagonal matrix with its diagonal elements equal to the first-order perturbations of eigenvalues, \mathbf{C}_m is an $m \times m$ matrix to be determined, and \mathbf{C}_A is an $(n - m) \times (n - m)$ matrix to be determined.

33.7.2 The First-Order Perturbation of Eigensolutions

$\boldsymbol{\Lambda}_1$ and $\boldsymbol{\alpha}$ can be computed from the following $(m \times m)$ eigenproblem:

$$\mathbf{W}\boldsymbol{\alpha} = \boldsymbol{\alpha}\boldsymbol{\Lambda}_1, \quad \boldsymbol{\alpha}^T \boldsymbol{\alpha} = \mathbf{I} \quad (33.69)$$

where

$$\mathbf{W} = \mathbf{U}_{0m}^T(\mathbf{K}_1 - \lambda_0\mathbf{M}_1)\mathbf{U}_{0m} \quad (33.70)$$

Solving the $m \times m$ eigenproblem of Equation 33.69 can produce $\boldsymbol{\Lambda}_1$ and $\boldsymbol{\alpha}$.

If matrix \mathbf{W} has no repeated eigenvalues, $\boldsymbol{\alpha}$ can be uniquely determined; if matrix \mathbf{W} has repeated eigenvalues, $\boldsymbol{\alpha}$ can be determined using the higher order perturbation equations. Here, we assume that matrix \mathbf{W} has no repeated eigenvalues; that is, $\lambda_{1i} \neq \lambda_{1j}$, ($i \neq j$), where λ_{1k} ($0 < k \leq m$) are the elements of the diagonal matrix $\boldsymbol{\Lambda}_1$.

The matrix \mathbf{C}_A is

$$\mathbf{C}_A = (\boldsymbol{\Lambda}_A - \lambda_0\mathbf{I})^{-1}\mathbf{U}_A^T(\lambda_0\mathbf{M}_1 - \mathbf{K}_1)\mathbf{U}_{0m}\boldsymbol{\alpha} \quad (33.71)$$

The elements of C_m are

$$C_{ij}^m = \frac{R_{ij}}{\lambda_{jm}^{(1)} - \lambda_{im}^{(1)}}, \quad i \neq j, \quad i, j = 1, 2, \dots, m \quad (33.72)$$

where R_{ij} are the elements of \mathbf{R} given by

$$\mathbf{R} = -\boldsymbol{\alpha}^T \mathbf{U}_{0m}^T \mathbf{M}_1 \mathbf{U}_{0m} \boldsymbol{\alpha} \boldsymbol{\Lambda}_1 + \boldsymbol{\alpha}^T \mathbf{U}_{0m} \mathbf{K}_1 \mathbf{U}_A \mathbf{C}_A - \lambda_0 \boldsymbol{\alpha}^T \mathbf{U}_{0m} \mathbf{M}_1 \mathbf{U}_A \mathbf{C}_A - \boldsymbol{\alpha}^T \mathbf{U}_{0m}^T \mathbf{M}_0 \mathbf{U}_A \mathbf{C}_A \boldsymbol{\Lambda}_1 \quad (33.73)$$

and

$$C_{ii}^m = \frac{1}{2} Q_{ii} \quad (33.74)$$

where Q_{ii} is the diagonal elements of \mathbf{Q} , given by

$$\mathbf{Q} = -\boldsymbol{\alpha}^T \mathbf{U}_{0m}^T \mathbf{M}_1 \mathbf{U}_{0m} \boldsymbol{\alpha} \quad (33.75)$$

33.7.3 High-Accuracy Modal Superposition for the First-Order Perturbation of Repeated Modes

In Section 33.5, the high-accuracy modal superposition for the first-order perturbation of eigenvectors of distinct eigenvalues is given. In this section, we extend these methods to the situation with repeated modes.

33.7.3.1 Method One for Computing \mathbf{U}_1

Assuming \mathbf{U}_{AL} and $\boldsymbol{\Lambda}_{AL}$ are the first L modes and eigenvalues excluding the repeated modes, the first-order perturbation of eigenvectors is

$$\mathbf{U}_1 = \mathbf{U}_{0m} \boldsymbol{\alpha} \mathbf{C}_m + \mathbf{U}_{AL} \mathbf{C}_{AL} + \mathbf{S}_R \quad (33.76)$$

$$\mathbf{S}_R = \mathbf{U}_S - [\mathbf{U}_{0m}; \mathbf{U}_{AL}] \text{diag}(\lambda_0^{-1}, \boldsymbol{\Lambda}_{AL}^{-1}) [\mathbf{U}_{0m}; \mathbf{U}_{AL}]^T \mathbf{T} \quad (33.77)$$

where \mathbf{U}_S is the static displacement obtained by

$$\mathbf{K} \mathbf{U}_S = \mathbf{T} \quad (33.78)$$

and

$$\mathbf{T} = \mathbf{M}_0 \mathbf{U}_{0m} \boldsymbol{\alpha} \boldsymbol{\Lambda}_1 + \lambda_0 \mathbf{M}_1 \mathbf{U}_{0m} \boldsymbol{\alpha} - \mathbf{K}_1 \mathbf{U}_{0m} \boldsymbol{\alpha} \quad (33.79)$$

In Equation 33.79, $\boldsymbol{\Lambda}_1$ and $\boldsymbol{\alpha}$ can be obtained from Equation 33.69.

The matrix \mathbf{C}_{AL} is given by

$$\mathbf{C}_{AL} = (\boldsymbol{\Lambda}_{AL} - \lambda_0 \mathbf{I})^{-1} \mathbf{U}_{AL}^T (\lambda_0 \mathbf{M}_1 - \mathbf{K}_1) \mathbf{U}_{0m} \boldsymbol{\alpha} \quad (33.80)$$

and the elements of matrix \mathbf{C}_m are

$$C_{ij}^m = \frac{R_{ij}}{\lambda_{jm}^{(1)} - \lambda_{im}^{(1)}}, \quad i \neq j, \quad i, j = 1, 2, \dots, m \quad (33.81)$$

where \mathbf{R} is given by

$$\mathbf{R} = \boldsymbol{\alpha}^T \mathbf{U}_{0m}^T \mathbf{M}_1 \mathbf{U}_{0m} \boldsymbol{\Lambda}_1 - \boldsymbol{\alpha}^T \mathbf{U}_{0m}^T (\lambda_0 \mathbf{M}_1 - \mathbf{K}_1) (\mathbf{U}_{AL} \mathbf{C}_{AL} + \mathbf{S}_R) - \boldsymbol{\alpha}^T \mathbf{U}_{0m}^T \mathbf{M}_0 \mathbf{S}_R \boldsymbol{\Lambda}_1 \quad (33.82)$$

The diagonal elements of \mathbf{C}_m are

$$C_{ii}^m = \frac{1}{2} Q_{ii} \quad (33.83)$$

where

$$\mathbf{Q} = -\boldsymbol{\alpha}^T \mathbf{U}_{0m}^T \mathbf{M}_1 \mathbf{U}_{0m} \boldsymbol{\alpha} - \boldsymbol{\alpha}^T \mathbf{U}_{0m}^T \mathbf{M}_0 \mathbf{S}_R - \mathbf{S}_R^T \mathbf{M}_0 \mathbf{U}_{0m} \boldsymbol{\alpha} \quad (33.84)$$

33.7.3.2 Method Two for Computing \mathbf{U}_1

The first-order perturbation of eigenvectors can be expressed as

$$\mathbf{U}_1 = \mathbf{U}_{0m} \boldsymbol{\alpha} \mathbf{C}_m + \mathbf{U}_{AL} \mathbf{C}_{AL} + \mathbf{S}_R \quad (33.85)$$

where \mathbf{C}_{AL} can also be calculated using Equation 33.80; that is

$$\mathbf{C}_{AL} = (\boldsymbol{\Lambda}_{AL} - \lambda_0 \mathbf{I})^{-1} \mathbf{U}_{AL}^T (\lambda_0 \mathbf{M}_1 - \mathbf{K}_1) \mathbf{U}_{0m} \boldsymbol{\alpha}$$

and \mathbf{S}_R is given by

$$\mathbf{S}_R = \sum_{j=0}^{\infty} \lambda_0^j (\mathbf{H}_j - \mathbf{W}_j) \quad (33.86)$$

where

$$\mathbf{W}_j = [\mathbf{U}_{0m} \dot{\mathbf{U}}_{AL}] \boldsymbol{\Lambda}_0^{-j-1} [\mathbf{U}_{0m} \dot{\mathbf{U}}_{AL}]^T \mathbf{T}, \quad j \geq 0 \quad (33.87)$$

$$\mathbf{T} = \mathbf{M}_0 \mathbf{U}_{0m} \boldsymbol{\alpha} \boldsymbol{\Lambda}_1 + \lambda_0 \mathbf{M}_1 \mathbf{U}_{0m} \boldsymbol{\alpha} - \mathbf{K}_1 \mathbf{U}_{0m} \boldsymbol{\alpha} \quad (33.88)$$

The iterative method for computing \mathbf{H}_j is as follows:

$$\begin{aligned} \mathbf{H}_0 &= \mathbf{K}^{-1} \mathbf{T}, \\ \mathbf{F}'_{j-1} &= \mathbf{M} \mathbf{H}_{j-1}, \quad j \geq 1 \\ \mathbf{H}_j &= \mathbf{K}^{-1} \mathbf{F}'_{j-1}, \end{aligned} \quad (33.89)$$

This iterative process can be terminated according to the accuracy requirement. If we define $\mathbf{S}_R(k)$ as

$$\mathbf{S}_R(k) = \sum_{j=0}^k \lambda_0^j (\mathbf{H}_j - \mathbf{W}_j) \quad (33.90)$$

the termination condition can be stated as

$$\|\mathbf{S}_R(k) - \mathbf{S}_R(k-1)\|_2 \leq \varepsilon, \quad j = 1, 2, \dots, m \quad (33.91)$$

where ε is a specified accuracy requirement.

The computation method for \mathbf{C}_m in Equation 33.85 is similar to that of Equation 33.81 to Equation 33.84. The only difference is that \mathbf{S}_R in Equation 33.82 and Equation 33.84 can be replaced with $\mathbf{S}_R(k)$ in Equation 33.90.

33.8 Matrix Perturbation Method for Closely Spaced Eigenvalues

The vibration modes with close frequencies, that is, with clusters of frequencies, often occur in certain structural systems including large space structures, multispan beams, and in some nearly periodic structures and symmetric structures. Therefore, it is important here to present the perturbation method for vibration modes with close eigenvalues (Liu, 2000).

The perturbation analysis of close eigenvalues can be transformed into a problem with a repeated eigenvalue, which is equal to the average value of the close eigenvalues (Chen, 1993).

33.8.1 Method One of Perturbation Analysis for Close Eigenvalues

Consider vibration eigenproblem

$$\mathbf{K}_0[\mathbf{U}_0; \dot{\mathbf{U}}_A] = \mathbf{M}_0[\mathbf{U}_0; \dot{\mathbf{U}}_A] \text{diag}(\mathbf{\Lambda}_0, \mathbf{\Lambda}_A) \quad (33.92)$$

$$[\mathbf{U}_0; \dot{\mathbf{U}}_A]^T \mathbf{M}_0[\mathbf{U}_0; \dot{\mathbf{U}}_A] = \mathbf{I} \quad (33.93)$$

where \mathbf{K}_0 and \mathbf{M}_0 are $n \times n$ real symmetric matrices, and $\mathbf{\Lambda}_0$ and \mathbf{U}_0 are the $m \times m$ diagonal matrix of close eigenvalues and the corresponding $n \times m$ modal matrix.

Using the spectral decomposition of \mathbf{K}_0 , the problem can be expressed as

$$\mathbf{K}_0 = \bar{\mathbf{K}}_0 + \varepsilon \delta \mathbf{K}_0 \quad (33.94)$$

where

$$\bar{\mathbf{K}}_0 = \mathbf{M}_0(\lambda_0 \mathbf{U}_0 \mathbf{U}_0^T) \mathbf{M}_0 + \mathbf{M}_0(\mathbf{U}_A \mathbf{\Lambda}_A \mathbf{U}_A^T) \mathbf{M}_0 \quad (33.95)$$

$$\varepsilon \delta \mathbf{K}_0 = \mathbf{M}_0(\mathbf{U}_0(\varepsilon \delta \mathbf{\Lambda}_0) \mathbf{U}_0^T) \mathbf{M}_0 \quad (33.96)$$

$$\varepsilon \delta \mathbf{\Lambda}_0 = \mathbf{\Lambda}_0 - \lambda_0 \mathbf{I} = \mathbf{\Lambda}_0 - \left(\frac{\sum_{i=1}^m \lambda_{0i}}{m} \right) \mathbf{I} \quad (33.97)$$

It can be seen that $\bar{\mathbf{K}}_0$ given by Equation 33.95 satisfies

$$\bar{\mathbf{K}}_0[\mathbf{U}_0; \dot{\mathbf{U}}_A] = \mathbf{M}_0[\mathbf{U}_0; \dot{\mathbf{U}}_A] \text{diag}(\lambda_0 \mathbf{I}, \mathbf{\Lambda}_A) \quad (33.98)$$

$$[\mathbf{U}_0; \dot{\mathbf{U}}_A]^T \mathbf{M}_0[\mathbf{U}_0; \dot{\mathbf{U}}_A] = \mathbf{I} \quad (33.99)$$

This indicates that λ_0 and \mathbf{U}_0 are the repeated eigenvalues and the corresponding eigenvector subspace with multiplicity m of the eigenproblem (Equation 33.92), and $\mathbf{\Lambda}_A$ and \mathbf{U}_A are also the eigensolution of eigenproblem (Equation 33.92).

If $\mathbf{\Lambda}_0 \rightarrow \lambda_0 \mathbf{I}$, $\varepsilon \delta \mathbf{\Lambda}_0 \rightarrow \mathbf{0}$, and $\bar{\mathbf{K}}_0 \rightarrow \mathbf{K}_0$, and if the small parameter modifications $\varepsilon \mathbf{K}_1$ and $\varepsilon \mathbf{M}_1$ are introduced to the matrices \mathbf{K}_0 and \mathbf{M}_0 , the eigenproblem with close eigenvalues becomes

$$(\mathbf{K}_0 + \varepsilon \mathbf{K}_1) \mathbf{U} = (\mathbf{M}_0 + \varepsilon \mathbf{M}_1) \mathbf{U} \mathbf{\Lambda} \quad (33.100)$$

$$\mathbf{U}(\mathbf{M}_0 + \varepsilon \mathbf{M}_1) \mathbf{U}^T = \mathbf{I} \quad (33.101)$$

Substituting Equation 33.94 into Equation 33.100, we obtain

$$(\bar{\mathbf{K}}_0 + \varepsilon \bar{\mathbf{K}}_1) \mathbf{U} = (\mathbf{M}_0 + \varepsilon \mathbf{M}_1) \mathbf{U} \mathbf{\Lambda} \quad (33.102)$$

$$\mathbf{U}(\mathbf{M}_0 + \varepsilon \mathbf{M}_1) \mathbf{U}^T = \mathbf{I} \quad (33.103)$$

where

$$\varepsilon \bar{\mathbf{K}}_1 = \varepsilon \delta \mathbf{K}_0 + \varepsilon \mathbf{K}_1 \quad (33.104)$$

$$\mathbf{\Lambda} = \lambda_0 \mathbf{I} + \varepsilon \mathbf{\Lambda}_1 + \varepsilon^2 \mathbf{\Lambda}_2 + \cdots \quad (33.105)$$

$$\mathbf{U} = \mathbf{U}_0 \alpha + \varepsilon \mathbf{U}_1 + \varepsilon^2 \mathbf{U}_2 + \cdots \quad (33.106)$$

Therefore, the eigenproblem of Equation 33.102 and Equation 33.103 can be considered to be a perturbed eigenproblem with the perturbation matrices equal to $(\delta \mathbf{K}_0 + \mathbf{K}_1)$ and \mathbf{M}_1 , respectively. The eigensolutions, $\mathbf{\Lambda}$ and \mathbf{U} , can be obtained from Equation 33.102 and Equation 33.103 by using the perturbation method for repeated eigenvalues as discussed in Section 33.7. Accordingly, the perturbation problem of modes with close eigenvalues is transformed into one of the repeated eigenvalues.

The complete algorithm for $\mathbf{\Lambda}$ and \mathbf{U} is given below.

- (1) Compute

$$\lambda_0 = \frac{\sum_{i=1}^m \lambda_{0i}}{m}$$

- (2) Compute

$$\mathbf{W} = \mathbf{U}_0^T (\delta \mathbf{K}_0 + \mathbf{K}_1 - \lambda_0 \mathbf{M}_1) \mathbf{U}_0$$

- (3) Solve the eigenvalue problem

$$\mathbf{W} \boldsymbol{\alpha} = \boldsymbol{\alpha} \mathbf{\Lambda}_1$$

$$\boldsymbol{\alpha}^T \boldsymbol{\alpha} = \mathbf{I}$$

- (4) Compute the perturbed eigenvalues of the close eigenvalues

$$\mathbf{\Lambda} = \lambda_0 \mathbf{I} + \mathbf{\Lambda}_1$$

- (5) Compute the new eigenvectors $\mathbf{U}_0 \boldsymbol{\alpha}$ corresponding to λ_0 .

- (6) Compute the matrix \mathbf{C}_A

$$\mathbf{C}_A = (\mathbf{\Lambda}_A - \lambda_0 \mathbf{I})^{-1} \mathbf{U}_A^T (\lambda_0 \mathbf{M}_1 - \mathbf{K}_1 - \delta \mathbf{K}_0) \mathbf{U}_0 \boldsymbol{\alpha}$$

- (7) Compute

$$\mathbf{R} = [R_{ij}]$$

$$\mathbf{R} = -\boldsymbol{\alpha}^T \mathbf{U}_0^T \mathbf{M}_1 \mathbf{U}_0 \boldsymbol{\alpha} \mathbf{\Lambda}_1 - \lambda_0 \boldsymbol{\alpha}^T \mathbf{U}_0^T \mathbf{M}_1 \mathbf{U}_A \mathbf{C}_A - \boldsymbol{\alpha}^T \mathbf{U}_0^T (\delta \mathbf{K}_0 + \mathbf{K}_1) \mathbf{U}_A \mathbf{C}_A - \boldsymbol{\alpha} \mathbf{U}_0^T \mathbf{M}_0 \mathbf{U}_A \mathbf{C}_A \mathbf{\Lambda}_1$$

- (8) Compute

$$\mathbf{C}_m = [C_{ij}^m]$$

$$C_{ij}^m = \frac{R_{ij}}{\lambda_{1j} - \lambda_{1i}}, \quad i \neq j, \quad i, j = 1, 2, \dots, m$$

$$C_{ii}^m = \frac{1}{2} Q_{ii}$$

$$\mathbf{Q} = -\boldsymbol{\alpha}^T \mathbf{U}_0^T \mathbf{M}_1 \mathbf{U}_0 \boldsymbol{\alpha}$$

(9) Compute the perturbed eigenvectors \mathbf{U}

$$\mathbf{U} = \mathbf{U}_0 \boldsymbol{\alpha} + \mathbf{U}_0 \boldsymbol{\alpha} \mathbf{C}_m + \mathbf{U}_A \mathbf{C}_A$$

33.8.2 Method Two of Perturbation Analysis for Close Eigenvalues

Because of the importance of the problem in both theory and practice, we now present method two of perturbation analysis for close eigenvalues, which is equivalent to method one given above.

Using the spectral decomposition of \mathbf{M}_0 , the problem can be expressed as

$$\mathbf{M}_0 = \tilde{\mathbf{M}}_0 + \varepsilon \delta \mathbf{M}_0 \quad (33.107)$$

Then, the following equations hold:

$$\mathbf{K}_0[\mathbf{U}_0; \mathbf{U}_A] = \tilde{\mathbf{M}}_0[\mathbf{U}_0; \mathbf{U}_A] \text{diag}(\lambda_0 \mathbf{I}, \boldsymbol{\Lambda}_A) \quad (33.108)$$

$$[\mathbf{U}_0; \mathbf{U}_A]^T \mathbf{M}_0[\mathbf{U}_0; \mathbf{U}_A] = \mathbf{I} \quad (33.109)$$

where

$$\tilde{\mathbf{M}} = \lambda_0^{-2} \mathbf{K}_0 \mathbf{U}_0 \mathbf{U}_0^T \mathbf{K}_0 + \mathbf{K}_0[\mathbf{U}_A (\boldsymbol{\Lambda}_A^{-1})^2 \mathbf{U}_A^T] \mathbf{K}_0 \quad (33.110)$$

$$\varepsilon \delta \mathbf{M}_0 = \mathbf{K}_0[\mathbf{U}_0 \varepsilon \delta (\boldsymbol{\Lambda}_0^{-1})^2 \mathbf{U}_0^T] \mathbf{K}_0 \quad (33.111)$$

$$\varepsilon \delta \boldsymbol{\Lambda}_0^{-2} = \boldsymbol{\Lambda}_0^{-2} - \lambda_0^{-2} \mathbf{I} \quad (33.112)$$

and

$$\lambda_0 = \frac{\sum_{i=1}^m \lambda_{0i}}{m} \quad (33.113)$$

It can be seen that $\tilde{\mathbf{M}}_0$ and $\varepsilon \delta \mathbf{M}_0$ given by Equation 33.110 and Equation 33.111 satisfy Equation 33.108 and Equation 33.109; that is, λ_0 and \mathbf{U}_0 are the repeated eigenvalues and corresponding modal matrix of Equation 33.108 and Equation 33.109. $\boldsymbol{\Lambda}_A$ and \mathbf{U}_A are the eigenvalue diagonal matrix and the corresponding modal matrix excluding λ_0 and \mathbf{U}_0 , respectively.

If \mathbf{K}_0 and \mathbf{M}_0 are modified to $\mathbf{K}_0 + \varepsilon \mathbf{K}_1$ and $\mathbf{M}_0 + \varepsilon \mathbf{M}_1$, the eigenvalue problem becomes

$$(\mathbf{K}_0 + \varepsilon \mathbf{K}_1) \mathbf{U} = (\mathbf{M}_0 + \varepsilon \mathbf{M}_1) \mathbf{U} \boldsymbol{\Lambda} \quad (33.114)$$

$$\mathbf{U}(\mathbf{M}_0 + \varepsilon \mathbf{M}_1) \mathbf{U}^T = \mathbf{I} \quad (33.115)$$

Substituting Equation 33.107 into Equation 33.114 yields

$$(\mathbf{K}_0 + \varepsilon \mathbf{K}_1) \mathbf{U} = (\tilde{\mathbf{M}}_0 + \varepsilon \tilde{\mathbf{M}}_1) \mathbf{U} \boldsymbol{\Lambda} \quad (33.116)$$

$$\mathbf{U}(\tilde{\mathbf{M}}_0 + \varepsilon \tilde{\mathbf{M}}_1) \mathbf{U}^T = \mathbf{I} \quad (33.117)$$

where

$$\varepsilon \tilde{\mathbf{M}}_1 = \varepsilon \delta \mathbf{M}_0 + \varepsilon \mathbf{M}_1 \quad (33.118)$$

Thus, Equation 33.116 and Equation 33.117 can be considered to be a perturbed eigenproblem with repeated eigenvalues, and the perturbation method for repeated eigenvalues can be used to obtain the perturbed eigensolutions of Equation 33.116 and Equation 33.117:

$$\boldsymbol{\Lambda} = \lambda_0 \mathbf{I} + \varepsilon \boldsymbol{\Lambda}_1 + \cdots \quad (33.119)$$

$$\mathbf{U} = \mathbf{U}_0 \boldsymbol{\alpha} + \varepsilon \mathbf{U}_1 + \cdots \quad (33.120)$$

Example 33.5

For the six-DoF mass–spring system shown in Figure 33.5, the stiffness and mass matrices \mathbf{K}_0 and \mathbf{M}_0 are given by

$$\mathbf{K}_0 = \begin{bmatrix} 1500 & -1000 & & & & \\ -1000 & 1200 & -200 & & & \\ & -200 & 15,200 & -5000 & -5000 & -5000 \\ & & -5000 & 5000 & & \\ & & -5000 & & 5000 & \\ & & -5000 & & & 5000 \end{bmatrix} \text{ (N/m)}$$

$$\mathbf{M}_0 = \text{diag}(200, 300, 50, 20, 20, 20.004) \text{ (kg)}$$

The perturbation eigensolutions are computed for the following three cases:

Case 1

$$\varepsilon \mathbf{K}_1 = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 5 & 0 & -5 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & -5 & 0 & 5 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \text{ (N/m)}$$

$$\varepsilon \mathbf{M}_1 = \text{diag}(0, \dots, 0) \text{ (kg)}$$

Case 2

$$\varepsilon \mathbf{K}_1 = \begin{bmatrix} 5.00 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \text{ (N/m)}$$

$$\varepsilon \mathbf{M}_1 = \text{diag}(0, 0, 0, 0, 0, 0.5) \text{ (kg)}$$

Case 3

$$\varepsilon \mathbf{K}_1 = \mathbf{0}, \varepsilon \mathbf{M}_1 = \text{diag}(0, 0, 0, 0, 2.0, 0) \text{ (kg)}$$

The unperturbed eigensolutions have a single pair of close eigenvalues given by

$$\Lambda_0 = \text{diag}(249.966642, 250.000000)$$

$$\mathbf{U}_0^T = \begin{bmatrix} 0.00000 & 0.00000 & -0.00012 & -0.091283 & -0.091283 & 0.182560 \\ 0.00000 & 0.00000 & 0.00000 & -0.158114 & 0.158114 & 0.00000 \end{bmatrix}$$

The other unperturbed eigensolutions are as follows:

$$\Lambda_A = \text{diag}(0.594885, 2.478725, 10.234656, 552.175102)$$

U_A

$$= \begin{bmatrix} -0.058595 & -0.027542 & 0.028427 & -0.000001 \\ 0.032047 & -0.027659 & 0.039259 & 0.000127 \\ -0.006732 & 0.074593 & 0.058387 & -0.104793 \\ -0.007020 & 0.075340 & 0.058527 & 0.086699 \\ -0.007020 & 0.075340 & 0.058527 & 0.086699 \\ -0.007020 & 0.075340 & 0.058527 & 0.086667 \end{bmatrix}$$

The perturbed eigensolutions associated with the single pair of close eigenvalues for the three cases are summarized in Table 33.6. These results show that the perturbation analysis of distinct eigenvalues is not only inaccurate but also misleading when applied to close eigenvalues, and that the perturbed eigensolutions given by the present method are in good agreement with the exact solutions.

For example, in Case 3, the eigenvalue errors induced by the present method are reduced to 1.047950 and 0.000000, while the errors induced by the perturbation of distinct eigenvalues are 4.174100 and 3.025595. The eigenvectors obtained by the perturbation method of distinct eigenvalues are not only

inaccurate but also misleading, while good agreement with the exact eigenvectors has been obtained by the present method.

33.8.3 Concluding Remarks

Perturbation analysis of vibration modes with close frequencies is presented in this section. It can be regarded as a general treatment of perturbation analysis, because the perturbation analysis of both distinct eigenvalues and repeated eigenvalues is contained in the present method. The results obtained by this method allow one to analyze the influence of parameter changes in a system on the dynamic characteristics of the system, which is very important for effective structural design.

33.9 Matrix Perturbation Theory for Complex Modes

In Section 33.2 to Section 33.8, the matrix perturbation for real modes of systems with real symmetric mass and stiffness matrices, \mathbf{M} and \mathbf{K} , was given. However, in many engineering problems such as systems with nonproportional damping (see Chapter 3 and Chapter 19), dynamic systems under nonconservative forces, analysis of aero-elastic flutter, and structural vibration control systems, the system matrices are not symmetric and may not be diagonalizable. In this case, the matrix perturbation for real modes cannot be used, and we must use the matrix perturbation for complex modes (Murthy and Haftka, 1988; Chen, 1993; Liu, 1999; Adhikari and Friswell, 2001). In the following, we assume that the system is not defective; that is, the system has a complete eigenvector set to span the eigenspace. The discussion in this chapter is limited to the nondefective systems.

33.9.1 Basic Equations

The vibration equation of a linear system with n -DoFs is given by

$$\mathbf{M}\ddot{\mathbf{q}} + \mathbf{C}\dot{\mathbf{q}} + \mathbf{K}\mathbf{q} = \mathbf{Q}(t) \quad (33.121)$$

where the matrices \mathbf{M} , \mathbf{C} , and \mathbf{K} , are assumed to be real and unsymmetric. The free vibration equation of the system is

$$\mathbf{M}\ddot{\mathbf{q}} + \mathbf{C}\dot{\mathbf{q}} + \mathbf{K}\mathbf{q} = \mathbf{0} \quad (33.122)$$

The corresponding right eigenvalues problem is

$$(\mathbf{M}s^2 + \mathbf{C}s + \mathbf{K})\mathbf{x} = \mathbf{0} \quad (33.123)$$

and its adjoint eigenvalue problem is

$$\begin{aligned} (\mathbf{M}s^2 + \mathbf{C}s + \mathbf{K})^T \mathbf{y} &= \mathbf{0} \\ \mathbf{y}^T (\mathbf{M}s^2 + \mathbf{C}s + \mathbf{K}) &= \mathbf{0} \end{aligned} \quad (33.124)$$

It is common in literature to call \mathbf{y} the *left eigenvector*, while \mathbf{x} in the original system, a column vector, is called the *right eigenvector*.

Let us introduce a state vector

$$\mathbf{u} = \begin{Bmatrix} s\mathbf{x} \\ \mathbf{x} \end{Bmatrix} = \mathbf{T}\mathbf{x} \quad (33.125)$$

where \mathbf{T} is the state transformation matrix

$$\mathbf{T} = \begin{Bmatrix} s\mathbf{I} \\ \mathbf{I} \end{Bmatrix} \quad (33.126)$$

Similarly, we introduce the state vector

$$\mathbf{v} = \begin{Bmatrix} s\mathbf{y} \\ \mathbf{y} \end{Bmatrix} = \mathbf{T}\mathbf{y} \quad (33.127)$$

Hence, Equations 33.123 and Equation 33.124 become

$$(\mathbf{A}s + \mathbf{B})\mathbf{u} = \mathbf{0} \quad (33.128)$$

$$(\mathbf{A}s + \mathbf{B})^T \mathbf{v} = \mathbf{0} \quad (33.129)$$

or

$$\mathbf{v}^T (\mathbf{A}s + \mathbf{B}) = \mathbf{0}$$

where

$$\mathbf{A} = \begin{bmatrix} -\mathbf{C} & -\mathbf{K} \\ \mathbf{I} & \mathbf{0} \end{bmatrix}$$

$$\mathbf{B} = \begin{bmatrix} \mathbf{M} & \mathbf{0} \\ \mathbf{0} & \mathbf{I} \end{bmatrix}$$

It is well known that the eigenvalues of the adjoint eigenproblem (Equation 33.129) are identical to that of the original eigenproblem (Equation 33.128). The *characteristic equation* is

$$\det(\mathbf{A} + s\mathbf{B}) = 0$$

This characteristic determinant is a polynomial of $2n$ order in s , and $2n$ eigenvalues s_i ($i = 1, 2, \dots, 2n$) can be found in the complex domain. The left and right modal vectors, \mathbf{v}_i and \mathbf{u}_i , corresponding to s_i satisfy

$$\mathbf{A}\mathbf{u}_i = s_i\mathbf{B}\mathbf{u}_i \quad (33.130)$$

and

$$\mathbf{A}^T \mathbf{v}_i = s_i \mathbf{B}^T \mathbf{v}_i \quad (33.131)$$

The *orthogonality conditions* are

$$\mathbf{v}_j^T \mathbf{B}\mathbf{u}_i = \mathbf{0} \quad (33.132)$$

$$\mathbf{v}_j^T \mathbf{A}\mathbf{u}_i = \mathbf{0} \quad (33.133)$$

The *normalization conditions* are

$$\mathbf{v}_i^T \mathbf{B}\mathbf{u}_i = 1$$

$$\mathbf{u}_i^T \mathbf{B}\mathbf{u}_i = 1 \quad (33.134)$$

Therefore, the orthogonality conditions can be written as

$$\mathbf{v}_j^T \mathbf{B}\mathbf{u}_i = \delta_{ij}$$

$$\mathbf{v}_j^T \mathbf{A}\mathbf{u}_i = s_i \delta_{ij} \quad (33.135)$$

33.9.2 Matrix Perturbation Method for Distinct Modes

If small changes are made on the structural parameters, the mass, damping, and stiffness matrices of the system also have small changes given by

$$\begin{aligned} \mathbf{M} &= \mathbf{M}_0 + \varepsilon \mathbf{M}_1 \\ \mathbf{C} &= \mathbf{C}_0 + \varepsilon \mathbf{C}_1 \\ \mathbf{K} &= \mathbf{K}_0 + \varepsilon \mathbf{K}_1 \end{aligned} \quad (33.136)$$

and we have

$$\mathbf{A} = \mathbf{A}_0 + \varepsilon \mathbf{A}_1 \quad (33.137)$$

$$\mathbf{B} = \mathbf{B}_0 + \varepsilon \mathbf{B}_1 \quad (33.138)$$

where ε is a small parameter.

In the following, we first consider the case of distinct eigenvalues, s_{0i} , of the original system. According to the matrix perturbation theory, the eigenvalues and eigenvectors can be expressed as a power series in ε , that is

$$\mathbf{S} = \mathbf{S}_0 + \varepsilon \mathbf{S}_1 + \varepsilon^2 \mathbf{S}_2 + \cdots \quad (33.139)$$

$$\mathbf{U} = \mathbf{U}_0 + \varepsilon \mathbf{U}_1 + \varepsilon^2 \mathbf{U}_2 + \cdots \quad (33.140)$$

$$\mathbf{V} = \mathbf{V}_0 + \varepsilon \mathbf{V}_1 + \varepsilon^2 \mathbf{V}_2 + \cdots \quad (33.141)$$

where \mathbf{S}_0 , \mathbf{U}_0 , and \mathbf{V}_0 are the eigensolutions of the original system; \mathbf{S}_1 , \mathbf{U}_1 , and \mathbf{V}_1 are the first-order perturbations of eigensolutions; and \mathbf{S}_2 , \mathbf{U}_2 , and \mathbf{V}_2 the second-order perturbations.

\mathbf{U}_1 can be expressed as a linear combination of the right eigenvectors of the original system as

$$\mathbf{U}_1 = \mathbf{U}_0 \mathbf{C}^1 \quad (33.142)$$

where \mathbf{C}^1 is to be the determined matrix given by

$$C_{ij}^1 = \frac{1}{S_{0j} - S_{0i}} P_{ij}^1, \quad j \neq i, \quad i, j = 1, 2, \dots \quad (33.143)$$

Also

$$\mathbf{S}_1 = \text{diag}(P_{11}^1, P_{22}^1, \dots) \quad (33.144)$$

where P_{ij}^1 are the elements of \mathbf{P}^1 given by

$$\mathbf{P}^1 = \mathbf{V}_0^T (-\mathbf{A}_1 \mathbf{U}_0 + \mathbf{B}_1 \mathbf{U}_0 \mathbf{S}_0) \quad (33.145)$$

The \mathbf{V}_1 can be expressed as the expansion of \mathbf{V}_0

$$\mathbf{V}_1 = \mathbf{V}_0 \mathbf{D}^1 \quad (33.146)$$

where \mathbf{D}^1 is to be the determined coefficient matrix given by

$$D_{ij}^1 = \frac{1}{S_{0j} - S_{0i}} R_{ij}^1, \quad j \neq i, \quad i, j = 1, 2, \dots \quad (33.147)$$

and R_{ij}^1 are the nondiagonal elements of \mathbf{R}^1

$$\mathbf{R}^1 = \mathbf{U}_0^T (\mathbf{B}_1^T \mathbf{V}_0 \mathbf{S}_0 - \mathbf{A}_1^T \mathbf{V}_0) \quad (33.148)$$

If the modification of the parameter is fairly large, the second-order perturbation must be used to obtain high accuracy. According to the expansion theorem, the second-order perturbation of eigenvectors, \mathbf{U}_2 , can be expressed as

$$\mathbf{U}_2 = \mathbf{U}_0 \mathbf{C}^2 \quad (33.149)$$

In a similar manner, \mathbf{S}_2 and the elements C_{ij}^2 can be obtained as

$$\mathbf{S}_2 = \text{diag}(P_{11}^2, P_{22}^2, \dots) \quad (33.150)$$

$$C_{ij}^2 = \frac{1}{S_{0j} - S_{0i}} P_{ij}^2, \quad j \neq i, i, \quad j = 1, 2, \dots \quad (33.151)$$

where P_{ij}^2 are the nondiagonal elements of \mathbf{P}^2

$$\mathbf{P}^2 = \mathbf{V}_0^T \mathbf{B}_0 \mathbf{U}_1 \mathbf{S}_1 + \mathbf{V}_0^T \mathbf{B}_1 \mathbf{U}_0 \mathbf{S}_1 + \mathbf{V}_0^T \mathbf{B}_1 \mathbf{U}_1 \mathbf{S}_0 - \mathbf{V}_0^T \mathbf{A}_1 \mathbf{U}_1 \quad (33.152)$$

\mathbf{V}_2 can be expressed as

$$\mathbf{V}_2 = \mathbf{V}_0 \mathbf{D}^2 \quad (33.153)$$

where \mathbf{D}^2 is to be the determined coefficient matrix given by

$$D_{ij}^2 = \frac{1}{S_{0j} - S_{0i}} R_{ij}^2, \quad j \neq i, \quad i, j = 1, 2, \dots \quad (33.154)$$

and R_{ij}^2 are the nondiagonal elements of \mathbf{R}^2

$$\mathbf{R}^2 = \mathbf{U}_0^T (\mathbf{B}_0^T \mathbf{V}_1 \mathbf{S}_1 + \mathbf{B}_1^T \mathbf{V}_0 \mathbf{S}_1 + \mathbf{B}_1^T \mathbf{V}_1 \mathbf{S}_0 - \mathbf{A}_1^T \mathbf{V}_1) \quad (33.155)$$

If $j = i$, the coefficients C_{ii}^1 , D_{ii}^1 , C_{ii}^2 , and D_{ii}^2 can be computed as

$$C_{ii}^1 = \frac{-1}{\mathbf{u}_{0i}^T (\mathbf{B}_0 + \mathbf{B}_0^T) \mathbf{u}_{0i}} \left(\mathbf{u}_{0i}^T \mathbf{B}_1 \mathbf{u}_{0i} + \sum_{\substack{j=1 \\ j \neq i}}^n C_{ij} \mathbf{u}_{0j}^T (\mathbf{B}_0 + \mathbf{B}_0^T) \mathbf{u}_{0i} \right) \quad (33.156)$$

$$D_{ii}^1 = Q_{ii}^1 - C_{ii}^1 \quad (33.157)$$

where Q_{ii}^1 is the diagonal element of \mathbf{Q}_1

$$\mathbf{Q}_1 = -\mathbf{V}_0^T \mathbf{B}_1 \mathbf{U}_0 \quad (33.158)$$

$$C_{ii}^2 = \frac{-\mathbf{u}_{1i}^T \mathbf{B}_0 \mathbf{u}_{1i} + \mathbf{u}_{0i}^T \mathbf{B}_1 \mathbf{u}_{1i} + \mathbf{u}_{1i}^T \mathbf{B}_1 \mathbf{u}_{0i} - \sum_{\substack{j=1 \\ j \neq i}}^n C_{ij} \mathbf{u}_{0j}^T (\mathbf{B}_0 + \mathbf{B}_0^T) \mathbf{u}_{0i}}{\mathbf{u}_{0i}^T (\mathbf{B}_0 + \mathbf{B}_0^T) \mathbf{u}_{0i}} \quad (33.159)$$

$$D_{ii}^2 = Q_{ii}^2 - C_{ii}^2 \quad (33.160)$$

and Q_{ii}^2 is the diagonal element of \mathbf{Q}^2

$$\mathbf{Q}^2 = -\mathbf{V}_0^T \mathbf{B}_0 \mathbf{U}_1 - \mathbf{V}_1^T \mathbf{B}_0 \mathbf{U}_1 - \mathbf{V}_1^T \mathbf{B}_1 \mathbf{U}_0 \quad (33.161)$$

33.9.3 High-Accuracy Modal Superposition for Eigenvector Derivatives

For a large-scale structure, only a small number of the first lower L modes are extracted, and the higher modes are truncated in order to reduce the computational cost. The modal superposition method may not only give inaccurate result, but also may be misleading if the truncation is considerable. In this section, we give a high-accuracy modal superposition method for derivatives of the complex mode of nonsymmetric matrices.

33.9.3.1 Improved Modal Superposition

An improved modal superposition (IMS) to reduce the computation errors by modal truncation was proposed (Lim et al., 1989). The derivatives of modes can be expressed as

$$\frac{\partial \mathbf{u}_i}{\partial \mathbf{b}} = \bar{\alpha}_{ii} \mathbf{u}_i + \bar{z}_i \quad (33.162)$$

$$\bar{z}_i = \sum_{\substack{j=1 \\ j \neq i}}^L \frac{\mathbf{v}_j^T \mathbf{F}_i}{S_i - S_j} \mathbf{u}_j + \mathbf{A}^{-1} \mathbf{F}_i + \sum_{j=1}^L \frac{\mathbf{v}_j^T \mathbf{F}_i}{S_j} \mathbf{u}_j \quad (33.163)$$

$$\mathbf{F}_i = \left(\frac{\partial \mathbf{A}}{\partial \mathbf{b}} - \frac{\partial S_i}{\partial \mathbf{b}} \mathbf{B} - S_i \frac{\partial \mathbf{B}}{\partial \mathbf{b}} \right) \mathbf{u}_i \quad (33.164)$$

where $\mathbf{A}^{-1}\mathbf{F}_i$ is the contribution of the truncated higher modes to the derivatives of modes, as given by

$$\bar{\alpha}_{ii} = -\frac{1}{2} \left(\mathbf{u}_i^T \frac{\partial \mathbf{B}}{\partial \mathbf{b}} \mathbf{u}_i + \mathbf{u}_i^T \mathbf{B} \bar{\mathbf{z}}_i + \bar{\mathbf{z}}_i^T \mathbf{B} \mathbf{u}_i \right) \quad (33.165)$$

33.9.3.2 High-Accuracy Modal Superposition

Assume that the eigenvalues are ordered according to their modular magnitude, and satisfy the following condition:

$$|S_i| < |S_j|, \quad j > L \quad (33.166)$$

The derivatives of modes can be expressed as

$$\frac{\partial \mathbf{u}_i}{\partial \mathbf{b}} = \bar{\alpha}_{ii} \mathbf{u}_i + \bar{\mathbf{z}}_i = \bar{\alpha}_{ii} \mathbf{u}_i + \mathbf{z}_{iL} + \mathbf{z}_{iH} \quad (33.167)$$

where

$$\bar{\mathbf{z}}_i = \mathbf{z}_{iL} + \mathbf{z}_{iH} \quad (33.168)$$

$$\mathbf{z}_{iL} = \sum_{\substack{j=1 \\ j \neq i}}^L \frac{\mathbf{v}_j^T \mathbf{F}_i}{S_i - S_j} \mathbf{u}_j \quad (33.169)$$

$$\mathbf{z}_{iH} = - \sum_{j=1}^K \left(\mathbf{A}^{-1} (\mathbf{B} \mathbf{A}^{-1})^{j-1} - \mathbf{U}_L ((\mathbf{S}_L)^{-1})^j \mathbf{V}_L^T \right) \mathbf{F}_i \quad (33.170)$$

Also, $\bar{\alpha}_{ii}$ can be obtained from Equation 33.165, and K denotes the number of terms used in series (Equation 33.170).

It can be shown that for $K = 1$, Equation 33.167 is equivalent to Equation 33.162.

33.9.3.3 Numerical Example

Example 33.6

Consider a 20-DoF system, as shown in Figure 33.6, with the parameters given by

$$m_1 = m_2 = \cdots = m_{19} = 2m, \quad m_{20} = m = 1.0 \text{ kg}$$

$$k_1 = k_2 = \cdots = k_{21} = 1.0 \times 10^3 \text{ N/m}$$

$$c_1 = c_2 = \cdots = c_7 = 3c, \quad c_8 = c_9 = \cdots = c_{14} = 2c$$

$$c_{15} = c_{16} = \cdots = c_{21} = c = 0.1 \text{ N sec/m}$$

	8	44.86	6.65	1.56	0.35	0.04
	12	23.76	3.23	0.37	0.11	0.02
$\partial u_1/\partial b_1$	4	72.52	15.07	8.46	1.11	0.03
	8	37.95	1.22	0.57	0.03	0.00
	12	28.54	0.52	0.03	0.00	0.00
$\partial u_1/\partial b_1$	4	63.33	9.19	1.92	0.42	0.00
	8	27.56	0.75	0.49	0.21	0.00
	12	25.00	0.47	0.15	0.01	0.00

For the purpose of comparison, the errors of the truncation modal superposition (TMS), the IMS, and the high-accuracy superposition (HAMS) in computing the derivatives of eigenvectors are listed in Table 33.7.

For the sake of simplicity, the errors of eigenvector derivatives are represented by

$$\left| \left(\frac{\partial u_i}{\partial b_j} \right)_\varepsilon - \left(\frac{\partial u_i}{\partial b_j} \right)_\alpha \right|$$

where $(\partial u_i/\partial b_j)_\varepsilon$ denotes the exact solution and $(\partial u_i/\partial b_j)_\alpha$ denotes those obtained by the three methods presented above. In the computation of the eigenvector derivatives, the parameters m_1 and m_{10} are functions of the design variable b_1 , the parameters c_8 and c_{15} are functions of design variable b_2 , and K denotes the number of terms used in series (Equation 33.170).

The results in Table 33.7 confirm that the solution accuracy of the high-accuracy modal superposition is much higher than that of the TMS and the IMS. For example, if only the first four modes are used, the errors of $\partial u_2/\partial b_1$ are 101.00 and 50.94% for the truncated modal superposition and the IMS, and the errors are reduced to about 27.27, 7.64, and 1.51% for the high-accuracy modal superposition. If the first 12 modes are used, the error of $\partial u_1/\partial b_1$ is 16.76% for the truncated modal superposition, and the errors are reduced to 0.01, 0.00 and 0.00% for the case of $K = 2, 3, 4$ in the series (Equation 33.170), where the first four modes are used, respectively.

33.9.4 Matrix Perturbation for Repeated Eigenvalues of Nondefective Systems

33.9.4.1 Basic Equation

Consider a system having repeated eigenvalues, $S_0 = S_1 = \cdots = S_{0m}$, with multiplicity m , and the corresponding right and left modal matrices

$$\mathbf{U}_{0m} = [\mathbf{u}_{01} \quad \mathbf{u}_{02} \quad \cdots \quad \mathbf{u}_{0m}] \quad (33.171)$$

$$\mathbf{V}_{0m} = [\mathbf{v}_{01} \quad \mathbf{v}_{02} \quad \cdots \quad \mathbf{v}_{0m}] \quad (33.172)$$

the remaining eigenvalues being distinct.

The repeated eigenvalues satisfy the following equations:

$$\mathbf{A}_0 \mathbf{U}_{0m} = \mathbf{B}_0 \mathbf{U}_{0m} \mathbf{S}_0 \quad (33.173)$$

$$\mathbf{A}_0^T \mathbf{V}_{0m} = \mathbf{B}_0^T \mathbf{V}_{0m} \mathbf{S}_0 \quad (33.174)$$

$$\mathbf{V}_{0m}^T \mathbf{B}_0 \mathbf{U}_{0m} = \mathbf{I} \quad (33.175)$$

$$\mathbf{u}_{0i}^T \mathbf{B}_0 \mathbf{u}_{0i} = 1 \quad (33.176)$$

If small changes are made to the parameters, we have

$$\mathbf{A} = \mathbf{A}_0 + \varepsilon \mathbf{A}_1 \quad (33.177)$$

$$\mathbf{B} = \mathbf{B}_0 + \varepsilon \mathbf{B}_1 \quad (33.178)$$

The eigenvalues and eigenvectors of the perturbed system can be expressed as power series expansions in ε :

$$\mathbf{S}_m = \mathbf{S}_0 + \varepsilon \mathbf{S}_1 + \varepsilon^2 \mathbf{S}_2 + \cdots \quad (33.179)$$

$$\mathbf{U}_m = \mathbf{U}_0 + \varepsilon \mathbf{U}_1 + \varepsilon^2 \mathbf{U}_2 + \cdots \quad (33.180)$$

$$\mathbf{V}_m = \mathbf{V}_0 + \varepsilon \mathbf{V}_1 + \varepsilon^2 \mathbf{V}_2 + \cdots \quad (33.181)$$

where

$$\mathbf{U}_0 = \mathbf{U}_{0m} \boldsymbol{\alpha} \quad (33.182)$$

$$\mathbf{V}_0 = \mathbf{V}_{0m} \boldsymbol{\beta} \quad (33.183)$$

and $\alpha_{m \times m}$ and $\beta_{m \times m}$ are to be determined coefficient matrices.

33.9.4.2 The First-Order Perturbation of Eigenvalues

The first-order perturbation diagonal matrix, \mathbf{S}_1 , of the repeated eigenvalues and the coefficient matrix, $\boldsymbol{\alpha}$, can be obtained from the equations:

$$\mathbf{W} \boldsymbol{\alpha} = \boldsymbol{\alpha} \mathbf{S}_1 \quad (33.184)$$

$$\mathbf{W}^T \boldsymbol{\beta} = \boldsymbol{\beta} \mathbf{S}_1 \quad (33.185)$$

$$\mathbf{W} = \mathbf{V}_{0m}^T (\mathbf{A}_1 - \mathbf{S}_0 \mathbf{B}_1) \mathbf{U}_{0m} \quad (33.186)$$

and the normalization conditions

$$\boldsymbol{\alpha}^T \boldsymbol{\alpha} = \mathbf{I} \quad (33.187)$$

$$\boldsymbol{\beta}^T \boldsymbol{\alpha} = \mathbf{I} \quad (33.188)$$

If matrix \mathbf{W} has no repeated eigenvalues, $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ can be uniquely determined. If \mathbf{W} has repeated eigenvalues, we must consider the higher order perturbation equations for determining $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$. Here, we assume that S_{1i} are distinct eigenvalues, that is, $S_{1i} \neq S_{1j}$ ($i \neq j$), where S_{1i} are the diagonal elements of \mathbf{S}_1 .

33.9.4.3 The First-Order Perturbation of Eigenvectors

According to the modal expansion theorem, the first-order perturbation of the right and left eigenvectors, \mathbf{U}_1 and \mathbf{V}_1 , can be expressed as

$$\mathbf{U}_1 = \mathbf{U}_{0m} \boldsymbol{\alpha} \mathbf{C}_m^1 + \mathbf{U}_A \mathbf{C}_A^1 \quad (33.189)$$

$$\mathbf{V}_1 = \mathbf{V}_{0m} \boldsymbol{\beta} \mathbf{D}_m^1 + \mathbf{V}_A \mathbf{D}_A^1 \quad (33.190)$$

where \mathbf{C}_m^1 and \mathbf{C}_A^1 are coefficient matrices which are to be determined, and \mathbf{U}_A and \mathbf{V}_A are the right and left modal matrices corresponding to the distinct eigenvalues:

$$\mathbf{C}_A^1 = (\mathbf{S}_A - \mathbf{S}_0)^{-1} \mathbf{V}_A^T (\mathbf{S}_0 \mathbf{B}_1 - \mathbf{A}_1) \mathbf{U}_{0m} \alpha \quad (33.191)$$

$$\mathbf{D}_A^1 = (\mathbf{S}_A - \mathbf{S}_0)^{-1} \mathbf{U}_A^T (\mathbf{S}_0 \mathbf{B}_1^T - \mathbf{A}_1^T) \mathbf{V}_{0m} \beta \quad (33.192)$$

The elements of matrix \mathbf{C}_m^1 can be computed by

$$C_{mij}^1 = \frac{R_{ij}^1}{\lambda_{1j} - \lambda_{1i}}, \quad i \neq j, \quad i, j = 1, 2, \dots, m \quad (33.193)$$

where R_{ij}^1 are the nondiagonal elements of \mathbf{R}^1 :

$$\mathbf{R}^1 = \beta^T \mathbf{V}_{0m}^T \mathbf{B}_0 \mathbf{U}_A \mathbf{C}_A^1 \mathbf{S}_1 + \beta^T \mathbf{V}_{0m}^T \mathbf{B}_1 \mathbf{U}_{0m} \alpha \mathbf{S}_1 + \beta^T \mathbf{V}_{0m}^T \mathbf{B}_1 \mathbf{U}_A \mathbf{C}_A^1 \mathbf{S}_0 - \beta^T \mathbf{V}_{0m}^T \mathbf{A}_1 \mathbf{U}_A \mathbf{C}_A^1 \quad (33.194)$$

$$C_{mii}^1 = \frac{-1}{\mathbf{u}_{0i}^T (\mathbf{B}_0 + \mathbf{B}_0^T) \mathbf{u}_{0i}} \left(\mathbf{u}_{0i}^T \mathbf{B}_1 \mathbf{u}_{0i} + \sum_{\substack{j=1 \\ j \neq i}}^m c_{mij}^1 \mathbf{u}_{0j}^T (\mathbf{B}_0 + \mathbf{B}_0^T) \mathbf{u}_{0i} + \sum_{j=m+1}^n c_{Aij}^1 \mathbf{u}_{0j}^T (\mathbf{B}_0 + \mathbf{B}_0^T) \mathbf{u}_{0i} \right) \quad (33.195)$$

$$D_{mij}^1 = \frac{R_{ij}^2}{S_{1j} - S_{1i}}, \quad i \neq j, \quad i, j = 1, 2, \dots, m \quad (33.196)$$

where R_{ij}^2 are the nondiagonal elements of \mathbf{R}^2 :

$$\mathbf{R}^2 = \alpha^T \mathbf{U}_{0m}^T \mathbf{B}_0 \mathbf{V}_A \mathbf{D}_A^1 \mathbf{S}_1 + \alpha^T \mathbf{U}_{0m}^T \mathbf{B}_1^T \mathbf{V}_{0m} \beta \mathbf{S}_1 + \alpha^T \mathbf{U}_{0m}^T \mathbf{B}_1^T \mathbf{V}_A \mathbf{D}_A^1 \mathbf{S}_0 - \alpha^T \mathbf{U}_{0m}^T \mathbf{A}_1^T \mathbf{V}_A \mathbf{D}_A^1 \quad (33.197)$$

$$D_{mii}^1 = Q_{ii}^2 - C_{mii}^1 \quad (33.198)$$

where Q_{ii}^2 are the diagonal elements of \mathbf{Q}^2 :

$$\mathbf{Q}^2 = -\beta^T \mathbf{V}_{0m}^T \mathbf{B}_1 \mathbf{U}_{0m} \alpha \quad (33.199)$$

33.9.5 Matrix Perturbation for Close Eigenvalues of Unsymmetric Matrices

Assume that \mathbf{S}_0 is a diagonal matrix with m close eigenvalues; $\mathbf{U}_{0n \times m}$ and $\mathbf{V}_{0n \times m}$ are the corresponding right and left eigenvectors matrices; \mathbf{S}_A is the remaining distinct eigenvalue diagonal matrix; $\mathbf{U}_{An \times (n-m)}$ and $\mathbf{V}_{An \times (n-m)}$ are the corresponding right and left eigenvector matrices. They satisfy the following equations:

$$\mathbf{A}_0 [\mathbf{U}_0; \mathbf{U}_A] = \mathbf{B}_0 [\mathbf{U}_0; \mathbf{U}_A] \text{diag}(\mathbf{S}_0, \mathbf{S}_A) \quad (33.200)$$

$$\mathbf{A}_0^T [\mathbf{V}_0; \mathbf{V}_A] = \mathbf{B}_0^T [\mathbf{V}_0; \mathbf{V}_A] \text{diag}(\mathbf{S}_0, \mathbf{S}_A) \quad (33.201)$$

$$[\mathbf{V}_0; \mathbf{V}_A]^T \mathbf{B}_0 [\mathbf{U}_0; \mathbf{U}_A] = \mathbf{I} \quad (33.202)$$

$$\mathbf{u}_{0i}^T \mathbf{B}_0 \mathbf{u}_{0i} = 1 \quad (33.203)$$

Construct the matrix $\bar{\mathbf{A}}_0$ as

$$\mathbf{A}_0 = \bar{\mathbf{A}}_0 + \varepsilon \bar{\mathbf{A}}_0 \quad (33.204)$$

where

$$\bar{\mathbf{A}}_0 = \mathbf{B}_0 [\mathbf{U}_0; \mathbf{U}_A] \text{diag}(\mathbf{S}_0 \mathbf{I}, \mathbf{S}_A) [\mathbf{V}_0; \mathbf{V}_A]^T \mathbf{B}_0 \quad (33.205)$$

$$\varepsilon \bar{\mathbf{A}}_0 = \mathbf{B}_0 \mathbf{U}_0 (\varepsilon [\delta \mathbf{S}_0]) \mathbf{V}_0^T \mathbf{B}_0 \quad (33.206)$$

$$\varepsilon [\delta \mathbf{S}_0] = \mathbf{S}_0 - \mathbf{S}_0 \mathbf{I} \quad (33.207)$$

$$S_0 = \frac{1}{m} \left(\sum_{k=1}^n S_{0i} \right) \quad (33.208)$$

Here, S_{0i} are the close eigenvalues, and S_0 is the average of S_{0i} ($i = 1, 2, \dots, m$).

It can be shown that the following equations hold:

$$\bar{\mathbf{A}}_0 \mathbf{U}_0 = \mathbf{B}_0 \mathbf{U}_0 S_0 \mathbf{I} \quad (33.209)$$

$$\bar{\mathbf{A}}_0^T \mathbf{V}_0 = \mathbf{B}_0^T \mathbf{V}_0 S_0 \mathbf{I} \quad (33.210)$$

These equations indicate that S_0 is the repeated eigenvalue with multiplicity, m , for the eigenproblem defined by Equation 33.209 and Equation 33.210, and \mathbf{U}_0 and \mathbf{V}_0 are the corresponding right and left modal matrices, respectively.

If small modifications $\varepsilon \mathbf{A}_1$ and $\varepsilon \mathbf{B}_1$ are imposed on the matrices \mathbf{A}_0 and \mathbf{B}_0 , then the eigenproblems of the perturbed system become

$$(\bar{\mathbf{A}}_0 + \varepsilon \bar{\mathbf{A}}_1) \mathbf{U} = (\mathbf{B}_0 + \varepsilon \mathbf{B}_1) \mathbf{U} \mathbf{S} \quad (33.211)$$

$$(\bar{\mathbf{A}}_0 + \varepsilon \bar{\mathbf{A}}_1)^T \mathbf{V} = (\mathbf{B}_0 + \varepsilon \mathbf{B}_1)^T \mathbf{V} \mathbf{S} \quad (33.212)$$

where

$$\varepsilon \bar{\mathbf{A}}_1 = \varepsilon \bar{\mathbf{A}}_0 + \varepsilon \mathbf{A}_1 \quad (33.213)$$

The eigensolutions of Equation 33.211 and Equation 33.212 are given by

$$\mathbf{U} = \mathbf{U}_0 \boldsymbol{\alpha} + \varepsilon \mathbf{U}_1 \quad (33.214)$$

$$\mathbf{V} = \mathbf{V}_0 \boldsymbol{\alpha} + \varepsilon \mathbf{V}_1 \quad (33.215)$$

$$\mathbf{S} = \mathbf{S}_0 + \varepsilon \mathbf{S}_1 \quad (33.216)$$

It should be noted that Equation 33.211 and Equation 33.212 are the eigenproblem for repeated eigenvalues. That is, the perturbation analysis for close eigenvalues has been transferred into that of repeated eigenvalues. Hence, the methods given by Section 33.9.4 can be used to compute \mathbf{S}_1 , $\boldsymbol{\alpha}$, $\boldsymbol{\beta}$, \mathbf{U}_1 , and \mathbf{V}_1 in Equation 33.214 to Equation 33.216.

Summary

This chapter concerns vibration in rotating machinery. Although it is impractical to totally eliminate such vibrations, it is essential that they be controlled to within acceptable limits for safe and reliable operation of such machines. The two major categories of vibration phenomena that occur in rotating machinery are forced vibration and self-excited instability. Monitoring, diagnosis and control of these vibrations requires a sound understanding of rotor dynamics in machinery. Predicting the vibration behavior of a rotating machine by analytical means has become customary in many industries. With the advent of computer technology, several computer-based programs have been developed to accurately predict the behavior of rotating machinery. Significant strides in modeling techniques have also been made over the past century to accurately represent components such as shaft sections, disks, impellers, bearings, seals, rotor dampers, and rotor–stator interactions. This has enhanced the accuracy and reliability of both analytical and computational procedures. The chapter presents useful techniques of analysis, measurement, diagnosis, and control of vibration in rotating machinery.

34.1 Introduction

Vibrations are an inherent part of all rotating machinery. Residual mass imbalance and dynamic interaction forces between the stationary and rotating components, which are practically impossible to eliminate, cause these vibrations. The challenge is to identify the source of vibration and control it to within reasonable limits. Because of economic advantages, the trend in industry has been to move towards high speed, high power, lighter and more compact machinery. This has resulted in machines operating above their first critical speeds, which was unheard of in the past. The new operating parameters have required concurrent development of vibration technology without which it is not

possible to safely and reliably operate such machinery. Industry has also come to realize that *vibration* is an essential phenomenon, which could be used to assess the performance, durability, and reliability of rotating machinery.

Engineers at different levels approach the subject of vibration in rotating machinery differently. The machinery designer has to recognize the potential sources of vibration and control them to within acceptable levels. In the past few decades, owing to the advancement in computers and modeling techniques, better understanding of the dynamics of rotating machinery, including the identification of potential sources of vibration, has been realized. This has enabled designers to accurately predict the rotordynamic behavior of machinery, allowing it to reach higher operating speeds and larger energy capacities safely and reliably.

Approaching vibration from a different perspective, the maintenance engineer uses vibration standards and guidelines to monitor the health of equipment for their timely repair and refurbishment. Reliable vibration monitoring and diagnostics techniques have moved industry into *predictive* rather than *preventive* maintenance practices, which considerably reduce plant downtimes that rely on key rotating machinery. Premature replacement of machinery components has also been minimized. The resulting financial and economic benefits provide an added incentive for the study and understanding of vibration in rotating machinery.

The vibration specialist or troubleshooter has to use his knowledge of rotordynamics and his diagnostic capabilities to solve vibration problems in rotating machinery. In most cases, it is also important to have an understanding of the interfacial dynamics of the rotating machinery with the surrounding system in order to solve a vibration problem.

From a safety and reliability standpoint, the public must be concerned with vibration in rotating machinery. Their concerns are addressed through vibration standards and guidelines. These procedures have been developed for rotating machinery by numerous organizations, both at the national and international levels. Some of these standards are industry specific and some are equipment type specific, while a number of them try to cover a wide range of rotating machinery. The objective of most of these standards is to establish and control quality, safety, durability and reliable performance of rotating machinery for the benefit of those who use or operate it.

34.1.1 History of Vibration in Rotating Machinery

Although various types of rotating machinery have been in use for many centuries, understanding of their rotordynamic behavior did not begin until 1869 (Rankine, 1869). Since that time, there has been steady growth in the development and understanding of the vibration behavior of rotating machinery. A tabulation of major historical events that have contributed to this growth is presented in [Table 34.1](#).

- All rotating machinery vibrates to some degree. For public safety and machine reliability, the vibrations have to be controlled to within acceptable limits.
- Modern trends towards more sophisticated, higher speed compact rotating machinery have contributed to the rapid development in vibration technology through a better understanding of their rotordynamics.
- Vibration technology is integrated into the areas of design, maintenance, and troubleshooting of rotating machinery.
- From a safety and reliability standpoint, the public is protected by the implementation of vibration standards and guidelines.
- The first publicly reported rotordynamic study was made in 1869.

TABLE 34.1 A Chronological Listing of Major Contributions that Have Led to the Development and Understanding of Vibration in Rotating Machinery

Year	Contributor	Description
1869	Rankine, W.J.M.	<p>He examined the equilibrium of a frictionless, uniform shaft disturbed from its initial position. The resulting recorded article is recognized to be the first on the subject of rotor dynamics. He proposed that motion is stable below the first critical speed, is neutral or indifferent at the critical speed, and unstable above the critical speed</p> <p>He also developed numerical formulae for critical speeds for the cases of a shaft resting freely on a bearing at each end and for an overhanging shaft fixed in direction at one end</p>
1883	Greenhill, A.G.	He studied the effect of end thrust and torque on the stability of a long shaft and concluded that they were both unimportant. He also obtained formulae for the cases of an unloaded shaft resting on bearings at each end and fixed in direction at each end
Circa 1890	Reynolds, O.	He extended the theory developed by Rankine and Greenhill for the case of a shaft loaded with pulleys
1893	Dunkerley, S.	<p>He developed formulae for critical speeds for loaded shafts in terms of the diameter of the shaft, weights of pulleys, the manner in which the shaft is supported, and so on, and verified them by experiment</p> <p>He postulated that any degree of unbalance will excite the shaft at the critical speed to very high amplitudes and that it is possible to operate above the first critical speed. The dependence of critical speed on the moment of inertia of the rotating pulley was identified</p>
1894	Rayleigh, J.W.S.	He developed an approximate method to calculate the natural frequency of a continuous beam with distributed mass and flexibility using the energy method
1895	DeLaval, G.	He was responsible for the first experimental demonstration that a steam turbine is capable of sustained operation above the first critical speed
1916	Timoshenko, T.	He discovered the effects of transverse shear deflection on the natural frequency of a continuous beam and applied the principle to the case of the rotating shaft
1919	Jeffcott, H.H.	<p>He examined the effect of unbalance on the whirl amplitudes and the forces transmitted to the bearings. The case of a light uniform shaft supported freely on bearings at its ends and carrying a thin pulley of mass m at the center of the span was studied. He assumed the moment of inertia of the pulley to be negligible. Using this model, later known as the <i>Jeffcott model</i>, a comprehensive theory was developed to explain the behavior of the rotor as it passed through the critical speed</p> <p>The effect of damping on the whirl amplitude, a phase change of angle π as it passes through the critical speed, and the concept of synchronous rotor whirling (precession) were introduced and explained. He also recognized that with a separation margin of 10% on either side of a critical speed, the amplitude of vibration would not be excessive. He demonstrated that it is better from the vibration point of view to design the shaft with its critical speed below the working speed rather than to have a critical speed the same proportion above the working speed. Accordingly, he explained the behavior of the De Laval steam turbine and the economic advantages of operation above the critical speed</p>
1921	Southwell, R.V. and Gough, B.S.	They found that a torque and an end thrust of constant magnitude lowers the critical speed of a rotating shaft, disproving Greenhill's earlier (1883) conclusions

(continued on next page)

TABLE 34.1 (continued)

Year	Contributor	Description
1921	Holzer, H.	He developed a numerical method to calculate torsional critical speeds and mode shapes for a multidisk rotor system
1924	Newkirk, B.L.	<p>He observed that a rotor operating at a speed above the first critical speed can enter into high, violent whirling and the center of the rotor will precess in the forward direction at a rate equal to that of the critical speed. Unlike in the case of synchronous whirling, if the speed is increased beyond the initial whirl speed, the whirl amplitude will continue to increase, eventually leading to failure. This was the first time that it was realized that nonsynchronous unstable motion can exist in a high-speed rotor</p> <p>Based on experiments, he made the following key observations on nonsynchronous whirling. The amplitude and the onset speed of whirling are independent of the rotor balance. Whirling always occurs at speeds above the critical speed, and the whirl speed is always constant at the critical speed, regardless of the rotor speed. The whirl threshold speed can vary even for machines of similar construction. Whirling occurs only in built up rotors, and not in single piece constructions. Increasing the foundation flexibility, distortion or misalignment of the bearing housings, or introducing damping to the foundation or increasing the axial thrust bearing load, increased the threshold speed of whirling</p>
1924	Kimball, A.T.	Suggested that internal friction or viscous action due to bending may cause a shaft to whirl when rotating at any speed above the first critical speed. He postulated that the nonsynchronous whirling observed by Newkirk was due to this phenomenon
1924	Newkirk, B.L.	Based on Mr Kimball's theory, he concluded that similar frictional forces are generated at the mating face between the shrunk on disk and the shaft of a built-up rotor, and the nonsynchronous whirling observed by him was due to this effect. However, he was unable to explain some of his experimental findings, in particular, the effects of bearing or foundation flexibility, damping, and misalignment
1925	Newkirk, B.L.	<p>He experienced another form of nonsynchronous whirling, similar but different to that caused by the frictional effects of a shrink-fit disk. It occurred at rotor speeds just exceeding twice the first critical speed on shafts mounted on journal bearings. He recognized that the oil in the journal bearing was responsible for the violent motion and called it <i>oil whip</i>. The whirl speed and direction of whirling were the same as that for friction induced whirling, that is, the first critical speed in the forward direction. A theory to explain how the oil film can produce the whirling motion of a journal and to account for why it took the same direction as rotation of the shaft was proposed. However, the theory does not explain why whirling does not commence until the rotor speed reaches twice the critical speed value. The influence of foundation flexibility on the rotor stability was also found to be confusing to Newkirk. In the case of friction-induced whirl, he was able to totally eliminate the rotor instability by means of a flexibly mounted bearing. When this was tried with the journal bearings, the whirl amplitudes magnified. External damping at the bearing was found to have a favorable influence on whirl amplitudes</p>
1925	Stodola, A.	He developed an iterative procedure to calculate the fundamental frequency of a vibrating system based on an assumed mode shape
1927	Stodola, A.	He provided an explanation and formulae for the gyroscopic moment effect on the critical speed of a rotor. He also introduced the notion of synchronous and nonsynchronous reverse precession of a rotor under specific conditions

TABLE 34.1 (continued)

Year	Contributor	Description
1933	Robertson, D.	In order to understand oil whip, he studied the stability of the ideal 360° infinitely long journal bearing, and erroneously concluded that the rotor will be unstable at all speeds and not only at speeds above twice the critical speed value
1933	Smith, D.M.	He studied the case of unsymmetrical rotors on unsymmetrical supports and obtained four different critical speed values in comparison to the single value for a symmetrical system. He also discussed the presence of additional critical speeds due to gyroscopic effects of large disks
1944	Myklestad, N.	A lumped parameter transfer matrix method to calculate natural frequencies for airplane wings was developed by him
1945	Prohl, M.	He developed a lumped parameter transfer matrix method for calculating critical speeds of flexible rotors
1953	Poritsky, H.	Using the small displacement theory, he derived a radial stiffness coefficient for the journal bearings and analyzed the rotor behavior under oil whirl conditions. He concluded that the rotor was stable below twice the critical speed and indicated that increasing the rotor or bearing flexibility will reduce the threshold speed of instability. He also proposed a stability criterion for a rotor based on the bearing and rotor stiffness
1953	Miller, D.F.	He introduced a solution to the steady-state forced vibration problem, for a beam or rotating shaft on damped, flexible end supports. The response of the rotor to an unbalance force and the damped resonance frequencies are calculated by this method
1955	Pinkus, O.	He investigated oil whirl in various journal bearing types and made the following major conclusions. The unbalance of the rotor has minimal effect on stability. The threshold of instability occurs at approximately twice the first critical speed of the rotor. In the unstable region, the whirl frequency remained constant at the first critical speed, irrespective of the shaft rotating speed. At speeds nearly equal to three times the first critical speed, whipping motion stops with a heavy shaft rotor, whereas with a light shaft rotor it does not cease. High loads, high viscosity, flexible mountings, and bearing asymmetry favor stability
1958	Lomakin, A.	The influence of the dynamic characteristics of seals on the critical speeds and stability of pump rotors were introduced by him
1958	Thomas, H.	He proposed that an eccentric turbine rotor would generate a destabilizing force due to the circumferential variation in clearance
1966	Gunter, E.J. Jr.	He combined the different theories on whirling developed by the rotor dynamist and the bearing specialist, and elegantly explained some of the conflicting experimental evidence gathered thus far. He emphasized the importance of considering the combined effects of rotor parameters and the bearing and foundation characteristics on rotor stability, and developed more comprehensive criteria for self-excited whirl instability
1969	Black, H.F.	He provided a comprehensive analysis of annular pressure seals on the vibrations of pump rotors
1970	Ruhl, R.	He introduced finite element models for flexible rotors for calculating rotor critical speeds and mode shapes. These models did not take into account gyroscopic effects and axial loading
1974	Lund, J.	A transfer matrix method to calculate damped critical speeds of a rotor taking into account the cross coupling terms as well were introduced by him
1976	Nelson, H. and McVaugh, J.	They extended the finite element model of a rotor to account for rotary inertia, gyroscopic effect, and axial loads

Year	Contributor	Description
1978–1980	Benckert, H. and Wachter, J.	A method to calculate flow induced spring constants for labyrinth gas seals and the use of <i>swirl breaks</i> to reduce the destabilizing force caused by tangential velocity in labyrinth seals was introduced by them
1980	Nelson, H.	He further developed a finite element model of a rotor to include shear deflection and axial torque effects
1980	Brennen, C. et al.	They recognized the presence of substantial shroud forces, which influences the rotor dynamics of a pump
1986	Muszynska, A.	She demonstrated that oil whirl occurs at about one-half the running speed in a vertical rotor. With further increase in speed, oil whip will commence when the whirl frequency approaches the critical speed of the rotor

34.2 Vibration Basics

The vibration phenomena that manifest in rotating machinery can be divided into two major categories: *forced vibration* and *self-excited instability*. A stimulus or a source of excitation is required to initiate and sustain vibratory motion in a rotor. When the stimulus is a forcing phenomenon such as mass unbalance, it will produce forced flexural vibration in the rotor analogous to linear forced vibration response in a simple spring–mass system. On the other hand, self-excited vibration (instability) does not require a forcing phenomenon for its initiation or sustenance. A description of these phenomena is given next.

34.2.1 Forced Vibration

A rotating force vector (unbalance), a steady directional force (gravity), or a periodic force (pump impeller/diffuser interface action), will cause forced vibration in a rotating machine. The response of the rotor will depend on the nature of the forcing function and how it relates to rotor characteristics. The rotor responses to the most common excitation phenomena are examined below.

34.2.1.1 Unbalance Response — Synchronous Whirling

As an introduction to the theory on rotating machinery vibration and understanding unbalance response, it is most appropriate to examine Jeffcott’s (1919) rotor, which is a simple model that has many of the basic characteristics of more complex rotating machinery. The Jeffcott rotor represents a massless elastic shaft supported freely in bearings at its ends and carrying a disk of mass m at the center of its span. The mass center of the disk is eccentric to its geometric center by a distance e . Refer to Figure 34.1.

C = geometric center of the disk
 β = phase angle

FIGURE 34.1 Jeffcott rotor.

M = mass center of the disk
 c = viscous damping coefficient of on the rotor
 O = bearing center
 r = deflection of rotor from origin
 θ = angle of precession
 k = shaft stiffness
 ω = angular velocity of the rotor = $\dot{\theta} + \dot{\beta}$

Whirling is defined as the angular velocity of rotation of the rotor geometric center (c) or the time derivative ($\dot{\theta}$) of the angle of precession (θ) (also see Chapter 32). *Synchronous whirling* is when the rate of whirling, $\dot{\theta}$, is equal to the total angular velocity, ω , of the system.

Applying Newton's Laws of motion to the rotor, the differential equations of motion in polar coordinates (r, θ) are obtained as

$$\ddot{r} + \frac{c}{m}\dot{r} + \left(\frac{k}{m} - \dot{\theta}^2\right)r = e\omega^2 \cos \beta \quad (34.1)$$

$$r\ddot{\theta} + \left(\frac{c}{m}r + 2\dot{r}\right)\dot{\theta} = e\omega^2 \sin \beta \quad (34.2)$$

For a steady-state condition, the values of r , β , $\dot{\theta}$, and ω are constant. For synchronous whirling, Equation 34.1 and Equation 34.2 reduce to

$$\left(\frac{k}{m} - \omega^2\right)r = e\omega^2 \cos \beta \quad (34.3)$$

$$\frac{c}{m}\omega r = e\omega^2 \sin \beta \quad (34.4)$$

From Equation 34.3 and Equation 34.4

$$r = \frac{e\omega^2}{\sqrt{\left(\frac{k}{m} - \omega^2\right)^2 + \left(\frac{c\omega}{m}\right)^2}} \quad (34.5)$$

$$\beta = \tan^{-1} \frac{c\omega}{m\left(\frac{k}{m} - \omega^2\right)} \quad (34.6)$$

$$F = \frac{kr}{2} = \frac{ke\omega^2}{2\sqrt{\left(\frac{k}{m} - \omega^2\right)^2 + \left(\frac{c\omega}{m}\right)^2}} \quad (34.7)$$

Using the following relationships:

$$\omega_N = \sqrt{\frac{k}{m}} \text{ — Natural frequency of rotor without damping}$$

$$c_{cr} = 2\sqrt{km} \text{ — Critical damping coefficient}$$

$$\zeta = \frac{c}{c_{cr}} \text{ — Damping ratio}$$

Equation 34.6 and Equation 34.7 are reduced to the following nondimensional form:

$$\frac{r}{e} = \frac{2F}{ke} = \frac{(\omega/\omega_N)^2}{\sqrt{(1 - (\omega/\omega_N)^2)^2 + (2\zeta\omega/\omega_N)^2}} \quad (34.8)$$

$$\beta = \tan^{-1} \frac{2\zeta(\omega/\omega_N)}{(1 - (\omega/\omega_N)^2)} \quad (34.9)$$

FIGURE 34.2 Jeffcott rotor response with mass eccentricity — amplification vs. speed.

Figure 34.2 is a graphical representation of the unbalance response of the rotor as a function of rotating speed, ω . Upon examination of the phase relationship, it is important to note that the phase angle, β , changes from approximately 0° at low speed to values approaching 180° at the higher speed. At ω_N , $\beta = 90^\circ$. A pictorial illustration of this phenomenon is given in Figure 34.3.

FIGURE 34.3 Jeffcott rotor response to unbalance — phase angle vs. speed.

For the case of zero damping, when $\omega = \omega_N$, the rotor deflection and the bearing forces are unbounded. For all other cases, the rotor deflection and the bearing forces are bounded, and their amplitude depends on the damping ratio. If a shaft is quickly accelerated through its critical speed to a higher working speed, then there may not be enough time for large rotor deflection to take place. At high speeds, $\omega \gg \omega_N$, the amplitude of the rotor deflection decreases and approaches the value e , the eccentricity of the rotor.

The critical speed, ω_{cr} , of a rotor in the general case, is the speed at which the rotor deflection amplitude or the force amplitude transmitted to the bearings is a maximum.

This implies that, at $\omega = \omega_{cr}$

$$\frac{dr}{d\omega} = \frac{dF}{d\omega} = 0$$

Using Equation 34.8, the following relationship between the natural frequency of the rotor and its critical speed is derived:

$$\omega_{cr} = \frac{\omega_N}{\sqrt{1 - 2\zeta^2}} \quad (34.10)$$

From Equation 34.10, it is evident that the critical speed of a rotor is not a fixed value and is dependent on the degree of rotor damping. When $\zeta = 1/\sqrt{2}$, the system is said to be critically damped.

It is important to note that rotor response to unbalance (or imbalance) is recognizable and controllable. The amplitude of the force transmitted to the bearing can be reduced by operation at speeds above the critical speed, reducing unbalance, increasing viscous damping, and avoiding operation close to critical speeds.

34.2.1.2 Shaft Bow

A rotor with a bent shaft will behave in a similar manner to a rotor with an eccentric mass (Ehrich, 1999). At high rotor speeds ($\omega \gg \omega_{cr}$), the shaft will tend to correct the bow as illustrated in Figure 34.4. When shaft bow is combined with mass eccentricity, unique behavior patterns are produced depending on the phase angle between the bow and the eccentric mass (Childs, 1993).

FIGURE 34.4 Jeffcott rotor response with shaft bow — amplification vs. speed.

34.2.1.3 Gravity Critical

A special case of synchronous whirling may occur in certain types of horizontal rotors due to the gravitational force. It is a secondary critical speed commonly called the *gravity critical*, which can occur in a very heavy lightly damped rotor. The critical speed will occur at approximately half the natural frequency of the rotor and its amplitudes of deflection at the critical speed are bounded and approximately twice the static deflection of the rotor (Gunter, 1966).

34.2.1.4 The Influence of Rotor Inertia and Gyroscopic Action

The effect of rotor inertia is ignored in the Jeffcott model. However, in practice, it is recognized that rotor inertia and gyroscopic action has an influence on the natural frequencies, critical speeds, and unbalance response of the rotor, including reverse whirling. In the case of the natural frequency of the rotor (zero speed), the diametral or rotary inertia provides an additional natural frequency associated with the rotational degree of freedom (DoF). Also, the inertia effect lowers the first natural frequency (Childs, 1993). In the rotating case, the effect of inertia generates both forward and reverse whirling critical speeds (Childs, 1993). These forward whirling critical speeds tend to be higher (stiffening effect) and the reverse whirling critical speed lower than the natural frequency of the rotor. At the forward critical speeds, large amplitude whirling motion due to imbalance occurs, whereas the reverse critical speeds are insensitive to imbalance of the rotor.

34.2.1.5 Rotor Housing Response across an Annular Clearance

If the rotor deflection due to imbalance exceeds the uniform annular gap, continuous contact would occur between the rotor and stator resulting in coupled motion between the rotor and stator (Childs, 1993). For low contact frictional forces, synchronous forward whirling driven by the imbalance forces will occur. If the contact friction force is large enough to prevent slipping between the rotor and stator, reverse whirling will take place. For the case of synchronous forward whirling in a certain range of running speeds, instability will occur due to engagement between the rotor and stator (Black, 1968). The zones of instability depend on the coupled natural frequency of the rotor and stator and the degree of rotor deflection with respect to the annular gap.

34.2.1.6 Effect of Nonlinearity and Asymmetry on Forced Vibration Response

The foregoing analysis has assumed that stiffness and damping are linear and symmetric and the resulting forces are proportional to the deflection and velocity of the rotor. However, in reality, rotating machinery components have inherent nonlinearities and asymmetries that can have a profound influence on their rotordynamic behavior. At large amplitudes of motion, stiffness and damping coefficients become nonlinear and result in modifying the response amplitude and critical speeds of the rotor. Nonlinearity in the support stiffness will introduce considerable distortion to the otherwise simple harmonic vibration behavior of a purely linear system. The stiffness and damping coefficients of the bearings and their supports are asymmetric in most cases, in particular in horizontal machines. As a result, the forced vibratory responses in the two principal directions are different and can behave independent of each other. Each principal direction will display a critical speed unique to itself. Ehrich (1999) has presented a discussion on how nonlinearity and asymmetry of stator systems influence forced vibration response.

The influence of rotor stiffness asymmetry and inertia asymmetry on rotor stability is discussed in Section 34.2.3.

34.2.2 Self-Excited Vibration

Instability (nonsynchronous whirling) is a self-induced excitation phenomenon, sometimes described as *sustained transient motion*, that can occur in rotating machinery. At the inception of instability, the rotor deflection will continue to build up with increase in speed, whereas in the case of a critical speed resonance, the amplitude of the deflection reaches a maximum value and then decreases. If the rotor speed is increased above the instability threshold speed, the large amplitudes of motion will normally

FIGURE 34.5 Rotor instability — general case.

result in damage to the machine. Unlike forced flexural vibration, rotor instability is self-induced and does not require a sustained forcing phenomenon to initiate or maintain the motion. It is known to occur only in machines operating at speeds well above the critical speeds of the rotor. Furthermore, the rotor whirling speed is different to the rotor speed (nonsynchronous whirling), and it is identical to the critical speed irrespective of the rotor speed.

In general, the rotor instability is associated with the existence of a tangential force vector, F_θ , acting at right angles to the deflection vector and directly opposing the damping force vector, as illustrated in Figure 34.5. The nature of F_θ is such that its magnitude increases proportionately with the rotor deflection. At the point where F_θ equals the external damping force, rotor instability will commence due to the nullification of the stabilizing force. This will produce a whirling motion of ever increasing amplitude. Several phenomena inherent in the rotor system that generates such tangential force vectors have been identified and are discussed below. Rotordynamists believe that there still remain more such phenomena to be discovered.

34.2.2.1 Internal Friction Damping

This type of instability was first experienced in the early 1920s in blast furnace compressors made by the General Electric Company. These machines were subject to occasional fits of violent vibration. Newkirk (1924) carried out a series of experiments to understand the unusual behavior of these machines. Based on the *internal friction theory* of Kimball (1924), Newkirk (1924) concluded that the interfacial friction damping forces at the disk shaft interface caused the subsynchronous whirling.

In order to understand the internal friction damping phenomena let us examine the shaft stresses in the whirling Jeffcott rotor (Figure 34.1). Figure 34.6 is a cross section of the shaft disk interface. Owing to its deflection, all of the fibers in the right half of the cross section are in tension, T_e , and those in the left half are in compression, C_e . These fiber stresses tend to straighten the shaft and produce a restoring force, F_r , which opposes the centrifugal force, $m\dot{\theta}r$. Furthermore, a set of frictional forces are generated at the shaft disk interface due to stretching and compression of the fibers. The fibers in the bottom lower half will be stretched and are under frictional tension, T_f , and those in the upper half are being compressed under frictional compression C_f . Similarly to the reaction force, F_r , produced from right to left by T_e and C_e , a reaction force, F_θ , from bottom to top will be produced by the frictional stresses T_f and C_f . The disturbing force, F_θ , is in the same direction as the whirling motion and as a result will increase as

FIGURE 34.6 Internal friction damping forces acting on a rotor.

the whirling motion increases. The force, F_θ , will oppose the external damping force, $c\dot{\theta}r$. At the threshold of instability, the two forces nullify each other. It is also known that the frequency of whirling, $\dot{\theta}$, at the threshold of instability equals the natural frequency, ω_n , of the rotor. Mathematically it can be expressed as follows:

$$F_\theta = c_i r (\omega - \dot{\theta}) \quad (34.11)$$

where c_i is the rotor internal damping coefficient:

$$c\dot{\theta}r = c_i r (\omega - \dot{\theta}) \quad (34.12)$$

$$\dot{\theta} = \omega_N \quad (34.13)$$

Equation 34.12 and Equation 34.13 yield the following relationship between the threshold speed of instability, the first critical speed, and the damping factors (both internal and external):

$$\frac{\omega}{\omega_N} = 1 + \frac{c}{c_i} \quad (34.14)$$

34.2.2.2 Tip Clearance Excitation (Alford's Force, Steam Whirl)

Thomas (1958) investigated the instability of steam turbines and suggested that nonsymmetric radial clearances caused by an eccentric rotor could result in destabilizing forces, and called them *clearance excitation forces*. Subsequently Alford (1965) discovered a similar phenomenon in aircraft gas turbines and, as a result, the destabilizing forces are sometimes referred to as *Alford forces* in North America.

The destabilizing force is created as a result of the variation in the gap between the blade tip and the stator. When the gap decreases, the leakage decreases and consequently the efficiency increases, resulting in a torque higher than the average torque produced by a uniform gap. When the gap increases, there is a corresponding decrease in the torque relative to the average. The variation in torque produced by the eccentricity results in a tangential force, which is normal to the radial deflection and is in the direction of the whirling motion as shown in Figure 34.7. Furthermore, it has been illustrated that the magnitude of the resulting force increases proportionately with the increase in rotor deflection, that is, the decrease

FIGURE 34.7 Tip clearance excitation (Alford forces).

in the gap. The resulting force is a destabilizing force that will oppose the external damping force, and at some point when they balance each other, rotor instability will occur. A detailed analysis of the tip clearance forces has been made by Urlichs (1977).

34.2.2.3 Impeller Diffuser Excitation Forces

Instability experienced in centrifugal compressors provides a strong suspicion that impeller–diffuser interaction phenomena are involved in the development of destabilizing forces. However, to date, no satisfactory destabilizing mechanism or source involving impellers has been identified. In the last two decades there have been several studies related to rotordynamic forces arising from shrouded centrifugal pump impellers, but very little work has been done on compressor impellers. The destabilizing force arising from the impeller–diffuser/volute interaction of a pump has been determined to be relatively small (Jery et al., 1984; Bolleter et al., 1985; Adkins and Brennen, 1986; Ohashi et al., 1986). The major portion of the destabilizing force is known to be generated in the narrow gap region between the casing and shroud of the impeller (Childs, 1986; Bolleter et al., 1989; Baskharone et al., 1994; Moore and Palazzolo, 2001). In the case of centrifugal compressors, an empirical method to determine stability of multistage machines has been proposed (Kirk and Donald, 1983). The stability maps proposed by them for flow through and back-to-back centrifugal compressors are shown in Figure 34.8 and Figure 34.9.

34.2.2.4 Propeller Whirl

Propeller whirl (Taylor and Browne, 1938; Houbolt and Reed, 1961) is another form of instability which occurs in aircraft rotors when there is a mismatch in the angular velocity vector of the propeller and the linear velocity vector of the aircraft. This angular mismatch results in the generation of a moment whose vector has a component of significant magnitude, which contributes to the instability of the

FIGURE 34.8 Proposed stability map for flow through centrifugal compressors. (Source: Rotor Dynamical Instability, 1983. With permission.)

propeller (Vance, 1988). Its magnitude is proportional to both the angular mismatch and the linear speed of the aircraft. With increasing speed, the magnitude of the destabilizing moment will exceed the rotor viscous damping moment and result in propeller instability (refer to Figure 34.5). Since the propeller is supported only from one end, the whirling motion is conical and is found to be in the reverse direction to propeller rotation. The instability is sensitive to the velocity and density of the air and not a function of the torque of the machine.

34.2.2.5 Fluid Trapped in a Hollow Rotor

Wolf (1968) has demonstrated that trapped fluid inside a hollow rotor can produce a force component tangential to the whirl orbit due to viscous drag forces. Under subsynchronous whirling speeds, this force component acts in the same direction of whirling motion and its magnitude is proportional to the rotor deflection. With reference to Figure 34.5, this force has all the markings of a destabilizing force, which can produce instability in the rotor. The threshold speed of instability is reached when the whirling speed equals the first critical speed of the rotor. It has been shown (Ehrich, 1999) that, at the threshold of instability, the rotor speed is less than twice the first critical speed. This results in a ratio of whirl speed to rotor speed in the range of 0.5 to 1.0.

34.2.2.6 Dry Friction Rubs

In Section 34.2.1.5, a dry friction rub situation was identified, where slipping was prevented between the rotor and stator under contact conditions. The contact was made possible by the deflection of the rotor

FIGURE 34.9 Proposed stability map for back-to-back centrifugal compressors. (Source: Rotor Dynamical Instability, 1983. With permission.)

due to unbalance forces. When contact is made between the rotor and stator, Coulomb friction produces a tangential force in the direction opposite to shaft rotation. Since the frictional force prevents slipping, whirling in the reverse direction to rotation occurs. The whirling speed is equal to $r\omega/C$, where r is the radius of the rotor, C the radial gap, and ω the speed of the rotor. Since the frictional force is in the same direction of whirling, it will cause the magnitude of whirling to increase, resulting in further increase of the frictional force. When the magnitude of this force exceeds the viscous damping force, rotor instability will occur. Another possibility is for the dry friction whirling speed to approach the coupled natural frequency of the rotor and stator, in which case unstable motion termed *dry friction whipping* takes place (Ehrich, 1999).

In addition to the case described above, dry friction rubs can occur in journal bearings, seals, wear rings, or any situation where a small clearance between a rotor and stator exists. The inadvertent closure of the clearance due to unbalance or lack of proper lubrication can initiate dry friction rub induced instability in these cases as well.

34.2.2.7 Torque Whirl/Load Torque

When the rotor disk axis is not aligned with the bearing axis, as in the case with an overhung rotor, Vance (1988) has shown that nonsynchronous whirling (torque whirl) can occur as a result of the misalignment between the load torque and the driving torque. His findings are based on the analysis of a simple

rotor model. It appears that torque whirl instability can occur only in the case of long slender shafts with high-load torque values. The practical implications of this theory are still to be fully explored.

34.2.2.8 Oil Whirl/Whip

Newkirk and Taylor (1925) first experienced shaft whipping due to oil action in journal bearings during their investigation into internal friction induced whirling of rotors. They found that under certain conditions, a rotor mounted on journal bearings whipped when the rotor was running at any speed above double the critical speed; the whirling motion was in the forward direction and its speed matched the critical speed of the rotor. He provided a qualitative explanation of the phenomenon based on the fact that the oil film rotates at half the velocity of the shaft due to friction drag. Hence, for rotational speeds near twice the critical speed, the oil film provides the stimulus as its speed matches the critical speed value resulting in large displacements and whipping. Others have also drawn similar conclusions based on the suggestion of an oil wedge rotating at half speed, or rotating fluid force fields at half shaft speed. However, the foregoing fails to explain why oil whip persists at speeds greater than twice the critical speed. Ehrich (1999) has also provided a qualitative explanation for oil whirl based on the general theory of rotor instability.

Although a comprehensive explanation of the physical phenomena of oil whirl is still outstanding, numerous analytical models to identify where it could be encountered have been suggested. Gunter (1966) has analytically demonstrated that the instability in a rotor supported on journal bearings can be attributed to the cross coupling bearing coefficients. As a result, most of the research on oil whirl instability has narrowed to accurate estimation of bearing cross coupling coefficients.

34.2.2.9 Influence of Bearings and Supports on Rotor Instability

The results of the Jeffcott model can be easily adopted to include bearing stiffness and bearing support stiffness effects, provided they are both linear and circumferentially symmetric (isotropic). For this particular case, the rotor stiffness, k , is the equivalent stiffness resulting from the series connection of the shaft, bearings, and support stiffness. The resulting values for ω_N and ω_{cr} will be less than those for the simply supported Jeffcott model. This will result in lowering the threshold speed of instability.

If the bearing stiffness or the bearing-support stiffness is not symmetric (orthotropic) then it can be shown (Childs, 1993) that the threshold speed of instability is increased and the maximum amplitude of deflection of the rotor is reduced in comparison to the case with symmetric bearings.

The effect of damping at the bearings or at the bearing-support is very similar to the influence of stiffness. It reduces the amplitude of the synchronous rotor response at the critical speed, and elevates the threshold speed of instability. However, there is a limit to the amount of damping that can be applied. Excessive damping causes a reduction in stability (Childs, 1993).

The mass of the bearings plays a significant role on rotor stability. If the bearing mass is significantly larger than the rotor mass, the threshold speed of instability is lowered.

34.2.3 Parametric Instability

The instability phenomena described in Section 34.2.2 can be represented by linear differential equations where the system parameters such as mass, inertia, stiffness, damping, and natural frequency are assumed to be constants. There is another subcategory of self-excited motion, referred to as *parametric instability*, since it is induced by the periodic variation of the system parameters such as inertia, mass, and stiffness. A discussion of the more common forms of this phenomenon follows.

34.2.3.1 Shaft Stiffness Asymmetry

If the shaft of a rotor contains a sufficient level of stiffness asymmetry in the two principal axis of flexure, rotor instability could occur. Smith (1933) investigated the rotor behavior under unsymmetrical flexibility of the bearing supports and unsymmetrical transverse flexibility of the shaft, taking into consideration the damping effects as well. The following conclusions were derived based on his investigation:

In the presence of stiffness asymmetry, the onset speed of internal-friction induced instability is lowered.

When there is no external damping, the rotor becomes unstable at all speeds between the two undamped natural frequencies in the two orthogonal directions. However, if external damping is significant, parametric instability may be eliminated.

Within the unstable range, the whirling motion is in the forward direction and is synchronous with the shaft speed. Further, unlike in the case of internal-friction induced instability; it is theoretically possible to run through parametric instability. This makes parametric instability quite similar to the case of unbalance response.

When the asymmetric rotor is acted upon by a transverse disturbing steady force such as gravitational force, the rotor whirls at twice the speed of the shaft. This motion exhibits a resonant increase in amplitude at a speed that is approximately half the mean of the two natural frequencies.

34.2.3.2 Rotor Inertia Asymmetry

Crandall and Brosens (1961) analyzed the parametric excitation of a rotor with nonsymmetrical principal moments of inertia. Their results indicate that the rotor behavior is very similar to the case of rotors with stiffness asymmetry described in Section 34.2.3.1, and parametric instability over similar speed ranges occurs.

34.2.3.3 Pulsating Torque

Constant torque acting on a rotor is known to lower its critical speeds because they effectively reduce the rotor's lateral stiffness. A pulsating torque introduces lateral vibrations and instabilities into a rotor. When a combination of a pulsating and constant torque is applied to a rotor, it will induce unstable lateral vibrations in a specific range of rotor speeds and certain combinations of torque amplitudes. In the region of unstable lateral motion, the whirling speed of the rotor will coincide with the first critical speed of the rotor regardless of the rotor speed or the frequency of the pulsating torque. At rotor speeds outside the unstable region, the whirling speed of the rotor will be coincident with the pulsating torque frequency.

34.2.3.4 Pulsating Longitudinal Loads

Pulsating axial forces on a shaft that are in the order of magnitude of the buckling load will effectively cause a periodic variation in its lateral stiffness. This will result in a proportionate reduction of the lateral natural frequency of the shaft. Therefore, pulsating axial loads are capable of inducing parametric instability in a shaft for both the rotating and the stationary cases.

34.2.3.5 Nonsymmetric Clearance Effects

Bentley (1974) recognized that large subsynchronous whirling can occur in rotating machinery due to certain types of nonsymmetric clearance conditions. One such condition is when a rotor's whirling motion causes rubbing with a stationary surface over a portion of the rotor orbit. This effectively results in an increase in the rotor stiffness during the contact portion of the orbit, producing a periodic variation in rotor stiffness during each cycle. Another situation that produces cyclic variation in rotor stiffness can occur in the case of a rotor supported on antifriction bearings mounted with a clearance fit to the housing. The cyclic variation of the effective rotor stiffness produces a subsynchronous whirling motion at exactly half the rotational speed. Occasionally, whirling at one third and one fourth the running speed has also been observed by Childs (1993). Instability will occur when the whirling speed corresponds to a critical speed of the rotor.

34.2.4 Torsional Vibration

Rotating machinery with rotors that have relatively large moments of inertia are susceptible to torsional vibration problems. Torsional vibration is an oscillatory angular motion that is superimposed on the steady rotational motion of the rotor. In practice it can easily go undetected, as standard vibration

monitoring equipment is not geared to measure torsional vibration. Special equipment must be used to detect torsional vibration in rotating machinery. Since the introduction of electric motor variable frequency drives (VFD), the incidence of field torsional vibration problems has increased. This has been attributed to the inherent torsional excitation forces present in current designs of VFDs. An added complication when using VFDs, as compared with using fixed speed drives, is the requirement of eliminating torsional natural frequencies over a wider speed range. Large synchronous electric motors are known to produce a large pulsating torque at a frequency that changes from twice the line frequency at the start, down to zero at the synchronous operating speed. In this case, any torsional natural frequency between zero and twice the line frequency may be subject to excitation. Most industries have come to recognize that torsional vibration is a potential hazard, and therefore, needs to be investigated at the design stage of rotating machinery. Several standard design specifications now require that torsional analysis is part of the design procedure.

The standard design practice in modeling the system for torsional analysis has been to calculate the undamped eigenvalues of the rotor as a free body in space. This practice is acceptable for most types of rotating machinery since the torsional stiffness and damping of bearings is insignificant. Also, in most cases, the torsional damping of the rotors itself is extremely low. Although the absence of damping is favorable from an analysis point of view, it makes it extremely difficult to eliminate a torsional vibration problem when encountered. This deficiency has been partly addressed with the introduction of several new lines of couplings that have a significant degree of torsional damping. Although not commonly used in rotating machinery, several torsional dampers such as the Lanchester damper have been developed for use on reciprocating machines. Dampers of similar design could be developed for use in rotating machinery to solve torsional vibration problems.

The torsional critical speeds of a simple rotor with one or two DoFs can be calculated by analytical methods. Numerical methods are used to calculate critical speeds and mode shapes of more complex systems with higher DoF. The Holzer numerical method (Holzer, 1921) described in Section 34.3.1.11 is one of the common methods used for these analyses.

- The two major categories of vibration phenomena that occur in rotating machinery are forced vibration and self-excited instability.
- Parametric instability is a special case of self-excited instability where some of the normally constant parameters vary, influencing rotor motion.
- Torsional vibrations are similar to lateral vibrations but occur in the planes perpendicular to the shaft axis.

34.3 Rotordynamic Analysis

Rotordynamic analysis is a part of current design procedures for rotating machinery that is carried out to predict the vibration behavior during operation of the machine. Potential problems are identified and eliminated by analytical means well before the manufacturing of components is begun. Furthermore, when a machine in operation displays unusual vibration behavior, analytical means are employed to study, identify, and help resolve the problem. In order for the analysis to be useful, it must be accurate and cost-effective.

During the last 100 years, several analytical procedures have been developed to understand the vibration behavior of rotating machinery. Some of these techniques are of historical interest only, and their usefulness in practical systems is very limited. With the advent of computer technology and advanced modeling techniques, several computer-based procedures have been developed to predict the vibration behavior of rotating machinery quite precisely. Of the most commonly used procedures, two are based on the lumped-parameter model where the distributed elastic and inertial properties are

represented as a collection of rigid bodies connected by massless elastic beam elements. These two procedures are the transfer matrix formulations introduced by Myklestad (1944) and Prohl (1945), and the direct stiffness matrix formulations proposed by Biezeno and Grammel (1954). Ruhl and Booker (1972) introduced the third commonly used method, based on the finite element analysis (FEA) model in which the rotor is represented as an assemblage of elements with distributed elastic and inertial properties. Several of the well-known procedures are discussed next, some of them for historical significance.

34.3.1 Analysis Methods

34.3.1.1 Rankine's Numerical Method

Rankine (1869) proposed that, for a shaft of a given length, diameter, and material, there is a limit of speed, and for a shaft of a given diameter and material, turning at a given speed, there is a limit of length, below which centrifugal whirling is impossible. The limits of length and speed depend on the way the shaft is supported. The critical speed of the shaft is given by the following equation:

$$\omega = \frac{k(Hg)^{1/2}}{b^2} \quad (34.15)$$

where

ω = critical speed in rad/sec

k = radius of gyration of the cross section of the shaft

g = acceleration due to gravity

H = modulus of elasticity expressed in units of height of itself ($H = E/\rho$)

E = Young's modulus

ρ = density of the material

l = shaft length

$b = l/\pi$ for a simply supported shaft

$b = l/0.595\pi$ for an overhanging shaft

34.3.1.2 Greenhill's Formulae

Greenhill (1883) introduced the following differential equation of motion for a uniform shaft slightly deformed from straightness by centrifugal whirling:

$$\frac{d^4 y}{dx^4} - \frac{m\omega^2}{gEak^2} y = 0 \quad (34.16)$$

The general solution to Equation 34.16 is given by

$$y = B \cosh \mu x + A \cos \mu x \quad (34.17)$$

where

$$\mu^4 = m\omega^2/gEak^2$$

m = weight of the shaft per unit length

ω = rotational speed

a = cross-sectional area of the shaft

The constants A and B depend on the boundary conditions at the support locations.

34.3.1.3 Reynolds' Equations

Reynolds extended the differential equation of motion for a uniform rotating shaft (Equation 34.16) to include shafts loaded with pulleys (disks) and for multispan rotors (Dunkerly, 1894).

At a bearing support, the difference in shear force must equal the bearing load P :

$$\frac{dM_r}{dx} - \frac{dM_l}{dx} = P \quad (34.18)$$

where M_r and M_l are bending moments in the right (r) and left (l) sides of the load.

At a load consisting of a revolving weight, W , the above equation becomes

$$\frac{dM_r}{dx} - \frac{dM_l}{dx} = \frac{W}{g} \omega^2 y \quad (34.19)$$

A further equation may be obtained by considering the *centrifugal couple* (gyroscopic moment) as given by

$$M_r - M_l = \omega^2 I' \frac{dy}{dx} \quad (34.20)$$

where I' = moment of inertia of the pulley.

The solution to Equation 34.20 is given by

$$y = A \cosh mx + B \sinh mx + C \cos mx + D \sin mx \quad (34.21)$$

The values of A , B , C , and D will depend on the boundary conditions between any two singular points.

34.3.1.4 Dunkerley Method

When considering the effects of the pulleys and the shaft together, the formulae derived by Reynolds were found to be limited for practical purposes. Dunkerly (1894) proposed an empirical method to consider the effects of the shaft and each of the pulleys separately, and then combine them using the following formula to obtain the critical speed of the rotor:

$$\frac{1}{\omega_c^2} = \frac{1}{\omega_s^2} + \sum_{i=1}^n \frac{1}{\omega_i^2} \quad (34.22)$$

where

ω_c = critical speed of the rotor

ω_s = critical speed of the shaft alone

ω_i = critical speed of the i th disk on a weightless shaft

In the case of the unloaded shaft, the critical speed, ω_s , is given by the following formula

$$\left(\frac{m\omega_s^2}{gEI} \right)^{1/4} l = a \quad (34.23)$$

where

I = sectional inertia of shaft

l = length of the span

a = a coefficient dependent on the manner of support of the shaft

The critical speed of the rotor ω_i with a single disk of weight W_i on a weightless shaft is given by

$$\omega_i = \theta \left(\frac{gEI}{W_i c^3} \right)^{1/2} \quad (34.24)$$

where

c = distance of disk from nearest support

θ = a coefficient dependant on the manner in which the shaft is supported, the position of the disk within the span and the dimensions of the disk

34.3.1.5 Rayleigh Method

The Rayleigh method is based on the premise that, when a system vibrates at its natural frequency, the maximum potential energy stored in the elastic components is equal to the maximum kinetic energy stored in the masses (Rayleigh, 1945).

The first natural frequency of a vibrating uniform beam is given by the following equation:

$$\omega^2 = \frac{EI \int_0^l \left(\frac{d^2 y}{dx^2} \right)^2 dx}{\mu \int_0^l y^2 dx} \quad (34.25)$$

The Rayleigh formula for a lumped mass system is

$$\omega^2 = \frac{\sum_{i=1}^n m_i y_i}{\sum_{i=1}^n m_i y_i^2} \quad (34.26)$$

where

ω = first natural frequency

y = deflection of the beam

x = distance along x -axis

l = length of the beam

m_i = i th lumped mass

y_i = static deflection of i th mass

The accuracy of the Rayleigh method depends upon the selection of a suitable deflection curve that approximates the fundamental mode shape. If the assumed curve represents the true mode shape, then the correct fundamental natural frequency will result. All deviations from the true mode shape will yield frequencies that are higher than the correct value.

34.3.1.6 Ritz Method

The Ritz method is an improvement on the Rayleigh method (Timoshenko et al., 1974) where the mode shape is represented by several orthogonal functions with unknown coefficients that satisfy the boundary conditions. The orthogonal functions are represented by a series of functions, $\Phi_i(x)$, where i varies from 1 to n . The mode shape is represented by the following expression:

$$y = \sum_{i=1}^n a_i \Phi_i(x) \quad (34.27)$$

In order for the coefficients a_i in the above equation to yield minimum values when substituted in the energy balance equation proposed by Rayleigh, the following expression needs to be satisfied:

$$\frac{\partial}{\partial a_i} \frac{\int_0^l \left(\frac{d^2 y}{dx^2} \right)^2 dx}{\int_0^l y^2 dx} = 0 \quad (34.28)$$

From Equation 34.25 and Equation 34.28, we find

$$\frac{\partial}{\partial a_i} \int_0^l \left[\left(\frac{d^2 y}{dx^2} \right)^2 - \frac{\omega^2 \mu}{EI} y^2 \right] dx = 0 \quad (34.29)$$

Substituting Equation 34.27 for y in Equation 34.29 and performing the mathematical operations, a system of linear equations in a_i is obtained. The number of such equations will be equal to n . These equations will yield solutions different from zero only if the determinant of the coefficients of a_i is equal to zero. This condition yields the frequency equation, from which the frequency of each mode can be derived.

34.3.1.7 Stodola–Vianello Method

The Stodola–Vianello method is a numerical iterative process (Timoshenko et al., 1974) that can be used to calculate the natural frequencies and mode shapes of vibrating systems. An approximate mode shape is first assumed and by successive iterations it is refined until convergence is obtained to the desired level of accuracy. This method can be used to refine the assumed mode shape when using the Rayleigh formulae or in the more general case of the matrix iteration process illustrated below.

Using Newton's Second law, the equations of motion for a multi-DoF system in matrix notation are

$$\{Y\} = \omega_i^2 [A][m]\{Y\} \quad (34.30)$$

where

$$[A] = [K]^{-1} \quad (34.31)$$

$[A]$ is the flexibility matrix

$[m]$ is the mass matrix

$[K]$ is the stiffness matrix

To start the iterative process a trial vector, $\{Y\}_1$, representing the mode shape is substituted to both sides of Equation 34.30 and solve for the natural frequency, ω_i . For this reason, let the product of $[A]$, $[m]$, and $\{Y\}_1$ be $\{Y\}'_2$. The first approximation for ω_i may be obtained by dividing any one of the elements on $\{Y\}_1$ by $\{Y\}'_2$ (Note that, if $\{Y\}_1$ was the true mode shape, then the ratio for all such elements will be equal.) The vector $\{Y\}'_2$ is then normalized by dividing all the elements by the first element to produce $\{Y\}_2$. The vector $\{Y\}_2$ is premultiplied by $[m]$ and $[A]$ to produce $\{Y\}'_3$. Once again the ratio of corresponding elements of $\{Y\}'_3$ and $\{Y\}_2$ are compared for equality.

This procedure is repeated until the mode shape and the associated frequency is determined to the desired level of accuracy. In the above iteration procedure, the mode shape converges to the one corresponding to the lowest natural frequency. If the stiffness matrix had been used instead of the flexibility matrix, then convergence at the highest natural frequency is obtained. After the first mode of vibration is determined, it is removed from the system matrices by the use of a sweeping matrix so that higher modes can be obtained. This procedure is repeated until all the desired mode shapes and natural frequencies are determined.

34.3.1.8 Myklestad–Prohl Method (Transfer Matrix Method)

The Myklestad–Prohl transfer matrix formulation (Myklestad, 1944; Prohl, 1945) is commonly used to analyze lumped parameter models of rotating machinery. The distributed elastic and inertial properties of the rotor are represented as a collection of rigid bodies connected by massless elastic beam elements as illustrated in Figure 34.10. This method is best suited to calculate critical speeds and mode shapes of rotors neglecting the effects of viscous damping. The Myklestad–Prohl procedure can also be adopted to perform synchronous response and stability analysis, including for the effects of damping.

In order to demonstrate the transfer matrix procedure, an axisymmetric rotor is analyzed to determine its undamped critical speeds and mode shapes. Referring to Figure 34.10, the rotor is divided into n nodes, and each node is connected to the adjacent node by a massless elastic beam with uniform cross-sectional properties. The mass of components such as disks, impellers, and so on, together with the mass of the adjacent portion of the shaft, is lumped at the nodes. The Myklestad–Prohl method is based on the solution of the Bernoulli–Euler equation and the variables of interest are displacement (y), slope (θ), moment (M), and shear (V). The development of the following procedure follows Childs (1993).

FIGURE 34.10 Lumped-parameter model of rotor.

At a typical nodal point (n), the variables on the left-hand side (l) are related to the variables on the right-hand side (r) by the following relationship:

$$\begin{Bmatrix} y_n^r \\ \theta_n^r \\ M_n^r \\ V_n^r \end{Bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & -J_n \omega^2 & 1 & 0 \\ -m_n \omega^2 & 0 & 0 & 1 \end{bmatrix} \begin{Bmatrix} y_n^l \\ \theta_n^l \\ M_n^l \\ V_n^l \end{Bmatrix} \quad (34.32)$$

For the purpose of abbreviation:

$$(Q)_n^T = (y_n \quad \theta_n \quad M_n \quad V_n) \quad (34.33)$$

and Equation 34.32 can be written in a more compact form as follows:

$$(Q)_n^r = [T_{mn}](Q)_n^l \quad (34.34)$$

where $[T_{mn}]$ represents the transfer mass matrix at node n .

At a massless beam section, connecting node n to node $n+1$ the transfer matrix is given by

$$\begin{Bmatrix} y_{n+1}^l \\ \theta_{n+1}^l \\ M_{n+1}^l \\ V_{n+1}^l \end{Bmatrix} = \begin{bmatrix} 1 & l_n & \frac{l_n^2}{2EI_n} & \frac{-l_n^3}{6EI_n} \\ 0 & 1 & \frac{l_n}{EI_n} & \frac{l_n^2}{2EI_n} \\ 0 & 0 & 1 & -l_n \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{Bmatrix} y_n^r \\ \theta_n^r \\ M_n^r \\ V_n^r \end{Bmatrix} \quad (34.35)$$

Equation 34.35 may be written in a more abbreviated form as

$$(Q)_{n+1}^l = [T_{bn}](Q)_n^r \quad (34.36)$$

where $[T_{bn}]$ represents the beam element transfer matrix connecting node n to node $n+1$.

From Equation 34.34 and Equation 34.36, we obtain the combined transfer matrix for nodes n and $n+1$:

$$(Q)_{n+1}^l = [T_{bn}][T_{mn}](Q)_n^l = [T_n](Q)_n^l \quad (34.37)$$

Starting with node one, successive matrix multiplications are carried out until node $n + 1$ is reached. The last node ($n + 1$) is a dummy node with the beam length, l , equal to zero, and the mass and inertias also equal to zero. This makes the nodal parameters on the left-hand side of node $n + 1$ equal to those on the right-hand side of node n . The result is as follows:

$$(Q)_n^r = [T_n][T_{n-1}] \cdots [T_1](Q)_1^l \quad \text{or} \quad (Q)_n^r = [T](Q)_1^l \quad (34.38)$$

The matrix $[T]$ is a function of the rotational speed, ω . The Myklestad–Prohl method uses a trial and error solution to determine the values of ω which satisfy the boundary conditions and Equation 34.38 simultaneously. It is not necessary to store and multiply all the matrices together. The transfer matrix procedure is used to proceed from one end to the other without having to store all the nodal matrices. In all cases, two boundary conditions each are known at the two ends of the shaft, and the frequencies that satisfy these boundary conditions are the critical speeds of the rotor. Once the critical speeds are calculated, the corresponding mode shapes can also be determined using the transfer matrix procedure. It should be noted that other types of elements, such as elastic supports, flexible couplings, and so on, could also be introduced very conveniently.

34.3.1.9 Direct Stiffness Method

The direct stiffness method uses a lumped-parameter formulation to evaluate the dynamic characteristics of a flexible rotor. The general differential equation of motion that characterizes its behavior (less the damping and gyroscopic forces) is as follows:

$$\begin{bmatrix} [m] & 0 \\ 0 & [J] \end{bmatrix} \begin{Bmatrix} (\ddot{Y}) \\ (\ddot{\theta}) \end{Bmatrix} + [K] \begin{Bmatrix} (Y) \\ (\theta) \end{Bmatrix} = \begin{Bmatrix} (F) \\ (T) \end{Bmatrix} \quad (34.39)$$

where $[m]$ and $[J]$ are diagonal matrices which contains the nodal masses, m_i , and nodal moments of inertia, J_i , respectively. The stiffness matrix, $[K]$, contains the internal stiffness terms of the beam elements as well as any external spring stiffness at the supports. The vectors (F) and (T) represent external forces and moments acting on the system, respectively.

The stiffness matrix for a typical beam element based on the Bernoulli–Euler equations is as follows (Childs, 1993):

$$[K^i] = \frac{2EI_i}{l_i^3} \begin{bmatrix} 6 & 3l_i & -6 & 3l_i \\ 3l_i & 2l_i^2 & -3l_i & l_i^2 \\ -6 & -3l_i & 6 & -3l_i \\ 3l_i & l_i^2 & -3l_i & 2l_i^2 \end{bmatrix} \quad (34.40)$$

The overall stiffness matrix, $[K]$, has to be assembled by combining the individual component matrices in a systematic manner. The following procedure illustrates the process.

The stiffness matrix of the i th beam element in matrix notation is

$$[K^i] = [k_{j,k}^i] \quad (34.41)$$

where j and k vary from $(2i - 1)$ to $(2i + 2)$.

To form the overall stiffness matrix, the elements with the same subscripts of adjacent beam elements are added over n beam elements as given by the following equation:

$$[K] = [K_{j,k}] = \sum_{i=1}^n \sum_{j=2i-1}^{2i+2} \sum_{k=2i-1}^{2i+2} k_{j,k}^i \quad (34.42)$$

Once the inertia matrix and the stiffness matrix for the entire system are assembled, the eigenvalues and eigenvectors can be evaluated by solving the following homogeneous equation derived

from Equation 34.39:

$$[M](\ddot{Y}) + [K](Y) = 0 \quad (34.43)$$

There are numerous analysis procedures (Meirovitch, 1986) for the solution of Equation 34.43 that yield the eigenvalues and eigenvectors of the system. The method of choice will depend on the complexity and nature of the inertia and stiffness matrices. Perhaps the most widely known is the matrix iteration using the power method in conjunction with the sweeping technique. However, this method is not necessarily the most efficient, particularly for higher-order systems. The Jacobi's method, which uses matrix iteration to diagonalize a matrix by successive rotations, is more commonly used owing to its higher efficiency. Details of these techniques are given in the text by Meirovitch (1986).

When the damping matrix and the gyroscopic matrix is also included in Equation 34.39, the direct stiffness method can be used to calculate damped critical speeds, forced rotor response, and instability of the rotor in addition to the eigenvalues using similar methods of solution.

34.3.1.10 The Finite Element Analysis Method

The basis of the FEA method is to provide formulation for complex and irregular systems that can utilize the automation capabilities of computers (also see Chapter 9). The FEA method considers a rotordynamic system as an assemblage of discrete elements, where every such element has distributed and continuous properties, namely, the consistent representation of both mass and stiffness as distributed parameters. As illustrated in Section 34.3.1.9, the lumped-parameter method uses a consistent stiffness matrix equation (Equation 34.40) in its formulation, and therefore, the identical procedure can be adopted for the finite element method as well. For the distributed mass representation of an element, Archer (1963) procedure, which is based on the assumption that the mass distribution is proportional to the elastic distribution similar to the Rayleigh–Ritz formulation, is utilized. The resulting mass matrix is as follows:

$$[m^i] = \frac{m^i l_i}{420} \begin{bmatrix} 156 & 22l_i & 54 & -13l_i \\ 22l_i & 4l_i^2 & 13l_i & -3l_i^2 \\ 54 & 13l_i & 156 & -22l_i \\ -13l_i & -3l_i^2 & -22l_i & 4l_i^2 \end{bmatrix} \quad (34.44)$$

The overall stiffness matrix, $[K]$, for the entire system is assembled by combining the individual component matrices in a systematic manner according to Equation 34.41 and Equation 34.42. The overall mass matrix can also be assembled in precisely the same manner, as given by Equation 34.45 and Equation 34.46.

The mass matrix of the i th beam element in matrix notation can be represented as

$$[m^i] = [m_{j,k}^i] \quad (34.45)$$

where j and k varies from $(2i - 1)$ to $(2i + 2)$:

$$[M] = [M_{j,k}] = \sum_{i=1}^n \sum_{j=2i-1}^{2i+2} \sum_{k=2i-1}^{2i+2} m_{j,k}^i \quad (34.46)$$

Once the mass matrix and the stiffness matrix for the entire system are assembled, Equation 34.43 that describes the free vibration of the complete system can be solved. The solution methods of the eigenvalue problem, which can be utilized, are the same as those used for the direct stiffness method illustrated in Section 34.3.1.9 above. Details of the FEA methods are given in Ruhl and Booker (1972).

34.3.1.11 Torsional Analysis (Holzer Method)

The development of torsional analysis methods have gone through a similar evolutionary process to lateral vibration methods. Holzer (1921) first introduced the lumped-parameter numerical method to calculate torsional natural frequencies of a multi-DoF system. Even to-date, this is the most commonly used method because of its simplicity and reasonable degree of accuracy. The Holzer method is a transfer matrix formulation that uses a lumped parameter model similar to that used in the Myklestad–Phrol method described in Section 34.3.1.8. The only difference is that the transfer matrices represented by Equation 34.32 and Equation 34.35 are replaced by the equations

$$\begin{Bmatrix} \theta \\ T \end{Bmatrix}_n^r = \begin{bmatrix} 1 & 0 \\ -\omega^2 J & 1 \end{bmatrix}_n \begin{Bmatrix} \theta \\ T \end{Bmatrix}_n^l \quad (34.47)$$

$$\begin{Bmatrix} \theta \\ T \end{Bmatrix}_{n+1}^l = \begin{bmatrix} 1 & \frac{1}{k} \\ 0 & 1 \end{bmatrix}_{n+1} \begin{Bmatrix} \theta \\ T \end{Bmatrix}_n^r \quad (34.48)$$

Starting with node one, successive matrix multiplications are carried out until node $n + 1$ is reached. The result can be represented by Equation 34.38. The matrix $[T]$ is a function of the rotational speed, ω . In all cases, one boundary condition at each end of the rotor is known. A trial-and-error solution to determine the values of ω which satisfy the boundary conditions and Equation 34.38 are simultaneously determined. These values are the torsional critical speeds of the rotor. Once the critical speeds are calculated, the corresponding torsional mode shapes can also be determined using the transfer matrix procedure.

In the case of branched systems and geared systems, particular attention has to be paid to the relative rotational speeds of the components. The rule is quite simple: multiply all stiffness and inertias of the geared shaft by N^2 , where N is the speed ratio of the geared shaft to the reference shaft.

Other methods such as the distributed mass matrix method, direct stiffness method, and finite element method can also be used to determine torsional critical speeds of rotors. These procedures are very similar to those for lateral critical speed analysis.

34.3.2 Modeling

The design and analysis of rotordynamic systems require the development of models that simulate the behavior of the physical system. In the past, the critical speed of the rotor was considered to be the main criterion for stable operation. Today, stable, well-damped rotordynamic response to the exciting forces within a machine is considered to be a necessary condition for high reliability. The accuracy and reliability of the results greatly depends on the credibility of the system model and its adaptability to the analytical procedure. Even the most accurate and efficient analytical method cannot produce good results from a bad model. The methods that are commonly used to model shaft sections and disks and other such elements attached to shafts have been discussed in the previous sections. Useful formulae for calculating critical speeds of simple systems are given in Table 34.2. Models to represent bearings, rotor dampers, seals, and rotor–stator interactions are discussed in the following sections.

34.3.2.1 Journal Bearings

Journal bearings were used in rotating machinery for a long time before their dynamic characteristics were fully understood. Considerable effort has been expended in the last few decades to understand and develop techniques for their accurate representation in rotordynamic analysis. A variety of bearing types with improved characteristics have been developed over the years. Figure 34.11 shows the most commonly used types in rotating machinery. Hagg and Sankey (1958) were amongst the first to provide dynamic stiffness and damping coefficients for a number of these bearing types. However, these coefficients are considered incomplete as cross-coupling terms were not considered. Soon after, there was a flurry of activity related to the analysis of journal bearings; Sternlicht (1959), Warner (1963),

TABLE 34.2 Useful Formulas in Vibration Analysis and Design

Rankine formula	$\omega = \frac{k(Hg)^{1/2}}{b^2}$	Note: This formula is of historical interest only and has limited practical value
Greenhill formula	$\frac{d^4 y}{dx^4} - \frac{m\omega^2}{gEak^2} y = 0$	
Dunkerly equation	$\frac{1}{\omega_c^2} = \frac{1}{\omega_s^2} + \sum_{i=1}^n \frac{1}{\omega_i^2}$	

The above equation reduces to

Lund (1964), Lund (1965), Glienicke (1966), Orcutt (1967), Lund (1968), Someya et al. (1988), and several others provided complete bearing coefficients, including cross-coupling terms, for several bearing types. This information is considered to be a valuable resource for those engaged in rotordynamic analysis. The general form of the rotordynamic model for a journal bearing resulting from the above contributions is given by the following equation:

$$\begin{Bmatrix} F_X \\ F_Y \end{Bmatrix} = - \begin{bmatrix} k_{11} & k_{12} \\ k_{21} & k_{22} \end{bmatrix} \begin{Bmatrix} X \\ Y \end{Bmatrix} - \begin{bmatrix} c_{11} & c_{12} \\ c_{21} & c_{22} \end{bmatrix} \begin{Bmatrix} \dot{X} \\ \dot{Y} \end{Bmatrix} \quad (34.49)$$

Since the dawn of the digital computer era, several computer codes have been developed to analyze all aspects of journal bearings, including stiffness and damping coefficients. Many of these codes have been developed by equipment manufactures and research centers for their exclusive use. Several commercially available software codes popularized in North America are given in Table 34.3. Although bearing coefficients given in the form of charts and tables from the earlier studies are still in use, computer-based codes are growing in popularity.

34.3.2.2 Rolling Element Bearings

Rolling element bearings are used in numerous types of rotating machinery which are required to be compact, manage high loads, and have low heat rejection and simple lubrication systems. Unlike journal bearings, their load-carrying capacity is not speed-dependent and as a result is capable of full load capacity down to zero speed. Some of these salient features make rolling element bearings very attractive to many industries.

From a rotordynamic standpoint, rolling element bearings are modeled as linear spring elements with direct spring coefficients only. The damping terms are insignificant and as a result do not attenuate rotor deflections at critical speeds. A typical rolling element bearing is represented by the following equation:

$$\begin{Bmatrix} F_X \\ F_Y \end{Bmatrix} = - \begin{bmatrix} k & 0 \\ 0 & k \end{bmatrix} \begin{Bmatrix} X \\ Y \end{Bmatrix} \quad (34.50)$$

The absence of cross-coupling stiffness and damping terms signifies that bearing induced rotor instability will not occur. Although, for convenience of analysis, the spring stiffness is considered linear, its

FIGURE 34.11 Common types of journal bearings.

true behavior can be quite the opposite, leading to some calculation inaccuracies. The nonlinearities are most significant where the bearings have no preload and some internal clearance in the bearings exists. Preloaded bearings with little or no internal clearance behave quite linearly. Jones (1960), Harris (1991), and Kramer (1993) have analyzed the bearing stiffness coefficients for the common types of rolling element bearings, and this data can be utilized for rotordynamic study of rotating machinery.

34.3.2.3 Squeeze-Film Dampers

Squeeze-film dampers are used to introduce damping capacity to a rolling element bearing or, in the case of journal bearings, to provide additional damping and stiffness to eliminate rotor instability problems. Squeeze-film dampers have come into prominence through the modern aircraft gas turbine industry where the bearing of choice is the rolling element bearing. In the mid-1970s, several designs were introduced to add damping capacity and predictable stiffness to the rolling element bearings. In its basic form, a squeeze-film damper is very similar to a nonrotating cylindrical journal bearing where the outer race of the rolling element bearing forms the journal as illustrated in Figure 34.12. The addition of end seals (to control leakage) and centering springs are modifications that have been introduced to enhance its performance. The interactive force at a bearing using a squeeze-film damper can be represented by the following equation:

$$\begin{Bmatrix} F_X \\ F_Y \end{Bmatrix} = - \begin{bmatrix} k & 0 \\ 0 & k \end{bmatrix} \begin{Bmatrix} X \\ Y \end{Bmatrix} - \begin{bmatrix} c & 0 \\ 0 & c \end{bmatrix} \begin{Bmatrix} \dot{X} \\ \dot{Y} \end{Bmatrix} \quad (34.51)$$

The stiffness and damping coefficients for the squeeze-film dampers have been derived (Ehrich, 1999), from the solution of the Reynolds' equation for the case of a nonrotating journal bearing. For dampers with end seals, the long journal bearing theory is used to generate the following stiffness and damping

coefficients:

$$k = \frac{24R^3 L \mu \omega \varepsilon}{C_r^3 (2 + \varepsilon^2)(1 - \varepsilon^2)} \quad (34.52)$$

$$c = \frac{12\pi R^3 L \mu}{C_r^3 (2 + \varepsilon^2)(1 - \varepsilon^2)^{1/2}} \quad (34.53)$$

where

R = the damper radius

ω = whirl speed

L = length of damper

μ = viscosity of oil

C_r = the radial clearance

ε = eccentricity ratio (orbit radius/ C_r)

Similarly, for a damper without end seals, the short journal bearing theory yields the following stiffness and damping coefficients:

$$k = \frac{2RL^3 \mu \omega \varepsilon}{C_r^3 (1 - \varepsilon^2)^2} \quad (34.54)$$

$$c = \frac{\pi RL^3 \mu}{2C_r^3 (1 - \varepsilon^2)^{3/2}} \quad (34.55)$$

Although the above equations, based on the Reynolds' equation, have been proposed to predict damper characteristics, the experimental evidence does not validate these equations. Therefore, these equations should be used with caution for practical purposes.

34.3.2.4 Annular Seals

Annular seals are primarily used in pumps, compressors, gas turbines, and steam turbines to minimize leakage and thereby improve the volumetric efficiency of the machine. In addition to their basic function, they also play a vital role in the rotordynamics of the machine, especially in multistage machines, providing stiffness and damping and thereby enhancing high-speed operational capability. In fact, in the last few decades, most of the development work on seals has focused on understanding and improving their dynamic vibration characteristics rather than improving their efficiency in sealing.

Lomakin (1958) was the first to publish on the restoring forces in smooth annular clearances in pumps. However, it was more than a decade later that Black (1968) provided the major initial impetus for the understanding and development of seals. Childs (1993) provided an excellent compendium of the research work conducted in the area of seals. His book also provides the most comprehensive coverage of the subject of seal dynamics.

In the present context, seals are handled in the same manner as the stiffness and damping characteristics of journal bearings with some degree of modifications. In particular, fluid inertia effects are included, and it is assumed that the center of the shaft orbit is the same as the center of the stationary seal ring. Assuming rotational symmetry the reaction force-seal motion model can be represented by the following equation:

$$\begin{Bmatrix} F_X \\ F_Y \end{Bmatrix} = - \begin{bmatrix} k & k_c \\ -k_c & k \end{bmatrix} \begin{Bmatrix} X \\ Y \end{Bmatrix} - \begin{bmatrix} c & c_c \\ -c_c & c \end{bmatrix} \begin{Bmatrix} \dot{X} \\ \dot{Y} \end{Bmatrix} - \begin{bmatrix} m & 0 \\ 0 & m \end{bmatrix} \begin{Bmatrix} \ddot{X} \\ \ddot{Y} \end{Bmatrix} \quad (34.56)$$

FIGURE 34.12 A squeeze-film damper.

An added complexity is the predominance of turbulent flow in annular seals. This invalidates the use of Reynolds' equation for the derivation of seal coefficients. The highest degree of accuracy can be obtained by the direct solution of the Navier–Stokes and continuity equations. However, at the present moment, such methods are considered to be excessively costly and impractical. As a result, two practical semiempirical methods have been developed to derive seal coefficients. In the first approach, the semiempirical turbulent model is directly substituted in the Navier–Stokes equation and a numerical technique is used for its solution. The second, most commonly used technique uses a bulk flow model together with control volume formulations, namely, the continuity equation and momentum equation, to obtain the desired results. For a detailed discussion of these methods, solution techniques, the influence of various physical parameters on the coefficients, and an excellent compilation of computational and experimental results, the publication by Childs (1993) is recommended.

34.3.2.5 Impeller–Diffuser/Volute Interface

It is widely known that the flow fields within certain types of rotating machinery can significantly influence its vibration behavior. Thomas (1958) recognized and explained the presence of destabilizing clearance excitation forces in axial flow steam turbines. Black (1974) was the first to suggest that centrifugal pump impellers could also develop destabilizing forces. The nature of these forces and their influence on rotor instability has been explained in Section 34.2.2.2 and Section 34.2.2.3 of this chapter. The impeller–diffuser/volute forces assuming rotational symmetry can generally be modeled by an equation of the following form:

$$\begin{Bmatrix} F_X \\ F_Y \end{Bmatrix} = - \begin{bmatrix} k & k_c \\ -k_c & k \end{bmatrix} \begin{Bmatrix} X \\ Y \end{Bmatrix} - \begin{bmatrix} c & c_c \\ -c_c & c \end{bmatrix} \begin{Bmatrix} \dot{X} \\ \dot{Y} \end{Bmatrix} - \begin{bmatrix} m & m_c \\ -m_c & m \end{bmatrix} \begin{Bmatrix} \ddot{X} \\ \ddot{Y} \end{Bmatrix} \quad (34.57)$$

For analytical procedures for the derivation of impeller interaction coefficients and a comparison of experimental data, the work by Childs (1993) is recommended. It is well recognized that a considerable amount of work still needs to be done towards understanding the complex nature of impeller–diffuser/volute interactive forces, especially at off-design conditions.

34.3.3 Design

Since the real machine is not available for tests, at the preliminary design stage it is a common practice to develop an accurate mathematical model of the machine to predict its dynamic behavior in operation. It is also prudent to understand and estimate how the machine will interact with its operating environment and how the environment could influence the operation of the machine. A suitable model of the rotor can be developed using the techniques described in Section 34.3.2, and the rotordynamic characteristics of the machine can be analyzed using one of the methods described in Section 34.3.1, above. Based on these methods, numerous computer-based rotordynamic analysis programs have been developed. A listing of the most widely known computer programs in North America is given in Table 34.3. The objectives of the analysis are to predict the critical speeds, excitation frequencies, the amplitudes of deflection, and the magnitude of the forces of the rotor within its full operating range. In certain situations, evaluation of the energy content of the excitation may also be required.

Once the mathematical model is developed, the eigenvalues of the rotor and the mode shapes can be determined. The results can then be presented in the form of a Campbell diagram, where the eigenvalues along with the excitation frequencies are plotted as a function of rotor speed. Critical speeds occur at the speeds corresponding to the points of intersection of the excitation frequency lines and the eigenvalue lines. The Campbell diagram presentation (Figure 34.13) of the results is very useful since the influence of key parameters such as stiffness, damping, clearances (new and worn conditions), and so on can all be shown on the same diagram. A critical speed, although present, may be of little consequence if it is associated with sufficient damping. As illustrated in Figure 34.4, when the damping ratio $\zeta \geq 0.707$, the system is critically damped and above this level of damping there is no amplification of the rotor deflection. At or near a critical speed the amplification factor is $\approx 1/2\zeta$. Using this estimated value,

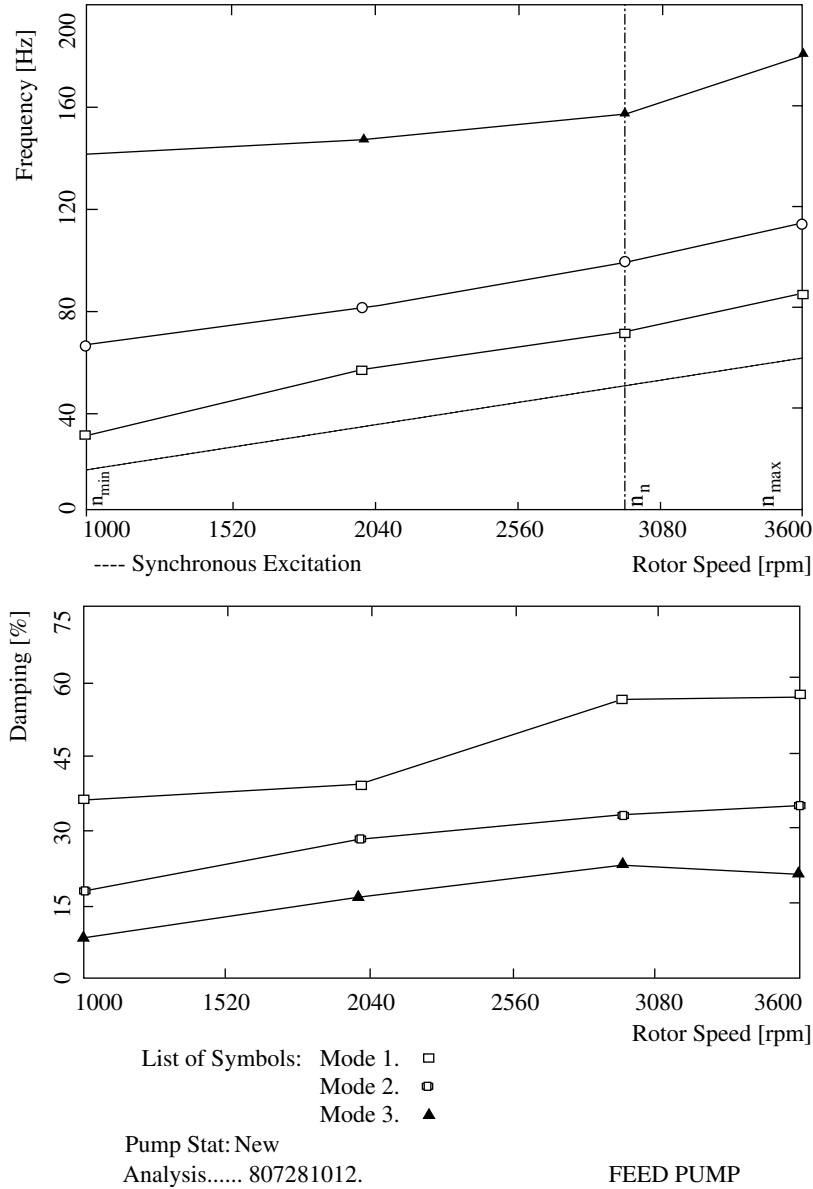

FIGURE 34.13 Campbell diagram for a multistage pump.

depending on the internal clearances of the machine, it is possible to assess if the rotor can pass through a critical speed without causing damage to the components. An amplification factor of 2.5 or below is a typical acceptance limit for centrifugal pumps, even for continuous operation at or near it. However, if the amplification factor exceeds the acceptable limits or the critical speeds are too close to the continuous operating speed, then design modifications have to be made to change the critical speed values. At the design stage, it is considered good practice to ensure that the critical speeds are not within $\pm 10\%$ of the continuous operating speed; these limits are sometimes referred to as *separation margins*. The mode shapes of the rotor are important from the standpoint of identifying where the maximum deflections occur. It also provides a good guide for assessing design modifications to improve damping or reduce sensitivity to unbalance forces.

The eigen analysis only provides relative deflections of the rotor. In order to estimate true deflections, a forced response analysis has to be made. Forcing functions of estimated magnitude are applied at selected locations to determine the resulting deflections at specific points on the rotor. This type of analysis is typically carried out for synchronous excitation forces only. The nature of the forcing function depends on the type of the machine; mechanical unbalance is common to all types of machines, whereas hydraulic unbalance is relevant to centrifugal pumps and electrical unbalance to electric motors. The challenge, of course, is to determine the magnitudes, directions, and locations of the forces to apply and how the resulting rotor response should be judged. Of course, these criteria are machine type-dependent and not necessarily applicable to all types of rotating machinery. An example of how forced response analysis on centrifugal pumps is evaluated is given below (Bolleter et al., 1992):

1. Maximum amplification factors and required separation margins are defined by specifications; example as shown in API 610, 8th edn., 1995.
2. Excitation forces are defined and the response is judged relative to admissible shaft vibration limits, and relative to clearances.
3. Apply unbalance forces of such a magnitude that maximum permissible vibration limits at the vibration probe locations are reached, and then evaluate if the deflections exceed the minimum clearances in the machine.
4. Apply an unbalance force of arbitrary magnitude and determine the resulting response at the same or another location, and calculate the sensitivity factor (SF) using the following formula:

$$SF = \frac{a}{U} M \quad (34.58)$$

where

a = rotor deflection

U = unbalance force

M = rotor mass

The sensitivity factor should then be compared with experimental base values of similar machines for acceptance. The rotor responses to the applied forces can be further analyzed to extract other parameters of interest, such as phase angles and force magnitudes at the bearings, in order to evaluate the design.

In order to optimize the rotating machine design in terms of placement of critical speeds and control of deflections and forces, a parameter sensitivity coefficients analysis (Lund, 1979; Rajan et al., 1986; Rajan et al. 1987) may be carried out. For speed and convenience of analysis, the optimization routine can be automated.

- Rotordynamic analysis is a part of the current rotating machinery design practice used to predict their vibration behavior.
- The most current rotordynamic analytical procedures are computer-based and are derived from the lump-parameter model or the transfer matrix method.
- In the lumped-parameter model method, the distributed elastic and inertial properties of the rotor are represented as a collection of rigid bodies connected by massless elastic beams.
- In the transfer matrix method, commonly called the FEA method, the rotor is represented as an assembly of elements with distributed elastic and inertial properties.
- Accurate modeling and representation of rotor components is vital to the accuracy and reliability of analysis results. As a result, significant advancement in modeling shaft sections, disks, impellers, bearings, seals, rotor dampers, and rotor–stator interactions have been made.

34.4 Vibration Measurement and Techniques

34.4.1 Units of Measurement

The most commonly used units of measurement of vibration are as follows:

- Displacement (peak to peak): millimeter (mm) or micron (10^{-6} m) in metric units, and *thou* or *mil* (0.001 in) in imperial units
- Velocity (peak, RMS or “true peak”): mm/sec or m/sec in metric units, and in./sec in imperial units
- Acceleration (RMS): *g* or m/sec^2 in metric units, and *g* or in./sec^2 in imperial units
- Frequency: hertz (Hz) or cycles/min (cpm) in both systems of units
- Phase angle: degrees in both systems of units

34.4.2 Measured Parameters and Methods

Under steady-state conditions, the vibration from a rotating machine is a periodic signal of a complex waveform. During unstable operation or upset conditions, the signal may become random in nature. In certain types of machines, transient signals that are nonperiodic could also be present due to internal impacts and damping. Based on the simple spring–mass system and the mathematical Fourier analysis procedure, all periodic complex waveforms can be reduced to the sum of a series of sinusoidal functions. In the case of random signals, averaging techniques are used to reduce them to periodic signals for convenience of analysis.

A quantitative assessment of the vibration can be made in terms of the amplitude, velocity, acceleration, or the magnitude of force of the motion. Other key parameters such as frequency, phase angle, and the time-varying nature of the signal are important in fully characterizing it. Because the true signal is not purely sinusoidal, it is important to identify its magnitude as, *peak*, *peak-to-peak* or *root mean square* (RMS). The preferred parameter of measurement varies throughout the industry and depends on the nature, complexity, and type of machine, and the purpose for which it is measured. A general classification of measured parameters and techniques based on industry and rotating machine type is given in [Table 34.4](#).

- The displacement amplitude, velocity, acceleration, frequency, and phase angle of the vibration signal are some of the parameters that can be used to assess the condition of a rotating machine.
 - The vibration signals generated by a typical rotating machine is complex in nature and, therefore, requires various mathematical analysis procedures and signal averaging techniques to reduce them to simple and interpretable forms.

34.5 Vibration Control and Diagnostics

34.5.1 Standards and Guidelines

Given the fact that some degree of vibration is always present in rotating machinery, some means of judging “how much is too much” has to be established so that vibrations can be controlled within reasonable limits. When such a judgment is not based on a scientific method, there is room for speculation and it will depend on the one making the decision, the manufacturer, end user, the governing authority, and so on. Since vibrations are a key indication parameter of the performance of rotating machinery, different interest groups monitor it for a variety of purposes. It can be used as a measure of

TABLE 34.4 Measurement Parameters and Techniques

Measurement/Technique	Description	When/Where Used
Acceleration, RMS	When high frequency or force of the vibration is of interest	Gear boxes, rolling element bearings, gas/steam turbines. Mainly used by defense and aerospace industry
Bode/Nyquist plot	Plot of displacement amplitude and phase angle vs. speed	Observe critical speeds and instability in machines using journal bearings
Cepstrum analysis	Inverse Fourier transform of logarithmic power spectrum	To detect families of harmonics and sidebands in gearboxes, rolling element bearings, and electric motors
Condition monitoring	Analysis of signals generated by the machine to determine its condition on a continuous or periodic basis	On critical equipment where predictive maintenance programs are used. Can reduce equipment redundancy
<i>Displacement peak-to-peak</i>		
(a) Absolute	Absolute displacement amplitude of rotor vibration	Where the rotor mass is very much larger than the stator mass. Large motors, generators, and fans
(b) Relative	Relative displacement amplitude of rotor vibration	Commonly used on machines with journal bearings or in close clearance seals
(c) External	Absolute displacement amplitude of stator component vibration	Low speed machines (less than 1000 rpm)
Modal analysis	To measure the vibration response of a structure to an applied force. The force can be periodic or an impact force	To determine the modal mass, stiffness and damping properties of a structure. Also used to measure structural natural frequencies
Orbit analysis	The path of the shaft centerline motion during rotation	Diagnostics of machines using journal bearings. Provides a picture of the motion of the journal in the bearing
Polar plots	A polar graph of amplitude versus phase at various machine speeds	Similar to Bode plots, can be used to detect critical speeds and instability. Modal properties can also be extracted from polar plots
Phase angle	Phase angle of vibration signal	Useful in balancing, diagnosing critical speeds, and misalignment problems
<i>Rolling element bearing analysis</i>		
(a) Acceleration	Measure the amplitude of all pass and discrete frequency accelerations	When damage has progressed to generate audible noise amplitudes increase. Useful from 5–5 kHz
(b) Shock pulse method	A high frequency resonance technique tuned to the detector natural frequency	Early detection of failure, measures ultrasonic noise. Proprietary technique
(c) Envelope technique	Bearing defects cause periodic impacts, which make bearing components resonate. Demodulation and enveloping techniques are used to detect the impact (fault) frequencies	Used for early failure detection (ultrasonic noise) as well as for advanced stages of damage (audible noise)
(d) Spike energy method	Measure the broadband acceleration over the 5–45 kHz range	Used for early failure detection (ultrasonic noise) as well as for advanced stages of damage (audible noise)
(e) Kurtosis method	The normalized fourth moment of the probability distribution of acceleration over the 2–80 kHz range	Used for early failure detection (ultrasonic noise) as well as for advanced stages of damage (audible noise)
Run-up, run-down analysis (waterfall/cascade plots)	Three-dimensional plot of frequency or time spectrum vs. time or speed	Used for diagnosing a variety of vibration problems. Helpful in analyzing transient signals

TABLE 34.4 (continued)

Measurement/Technique	Description	When/Where Used
Spectrum analysis	Plot of amplitude vs. frequency of vibration	Used for diagnostics, to determine frequency, harmonics, side bands, beats, transfer functions, etc., and to control of vibrations levels at discreet frequencies
Trend analysis	Vibration data collected periodically over an extended time domain	Useful in predictive maintenance programs in assessing machine conditions
Time averaging	Averaging of time records using triggering at the same point of the waveform of a repetitive signal	Used in the analysis of faulty gearboxes. Can reduce asynchronous components in the signal and improve signal-to-noise ratio
Time-domain analysis	Plot of amplitude versus time	To observe amplitude modulation, beats, impacts, transients, and phase angle. Very useful in diagnostics
Velocity-peak or RMS	Velocity amplitude of vibration signal	Parameter most commonly used in many industries to monitor vibrations. Peak readings relate to peak stress levels and rms to energy of vibrations

quality and workmanship or the common basis for acceptance between the user and manufacturer. From a safety point of view, the operator can establish *normal*, *alarm*, and *shutdown levels* based on vibration limits. Vibration levels are also used in making maintenance decisions in rotating machinery.

Rathbone (1939) was the first to publish guidelines for vibration limits for machinery, based on his experience as an insurance agent. Since that time, numerous individuals, organizations, and governing bodies have developed a variety of guidelines and standards for vibration levels in rotating machinery. A listing of the more commonly used guidelines and standards is given in [Table 34.5](#). It should be recognized that these are experience-based standards, and therefore, will grow and develop with technology.

ISO 10816 Part 1 to Part 5 is a comprehensive set of standards that has been developed for the evaluation of vibration of rotating machinery by measuring the vibration response on nonrotating, structural components such as bearing housings. Vibration measuring points as specified by these standards are shown in [Figure 34.14](#). In a similar vein, ISO 7919 Part 1 to Part 5 has been developed for the evaluation of vibration by measuring the vibration on rotating shafts. These standards cover the most widely used types of rotating machinery and they relate to both operational monitoring and acceptance testing of equipment. [Table 34.6](#) and [Table 34.7](#) are derived from these standards and are presented as a general guideline for vibration limits of rotating machinery. For specific details, including the limitations of the standards, the reader is advised to refer to the relevant sections of ISO 10816 and ISO 7919 Standards.

34.5.2 Vibration Cause Identification

Vibrations are an inherent part of all rotating machinery. Vibration can be due to many causes: improper design, practical manufacturing limits, poor installation, the effect of system environment, component deterioration, operation outside of design limits, or a combination of the above. At times, finding the exact cause of vibration can be quite a challenge, as several of the causes have similar symptoms. [Table 34.8](#) is a list of the more commonly known causes of vibration in rotating machinery and their symptoms.

34.5.3 Vibration Analysis — Case Study

In the past, it was common practice to operate centrifugal pumps at a fixed speed and attain required flow changes by means of throttling. This forces the pump to operate at low efficiency conditions

TABLE 34.6A Acceptable Vibration Levels for Rotating Machinery Measured on Nonrotating Parts

Machinery Type	Power Level	Speed Range (rpm)	Applicable Vibration Level	
			Rigid Support	Flexible Support
Steam turbines	$15 \leq P \leq 300$ kW	$120 \leq N \leq 15,000$	V1 and D3	V3 and D7
	$300 \text{ kW} \leq P \leq 50$ MW	$120 \leq N \leq 15,000$	V3 and D5	V6 and D8
	$P > 50$ MW	$N < 1,500$ or $N > 3,600$	V3 and D5	V6 and D8
	$P > 50$ MW	$N = 1,500$ or $1,800$	V5	V5
	$P > 50$ MW	$N = 3,000$ or $3,600$	V7	V7
Gas turbines	$15 \leq P \leq 300$ kW	$120 \leq N \leq 15,000$	V1 and D3	V3 and D7
	$300 \text{ kW} \leq P \leq 3$ MW	$120 \leq N \leq 15,000$	V3 and D5	V6 and D8
	$P > 3$ MW	$3,000 \leq N \leq 20,000$	V8	V8
Hydraulic turbines and pump turbine	Horizontal machines			
	$P > 1$ MW	$60 \leq N \leq 300$	N/A	V4
	$P > 1$ MW	$300 < N \leq 1,800$	V2 and D6	N/A
Vertical machines	$P > 1$ MW	$60 < N \leq 1,800$	V2 and D6	N/A
	$P > 1$ MW	$60 < N \leq 1,000$	V2 and D6	V4 and D9
Centrifugal pumps				
Separate driver	$P > 15$ kW	$120 \leq N \leq 15,000$	V3 and D2	V6 and D4
Integral driver	$P > 15$ kW	$120 \leq N \leq 15,000$	V1 and D1	V3 and D2
Electric motors				
Shaft height $H \geq 315$ mm	$P > 15$ kW	$120 \leq N \leq 15,000$	V3 and D5	V6 and D8
Shaft height $160 \leq H < 315$ mm	$P > 15$ kW	$120 \leq N \leq 15,000$	V1 and D3	V3 and D7
Generators, excluding those used in hydraulic power generation	$15 \leq P \leq 300$ kW	$120 \leq N \leq 15,000$	V1 and D3	V3 and D7
	$300 \text{ kW} \leq P \leq 50$ MW	$120 \leq N \leq 15,000$	V3 and D5	V6 and D8
	$P > 50$ MW	$N < 1,500$ or $N > 3,600$	V3 and D5	V6 and D8
	$P > 50$ MW	$N = 1,500$ or $1,800$	V5	V5
	$P > 50$ MW	$N = 3,000$ or $3,600$	V7	V7
Generators and motors used in hydraulic power generation	Horizontal machines			
	$P > 1$ MW	$60 \leq N \leq 300$	N/A	V4
	$P > 1$ MW	$300 < N \leq 1,800$	V2 and D6	N/A
Vertical machines	$P > 1$ MW	$60 < N \leq 1,800$	V2 and D6	N/A
	$P > 1$ MW	$60 < N \leq 1,000$	V2 and D6	V4 and D9
Compressors, rotary, blowers, and fans	$15 \leq P \leq 300$ kW	$120 \leq N \leq 15,000$	V1 and D3	V3 and D7
	$300 \text{ kW} \leq P \leq 50$ MW	$120 \leq N \leq 15,000$	V3 and D5	V6 and D8

resulting in wasted energy and premature failure of components due to high vibration. The current practice to obtain flow changes in the pump is by means of speed change. This eliminates flow throttling and allows the pump to operate close to its best efficiency point, where energy is not wasted and vibrations are a minimum. However, as illustrated below, variable speed operation of a pump-motor set over a wide speed range could pose several challenging problems.

TABLE 34.6B Maximum Vibration Velocity Limits for Different Levels (mm/sec, RMS)

Vibration Level	Zone A	Zone B	Zone C	Alarm	Trip
V1	1.4	2.8	4.5	3.5	5.6
V2	1.6	2.5	4.0	3.1	5.0
V3	2.3	4.5	7.1	5.6	8.9
V4	2.5	4.0	6.4	5.0	8.0
V5	2.8	5.3	8.5	6.6	10.6
V6	3.5	7.1	11.0	8.9	13.8
V7	3.8	7.5	11.8	9.4	14.8
V8	4.5	9.3	14.7	11.6	18.4

TABLE 34.6C Maximum Vibration Displacement Limits for Different Levels (μm , RMS)

Vibration Level	Zone A	Zone B	Zone C	Alarm	Trip
D1	11	22	36	28	45
D2	18	36	56	45	70
D3	22	45	71	56	89
D4	28	56	90	70	113
D5	29	57	90	71	113
D6	30	50	80	63	100
D7	37	71	113	89	141
D8	45	90	140	113	175
D9	65	100	160	125	200

Zone A: Newly commissioned machines should fall within this zone. *Zone B:* Machines with vibrations within this zone are considered acceptable for long-term operation. *Zone C:* Machines with vibrations within this zone are normally considered unsatisfactory for long-term operation. Such a machine may be operated for a short period in this condition. *Alarm:* The values chosen will normally be set relative to a baseline value determined from experience. However, it is recommended that the alarm value shall not exceed those given herein. *Trip:* The values will generally relate to the mechanical integrity of the machine. They will generally be the same for all machines with similar design. It is recommended that the trip value shall not exceed those given herein. *Notes:* (1) The measured vibration is broadband, and the frequency range will depend on the type of machine being considered. A range from 2 to 1000 Hz is typical except for in high-speed machines, $>10,000$ rpm, where the upper limit should at least be six times the rotational frequency. (2) It is common practice to evaluate rotating machinery based on the broadband RMS vibration velocity, since it can be related to the vibration energy levels. However, other quantities such as vibration displacement or acceleration may be preferred. Especially low speed machines can have unacceptably large vibration displacements when the $1 \times$ rpm component is dominant. Therefore, where specified, both the velocity and displacement criteria are met. (3) Since typical vibration waveforms measured on rotating machinery are complex in nature, there is no simple relationship between broadband velocity, displacement, and acceleration. (4) Vibration measurements shall be taken on bearing support housings, or other structural components, which adequately respond to the dynamic forces of the machine. Recommended locations for bearing housings are shown in Figure 34.14. (5) For certain types of machines, the axial vibration limits may differ from those for radial directions. Also, within the same machine set, in particular hydraulic power-generating sets, the applicable level may differ from bearing to bearing depending on its classification as a rigid or flexible support. (6) Above vibration limits apply to steady-state/normal operating conditions of the machine. If the vibration levels are sensitive to the operational conditions, then evaluation of the machine for operating conditions outside steady-state conditions will have to be based on different criteria. (7) The vibration limits specified herein should not be used to assess the condition of rolling element type bearings although it encompasses machines that may have these types of bearings. (8) It must be recognized that the vibration measurement on nonrotating parts alone does not form the only basis for judging the condition of a machine. In certain types of machines, it is common practice also to judge the vibration based on measurements taken on rotating shafts. (9) A support may be considered as rigid in a specific direction only if its natural frequency in that direction exceeds the main excitation frequency by at least 25%, otherwise it is considered to be flexible. In some cases, a support may be rigid in one direction and flexible in another. (10) In the case of hydraulic machine sets, major differences in radial bearing support arrangement can occur. For evaluation of the support type it is recommended that the reader refer to ISO 10816-5.

Description. The following case study is taken from a petroleum pipeline pump application where pump-motor sets with VFDs were installed in a new pipeline starting in Alberta, Canada and terminating in Minnesota, USA. VFDs are frequently used in the pipeline industry to power high horsepower pumps to eliminate power wasted by throttling, reduce inrush current at motor startup, and to provide greater operating flexibility. However, variable speed operation can cause vibration problems in the pump, motor, and the couplings that are not normally experienced with fixed speed pumps. Unexpected high torsional and lateral vibrations were experienced with these pumps and motors at certain operating speeds. A rotor torsional resonance, motor housing resonance, acoustic resonance in the internals of the pump, and discharge piping were identified to be the causes of the high vibration in the pump-motor set. Details on diagnosing the problems and the corrective measures taken to resolve them are given below:

Pump type: The pump was a centrifugal, two-stage, double volute horizontal pump, with six vane impellers, normally designed to operate at a fixed speed. Generation of pressure pulsations at the vane passing frequencies of $6 \times$ and $12 \times$ rotational speed is normally expected.

TABLE 34.7A Acceptable Vibration Levels for Rotating Machinery, Measured on Rotating Shafts

Machinery Type	Power Level	Speed Range (RPM)	Applicable Vibration Level	
			Relative Displacement	Absolute Displacement
Steam turbines	$P \leq 50$ MW	$1,000 \leq N \leq 30,000$	D8	—
	$P > 50$ MW	$N = 1,500$	D5	D7
	$P > 50$ MW	$N = 1,800$	D4	D6
	$P > 50$ MW	$N = 3,000$	D2	D5
	$P > 50$ MW	$N = 3,600$	D1	D3
Gas turbines	$P > 3$ MW	$3,000 \leq N \leq 30,000$	D8	—
	$P \leq 3$ MW	$1,000 \leq N \leq 30,000$	D8	—
Hydraulic turbines and pumps used in hydraulic power generation and pumping plants	$P > 1$ MW	$60 \leq N \leq 1,800$	D9	D9
Centrifugal pumps	All	$1,000 \leq N \leq 30,000$	D8	—
Electric motors	All	$1,000 \leq N \leq 30,000$	D8	—
Generators, excluding those used in hydraulic power generation	$P \leq 50$ MW	$1,000 \leq N \leq 30,000$	D8	—
	$P > 50$ MW	$N = 1,500$	D5	D7
	$P > 50$ MW	$N = 1,800$	D4	D6
	$P > 50$ MW	$N = 3,000$	D2	D5
	$P > 50$ MW	$N = 3,600$	D1	D3
Generators and motors used in hydraulic power generation	$P > 1$ MW	$60 \leq N \leq 1,000$	D9	D9
	$P > 1$ MW	$1,000 < N \leq 1,800$	D8	—
Compressors, rotary, blowers, and fans	All	$1,000 \leq N \leq 30,000$	D8	—

Motor: The motor was a 3000 hp, two pole horizontal induction motor, designed to operate at 3600 rpm.

Supply: The supply was a VFD of the current source inverter type. These drives are known to generate an oscillatory torque at $6 \times$ and $12 \times$ the operating frequency.

Coupling: Flexible disc type coupling with a spacer was used. These couplings have very little torsional damping capacity.

Speed range: The speed range was from 1440 rpm (24 Hz) to 3900 rpm (65 Hz).

Reference: Refer to [Figure 34.15](#) to [Figure 34.18](#).

As for the resonance at second and third torsional critical speeds ([Figure 34.15](#)) the second and third torsional modes are excited when the $6 \times$ component of rotational speed corresponds to the critical speeds of 92 and 268 Hz, respectively. The $6 \times$ rpm torsional excitation is caused by the pressure pulsations in the pump. The waterfall plot ([Figure 34.15a](#)) was taken during a run down of the set with the power to the motor turned off.

A similar plot taken during run up of the motor ([Figure 34.15b](#)) shows excitations at the same frequencies but having different amplitude. Since both the pump and motor generate $6 \times$ excitation, it suggests a phase difference between the excitation torques.

It is important to note that the conventional vibration monitoring devices cannot detect the torsional resonance problem. The only indication of a problem was the unusual chattering noise emitted by the coupling. Special techniques to measure dynamic torque using strain gauges had to be used to detect the torsional vibrations.

As for the motor housing resonance ([Figure 34.16](#)), the $2 \times$ rotational speed vibration of the motor is dominant and peaks at 118 Hz corresponding to a natural frequency of the motor frame. In the waterfall plot, the natural frequencies corresponds to excitations that are parallel to the axis. Excitation at harmonics, including the $6 \times$ component, is present but is not dominant.

As for the pump vibrations at the vane passing frequency ([Figure 34.17](#)), the $6 \times$ vane passing frequency is dominant at all operating speeds. It peaks at 238 Hz, possibly due to an acoustic resonance in

D7	120	240	385
D8	$4800/\sqrt{n}$	$9000/\sqrt{n}$	$13,200/\sqrt{n}$
D9	$10^{(2.3381-0.0704 \log n)}$	$10^{(2.5599-0.0704 \log n)}$	$10^{(2.8609-0.0704 \log n)}$

Zone A: Newly commissioned machines should fall within this zone. **Zone B:** Machines with vibrations within this zone are considered acceptable for long-term operation. **Zone C:** Machines with vibrations within this zone are normally considered unsatisfactory for long-term operation. Such a machine may be operated for a short period in this condition. **Alarm:** The values chosen will normally be set relative to a baseline value determined from experience. However, it is recommended that the alarm value shall not exceed those given herein. **Trip:** The values will generally relate to the mechanical integrity of the machine. They will generally be the same for all machines with similar design. It is recommended that the trip value shall not exceed those given herein. **Notes:** (1) The measured vibration is broadband and is shaft vibration displacement peak to peak. Where applicable, vibration limits for both absolute and relative radial shaft vibrations are given in certain cases. (2) Relative displacement is the vibratory displacement between the shaft and an appropriate structural component such as the bearing housing. Absolute displacement is the vibratory displacement of the shaft with reference to an inertial frame of reference. (3) Relative measurements are carried out with a noncontacting transducer. Absolute readings are obtained by one of the following methods: by a shaft riding probe on which a seismic transducer is mounted so that it measures absolute shaft displacement directly, or with the combination of a noncontacting transducer which measures relative shaft displacement and a seismic transducer which measures support vibration. Their conditioned outputs are vectorially added to provide a measure of the absolute shaft motion. (4) The vibration evaluation criteria are dependent upon a variety of factors and the criteria adopted will vary for different types of machines. Some of these factors are the bearing type, clearance, and diameter. The adopted criteria have to be compared with the bearing diametral clearance (C) and adjusted to suit. Typical values are: Zone A $\leq 0.4C$; Zone B $\leq 0.6C$; and Zone C $\leq 0.7C$. (5) Above vibration limits apply to steady state/normal operating conditions of the machine. If the vibration levels are sensitive to the operational conditions then evaluation of the machine for operating conditions outside steady-state conditions will have to be based on different criteria. (6) It is recommended that vibration readings at each location be made with a pair of transducers and that the transducers are mounted perpendicular to the shaft axis and they are at an angle of 90° to one another. The vibration limits apply to each measured direction. (7) The mechanical and electrical run-out at each measurement location must be assessed and should be $<25\%$ of the allowable limit or $6 \mu\text{m}$, whichever is greater. (8) It must be recognized that the vibration measurement on rotating shafts does not form the only basis for judging the condition of a machine. In certain types of machine, it is common practice also to judge the vibration based on measurements taken on nonrotating parts. (9) ALARM levels should be set relative to a baseline value determined from experience for the measurement position, direction and type of machine. It must provide a warning that a defined value, which is significantly above the baseline value, has been reached. The maximum ALARM setting should be $\leq 0.75C$. (10) The TRIP values should be based on protecting the mechanical integrity of the machine. Consideration of damage to bearings is typical; therefore, maximum TRIP setting should be $\leq 0.9C$.

the discharge pipe. It does not seem to correspond to a structural natural frequency due to the absence of excitations at 238 Hz at all speeds.

As for the acoustic resonance in the pump cross-over pipe (Figure 34.18), dynamic pressure pulsation measurements made on the pump cross-over pipe from the first stage discharge to the second stage suction show an acoustic resonance at 540 Hz. The consistent presence of some excitation at 540 Hz at all speeds confirms that it is an acoustic natural frequency of the cross-over pipe. When the $6 \times \text{rpm}$ pressure pulsation frequency coincides with the acoustic natural frequency, a resonance condition occurs and the magnitude of the pressure pulsation increases by almost a factor of 30.

As for corrective action, for a pump that has to operate over a wide speed range, totally eliminating the coincidence of all the frequencies of exciting forces with the system natural frequencies is impractical. Therefore, the system has to be designed such that the resulting magnitudes of the forces are controlled to within tolerable levels so that safe and reliable operation can take place. This can be accomplished by a

TABLE 34.8 Vibration Cause Identification

Cause	Dominant Frequency	Spectrum, Time Domain, Orbit Shape	Characteristics, Corrections, Comments
Mass unbalance	1 ×	High 1 × with much lower harmonics; circular or elliptic orbits	Corrected by shop or field balancing
Shaft bow	1 ×	Run down plot shows decrease of vibration at critical speed	The shaft has to be straightened using an acceptable method
Misalignment	1 × and 2 ×	Equally high 1 × and 2 ×, figure 8 orbits	Realign at operating conditions; loads causing misalignment, such as nozzle loads, may have to be reduced
Worn journal bearings	1 ×, 1/2 ×	Equally high 1 × and 1/2 ×	Difficult to balance
Gravity critical	2 ×	Run down plot will show excitation at 1/2 critical speed	Can be corrected by balancing
Asymmetric shaft	2 ×	Run down plot will show excitation at 1/2 critical speed	Typically occurs on multistage machines when all the keyways lie in the same plane; correct by staggering them
Shaft crack	1 × and 2 ×	High 1 × and run down plots may show excitation at 1/2 critical speed	Confirmation and detection of location of the crack may require NDE techniques
Loose components	1 × and higher orders plus fractional subharmonics	High 1 × with lower level orders and fractional subharmonics	Shimming and peening may be used as temporary methods to fix the problem
Coupling lockup	1 × and 2 ×	Equally high 1 × and 2 ×, figure 8 orbits	Stop starts may change vibration pattern
Thermal instability	1 ×	High 1 × varies with temperature. Phase angle may change	Proper prewarming or compromise balancing can correct the problem
Oil whirl	<1/2 ×, typically 0.35 × to 0.47 ×	Run-up plot will show 1/2 × increasing and locking into fixed value <1/2 ×	Temporary problem may be caused by excess clearances, oil viscosity, or unloading of the bearing; if it is a design problem, correct by changing to tilting pad bearings
Internal rubs	1/4 ×, 1/3 ×, 1/2 ×, 2 ×, 3 ×, 4 ×, etc.	Run down plots may show decreasing amplitudes and disappearance; loops in orbits	May get progressively worse; galling between contact surfaces or heat build-up may cause seizure and shaft failure
Trapped fluids in rotor	0.8 × to 0.9 ×	Time domain signal will show beating	Balancing the rotor may reduce the vibration
Defective rolling element bearings	At bearing defect frequency	Peaks at defect frequencies in spectrum	Shock pulse measurements can also be used to detect problem
Damaged gears	Gear mesh frequency	High peaks at gear mesh frequency with side bands. Time domain may also show pulses	To determine exact nature of damage further analysis may be required

TABLE 34.8 (continued)

Cause	Dominant Frequency	Spectrum, Time Domain, Orbit Shape	Characteristics, Corrections, Comments
Electric motor problems	$1 \times$ (line frequency), $2 \times$ (line frequency)	High peaks at $1 \times$ and $2 \times$ line frequency with side bands; disappears when power to motor is turned off	In the case of two pole motors, it can be confused with mechanical causes as the rotational speed is the same as line frequency
Casing distortion	$1 \times$	High $1 \times$, may change with time	Caused by high nozzle loads, casing not free to expand, soft foot or foundation distortion
Piping forces	$1 \times$, $2 \times$	Equally high $1 \times$ and $2 \times$	Causes misalignment between bearings or between coupled equipment
Rotor and bearing critical	$1 \times$	High $1 \times$, on rundown plot $1 \times$ decreases rapidly, may also show a large phase angle change	More common in machines originally designed for fixed speed operation, later converted to variable speed operation
Structural resonance	$1 \times$, $2 \times$	High $1 \times$ and some $2 \times$; can be easily identified on run down plot	Increase or decrease stiffness of structure or add or remove mass to change natural frequency
Rotor hysteresis	$0.65 \times$ to $0.85 \times$	Spectrum will show high magnitudes at $0.65 \times$ to $0.85 \times$	Occurs in built up rotors with transitional fits
Hydraulic causes	$1 \times$ (vane pass frequency), $2 \times$ (vane pass frequency)	High $1 \times$ and $2 \times$ vane pass frequency	Common in centrifugal pumps due to flow recirculation or inadequate gap between impeller and casing

direct reduction of the exciting force or by means of increased damping. Based on these guidelines, the following modifications were proposed to correct the problem:

1. Torsional resonance

- Use an electrometric type coupling that has a high degree of torsional damping to reduce the magnitude of the torsional excitation forces such that the torsional stresses within the rotors are within acceptable limits.
- Since both the pump and VFD generate excitation at $6 \times$ rpm, their effects could be compounding one another. Introducing either five vane or seven vane impellers into the pump will eliminate this possibility.
- Additional filters could be introduced into the VFD to reduce the $6 \times$ and $12 \times$ component periodic torsional excitation.
- Consider not operating (lock out) the pump within $\pm 10\%$ of the frequency at which torsional resonance occurs.

2. Motor housing resonance at $2 \times$

- Although the $2 \times$ vibration is dominant, its magnitude is within tolerable levels. The fact that some $2 \times$ vibration is also present in the pump indicates that the $2 \times$ vibration is perhaps caused by misalignment between the pump and the motor. This can be corrected by proper

alignment and thus reducing the $2 \times$ excitation forces. In some cases, due to an unequal air gap between the rotor and stator of the motor, the motor could generate the $2 \times$ vibration. Under such conditions, accurate centering of the motor bearings will generally correct the problem.

3. Pump vibrations at vane passing frequency

- Generally, high vibrations at vane passing frequency are caused by pressure pulsations generated at the discharge of the impeller. There are several hydraulic modifications that can be made to the pump to reduce the amplitude of these pulsations that occur at vane passing frequency. The most common method is to increase the gap between the impeller discharge vanes and diffuser/volute. Also, changing the ratio of the number of impeller vanes to diffuser/volute vanes can help in reducing vane passing frequency pressure pulsations and the resulting vibration.

4. Acoustic resonance in the pump cross-over pipe

- Once the pump is constructed, it is not possible to change the acoustic natural frequency of the cross-over pipe. However, the excitation force, pressure pulsations generated at the impeller discharge, can be reduced by the methods outlined above.

- The root cause of a vibration problem in a rotating machine can be determined by careful study and analysis of the vibration signals.
- Industrial and international vibration standards and guidelines have been developed to ensure safe and reliable operation of rotating machinery.
- Equipment manufacturers, users, insurance companies, and public interest groups use vibration standards to control vibration to within acceptable levels.

University of Missouri at Rolla

Summary

Regenerative chatter, a result of unstable interactions between machining forces and structural deflections, is a great limitation in machining operations. This chapter describes the modeling, analysis, simulation, detection, and control of regenerative chatter in machining operations, and, in particular, turning and face milling. An analytical method is applied to calculate the limiting stable depth-of-cut and corresponding spindle speeds to generate stability lobe diagrams. The method is applied to both turning and face-milling operations. Time-domain simulation is described and applied to turning and face-milling operations. Methods for chatter detection are presented and experimental results from a face-milling operation are given. Chatter suppression techniques, namely spindle-speed selection, feed selection, depth-of-cut selection, and spindle-speed variation, are presented and two simulations of a turning operation are used to illustrate the spindle-speed selection and spindle-speed variation techniques. Finally, a case study of a face-milling operation is presented. The nomenclature used in the presentation is listed at the end of the chapter.

35.1 Introduction

Regenerative chatter is a major limitation in machining operations. This phenomenon is a result of an unstable interaction between the machining forces and the structural deflections. The forces generated when the cutting tool and part come into contact produce significant structural deflections. These structural deflections modulate the chip thickness that, in turn, changes the machining forces. For certain cutting conditions, this closed-loop, self-excited system becomes unstable and regenerative chatter occurs. Regenerative chatter may result in excessive machining forces and tool wear, tool failure, and scrap parts due to unacceptable surface finish, thus severely decreasing operation productivity and part quality.

A typical chatter stability chart, the so-called stability lobe diagram, is shown in Figure 35.1. If the process parameters are above the stability borderline, chatter will occur, and if the process parameters are below the stability borderline, chatter will not occur. The asymptotic stability borderline is the depth-of-cut below which stable machining is guaranteed regardless of the spindle speed. The lobed nature of the stability borderline allows stable pockets to form; thus, at specific ranges of spindle speeds, the depth-of-cut may be substantially increased beyond the asymptotic stability limit. These pockets become smaller as the spindle speed decreases. The stability borderline is “pulled up” for low spindle speeds due to process damping (i.e., the back side of the tool rubbing on the part surface). If accurate models of the structural components and the cutting process are available, the stability lobe diagram may be used to plan chatter-free machining operations.

FIGURE 35.1 Stability lobe diagram.

The analysis of regenerative chatter as the interaction between the cutting forces and structural vibrations was established by Tobias (1965) and Koenigsberger and Tlustý (1971). Merritt (1965) used systems theory to determine stability and construct the stability lobe diagram by generating specialized plots from the harmonic solutions of the system's characteristic equation. Chatter analysis reveals a natural delay in the system leading many researchers to use Nyquist techniques to generate stability lobe diagrams (Minis et al., 1990a, 1990b; Lee and Liu, 1991a, 1991b; Minis and Yanushevsky, 1993).

A set of process parameters is selected and the characteristic equation is formed. The Nyquist criterion is applied to determine if the system for this process parameter set is stable. The depth-of-cut is adjusted and the procedure is repeated until the critical depth-of-cut is determined. Another chatter analysis technique capable of generating stability lobe diagrams analytically for linear systems has recently been introduced (Altintas and Budak, 1995; Budak and Altintas, 1998a, 1998b). This technique is utilized in this chapter.

The theoretical analysis of regenerative chatter laid the foundation for developing techniques to automatically detect its occurrence and to automatically suppress it. Since there is a dominant chatter frequency, which is near a structural frequency, that occurs when chatter develops, most monitoring techniques analyze the frequency of a process variable, and chatter is detected when significant energy is present near a structural frequency. Most automatic chatter suppression routines either adjust the spindle speed to be in a pocket of the stability lobe diagram or vary the spindle speed to bring the current and previous tooth passes into phase. While automatic monitoring and control of regenerative chatter shows great promise, it has been mostly limited to laboratory applications. Therefore, commercial tools are not currently available.

While regenerative chatter in turning and face-milling operations is discussed in this chapter, this phenomenon is not limited to these specific manufacturing operations. Other machining operations for which chatter has been analyzed include end milling (Budak and Altintas, 1998a, 1998b), grinding (Inasaki et al., 2001), drilling (Tarng and Li, 1994), and so on. Also, the regenerative chatter phenomenon occurs in other manufacturing operations, most notably in rolling (Yun et al., 1998; Tlustý, 2000).

Section 35.2 and Section 35.3 present an analytical method to examine regenerative chatter in turning and face-milling operations, respectively. Section 35.4 discusses a numerical technique known as time domain simulation that may be used to analyze regenerative chatter for nonlinear systems. The subject of chatter detection is presented in Section 35.5, then methods to perform chatter suppression are discussed and illustrated in Section 35.6. Section 35.7 presents a case study of a face-milling operation.

35.2 Chatter in Turning Operations

A schematic of a turning operation is shown in Figure 35.2. The part structure is assumed to be perfectly rigid, while the cutting-tool structure is capable of vibrations in the longitudinal (i.e., the z) direction only. The machining force in the longitudinal direction is

$$F(t) = Pdf(t) \quad (35.1)$$

The depth-of-cut is assumed to be constant; however, the feed, and hence the machining force, is time-varying due to structural vibrations. It is assumed here that the machining force does not explicitly depend upon the cutting speed.

The feed is the chip thickness in the longitudinal direction. The nominal feed is the distance the tool advances relative to the part each spindle revolution and is constant once the tool fully engages the part. However, the cutting tool vibrates, leaving an undulated surface on the part and, thus, modulates the feed. The instantaneous feed is

$$f(t) = f_{\text{nom}} + \Delta z(t) = f_{\text{nom}} + z(t) - z(t - T) \quad (35.2)$$

The term f_{nom} is the nominal feed, also known as the static feed. The term $\Delta z(t)$ is the feed due to the cutting-tool vibrations and is known as the dynamic feed. The parameter T is the spindle-rotation period. The structural vibration, $z(t)$, known as the inner modulation, is the cutting-tool vibration at the current time. The delayed structural vibration $z(t - T)$, known as the outer modulation, is the cutting-tool vibration as of when the part was at the current angular during the previous spindle rotation. The modulation in feed due to structural vibrations is illustrated in Figure 35.3.

Inserting Equation 35.2 into Equation 35.1:

$$F(t) = Pdf_{\text{nom}} + Pd\Delta z(t) = F_{\text{nom}} + \Delta F(t) \quad (35.3)$$

The force $F_{\text{nom}} = Pdf_{\text{nom}}$ is due to the nominal chip thickness and does not vary since the depth-of-cut and nominal feed are constant. The force $\Delta F(t) = Pd\Delta z(t)$ is due to changes in the nominal feed caused by structural vibrations.

The structural vibrations are related to the machining force by

$$z(s) = -g(s)F(s) \quad (35.4)$$

where $g(s)$ is the transfer function relating the structural vibrations to the machining forces. Since $F(t) - F(t - T) = \Delta F(t) - \Delta F(t - T)$, the structural vibrations are related to the machining

FIGURE 35.2 Turning operation schematic: current pass (solid line) and previous pass (dotted line).

FIGURE 35.3 Modulation in feed due to structural vibrations in a turning operation: current pass (solid line) and previous pass (dotted line).

forces by

$$\Delta z(s) = -(1 - e^{-sT})g(s)\Delta F(s) \quad (35.5)$$

Substituting for Δz in Equation 35.5 and rearranging:

$$\Delta F(s)\{1 + Pd[1 - e^{-sT}]g(s)\} = 0 \quad (35.6)$$

Equation 35.6 is now solved, based on the method presented by Budak and Altintas (1998a, 1998b), to determine the stability lobe diagram. Assuming the steady-state solution is a harmonic function at a single chatter frequency ω_c , Equation 35.6 becomes

$$\Delta F(j\omega_c)e^{j\omega_c T}\{1 + Pd[1 - e^{-j\omega_c T}]g(j\omega_c)\} = 0 \quad (35.7)$$

where $j^2 = -1$. For nontrivial solutions of Equation 35.7, the following eigenvalue problem is derived:

$$\det\{1 + Pd[1 - e^{-j\omega_c T}]g(j\omega_c)\} = 0 \quad (35.8)$$

Since the structural dynamics are one-dimensional, Equation 35.8 reduces to

$$1 + Pd[1 - e^{-j\omega_c T}]g(j\omega_c) = 0 \quad (35.9)$$

The parameter Λ is defined as

$$\Lambda = Pd[1 - e^{-j\omega_c T}] = \Lambda_R + j\Lambda_I \quad (35.10)$$

Using the Euler identity $1 - e^{-j\omega_c T} = 1 - \cos(\omega_c T) + j \sin(\omega_c T)$, the limiting stable depth-of-cut is

$$d_{\lim} = \left(\frac{1}{P}\right) \frac{\Lambda_R + j\Lambda_I}{1 - \cos(\omega_c T) + j \sin(\omega_c T)} \quad (35.11)$$

Equation 35.11 is rewritten as

$$d_{\lim} = \left(\frac{1}{2P}\right) \left\{ \frac{\Lambda_R[1 - \cos(\omega_c T)] + \Lambda_I \sin(\omega_c T)}{1 - \cos(\omega_c T)} + j \frac{\Lambda_R \sin(\omega_c T) + \Lambda_I[1 - \cos(\omega_c T)]}{1 - \cos(\omega_c T)} \right\} \quad (35.12)$$

Since the limiting depth-of-cut must be a real number:

$$\Lambda_R \sin(\omega_c T) + \Lambda_I[1 - \cos(\omega_c T)] = 0 \quad (35.13)$$

The parameter κ is defined as

$$\kappa = \frac{\Lambda_I}{\Lambda_R} = \frac{\sin(\omega_c T)}{1 - \cos(\omega_c T)} \quad (35.14)$$

The limiting stable depth-of-cut is solved explicitly as

$$d_{\lim} = \frac{\Lambda_R}{2P}(1 + \kappa^2) \quad (35.15)$$

Note that Λ_R must be positive for d_{\lim} to be positive. From Equation 35.9, the parameter Λ is

$$\Lambda = -\frac{1}{g(j\omega_c)} \quad (35.16)$$

Equation 35.16 is used to determine Λ_R and Λ_I , and these values are used to solve for d_{\lim} . Next, the spindle speed at which the limiting depth-of-cut occurs is determined. The trivial solution to Equation 35.14 is

$$\omega_c T = 0 + 2l\pi, \quad l = 0, 1, 2, \dots \quad (35.17)$$

The quantity $\omega_c T$ may be interpreted as the number of vibration cycles during a spindle rotation. The trivial solution indicates that the successive vibrations are in phase (i.e., there is no regeneration). The nontrivial solution to Equation 35.14 is

$$\cos(\omega_c T) = \frac{\kappa^2 - 1}{\kappa^2 + 1} \quad (35.18)$$

and may be rewritten as

$$\omega_c T = \varepsilon + 2l\pi, \quad l = 0, 1, 2, \dots \quad (35.19)$$

where

$$\varepsilon = \cos^{-1} \left(\frac{\kappa^2 - 1}{\kappa^2 + 1} \right) \quad (35.20)$$

The parameter ε is the fraction of the vibration cycles during a spindle rotation. The angle of Λ in the complex plane is

$$\varphi = \tan^{-1} \left(\frac{\Lambda_I}{\Lambda_R} \right) = \tan^{-1}(\kappa) \quad (35.21)$$

Substituting $\kappa = \tan(\varphi)$ into Equation 35.18 yields

$$\cos(\omega_c T) = -\cos(2\varphi) \quad (35.22)$$

A solution to Equation 35.22 is

$$\omega_c T = \pi - 2\varphi + 2l\pi, \quad l = 0, 1, 2, \dots \quad (35.23)$$

Comparing Equation 35.19 and Equation 35.23, it is seen that the fraction of vibration cycles is $\varepsilon = \pi - 2\varphi$. Since $0 \leq \varepsilon \leq 2\pi$, one must ensure that $-\pi/2 \leq \varphi \leq \pi/2$ when computing φ . For example, if Equation 35.21 is solved using a four-quadrant inverse tangent function whose solution is bounded between $-\pi$ and π , then $-\pi/2 \leq \varphi \leq \pi/2$ since Λ_R is positive. For milling applications, it will be seen that Λ_R must be negative; therefore, the following conditions must be enforced to ensure $0 \leq \varepsilon \leq 2\pi$:

$$\begin{aligned} \text{if } \Lambda_I < 0 \quad \text{then } \varphi &\rightarrow \varphi + \pi \\ \text{if } \Lambda_I > 0 \quad \text{then } \varphi &\rightarrow \varphi - \pi \end{aligned} \quad (35.24)$$

The spindle speed is

$$N_s = \frac{60}{T} = \frac{60\omega_c}{\varepsilon + 2l\pi}, \quad l = 0, 1, 2, \dots \quad (35.25)$$

To construct a stability lobe diagram, the following steps are implemented:

1. Select a chatter frequency (ω_c) near a dominant structural frequency.
2. Calculate Λ_R and Λ_I using Equation 35.16.
3. Calculate d_{lim} using Equation 35.15.
4. Select a stability lobe number (l) and calculate N_s using Equation 35.25. The point (N_s, d_{lim}) is the point on the stability lobe diagram corresponding to the chatter frequency, ω_c , and the stability lobe number, l .
5. Repeat Step 4 for the desired number of stability lobes. The result is a vector of spindle speeds, $\vec{N}_s = \{N_{s_1} \ N_{s_2} \ \cdots \ N_{s_n}\}$. Each point $\{(N_{s_1}, d_{lim}) \ (N_{s_2}, d_{lim}) \ \cdots \ (N_{s_n}, d_{lim})\}$ corresponds to a different stability lobe, and all of the points correspond to the chatter frequency ω_c .
6. Select another chatter frequency and repeat Steps 2 to 5. In this manner, the stability lobe diagram is constructed. The smaller the difference between successive chatter frequencies, the greater the resolution of the stability lobe diagram. In general, the lobes will overlap. In this case, the

minimum limiting depth-of-cut is the smallest depth-of-cut. If the lobes do not overlap, then the range of chatter frequencies must be increased.

35.2.1 Example 1

The feed force for a turning operation is given by Equation 35.1 and the structural dynamics are given by Equation 35.26. An analytical expression for the limiting depth-of-cut and corresponding spindle speed for a given chatter frequency and stability lobe number is developed. The stability lobe diagram is plotted for $P = 0.6 \text{ kN/mm}^2$, $\omega_n = 600 \text{ Hz}$, $\zeta = 0.2$, and $k = 12 \text{ kN/mm}$. The stability lobe diagram is compared to stability lobe diagrams for $\zeta = 0.1, 0.3$, and 0.4 . The stability lobe diagram is then compared with stability lobe diagrams for $\omega_n = 500, 700$, and 800 Hz . The first ten lobes are included for all stability lobe diagrams:

$$\ddot{z}(t) + 2\zeta\omega_n\dot{z}(t) + \omega_n^2z(t) = -\frac{\omega_n^2}{k}F(t) \quad (35.26)$$

The parameter Λ is

$$\Lambda = \frac{-1}{g(j\omega_c)} = \Lambda_R + j\Lambda_I = \frac{k}{\omega_n^2}(\omega_c^2 - \omega_n^2) - j\frac{k}{\omega_n^2}(2\zeta\omega_c\omega_n) \quad (35.27)$$

The limiting depth-of-cut is

$$d_{\text{lim}} = \frac{k(\omega_c^2 - \omega_n^2)}{2K\omega_n^2} \left[1 + \frac{4\zeta^2\omega_c^2\omega_n^2}{(\omega_c^2 - \omega_n^2)^2} \right] \quad (35.28)$$

The spindle speed is

$$N_s = \frac{60\omega_c}{\pi - 2 \tan^{-1} \left(\frac{-2\zeta\omega_c\omega_n}{\omega_c^2 - \omega_n^2} \right) + 2l\pi}, \quad l = 0, 1, 2, \dots \quad (35.29)$$

where l is the stability lobe number. Note that the chatter frequency must be greater than the structural natural frequency for the limiting depth-of-cut to be positive. The first ten lobes of the

FIGURE 35.4 Unprocessed stability lobe diagram for Example 1.

FIGURE 35.5 Processed stability lobe diagram for Example 1.

stability lobe diagram are plotted in Figure 35.4 and Figure 35.5. In Figure 35.4, the entire solution for each of the ten stability lobes is shown. The largest stability lobe is the zeroth lobe on the right. The lobe number increases from right to left on the stability lobe diagram and successive lobes become closer together. The stability lobe diagram is processed in Figure 35.5 such that the minimum depth-of-cut is selected at each spindle speed showing the true stability borderline.

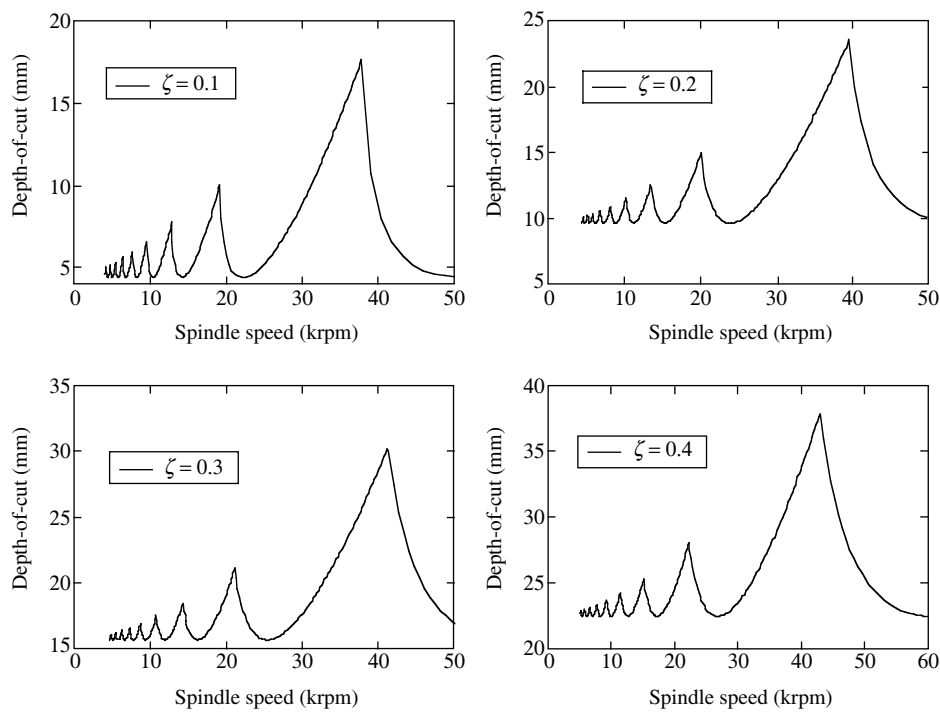

FIGURE 35.6 Stability lobe diagrams for Example 1 with $\zeta = 0.1, 0.2, 0.3,$ and 0.4 .

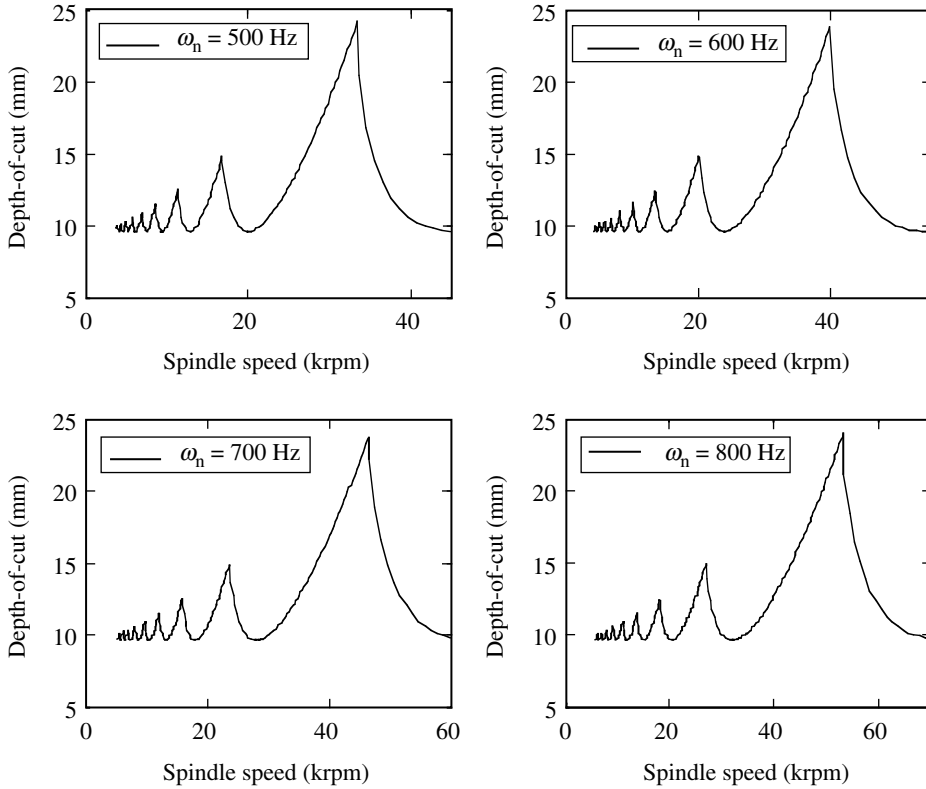

FIGURE 35.7 Stability lobe diagrams for Example 1 with $\omega_n = 500, 600, 700$, and 800 Hz.

In [Figure 35.6](#), the effect of the structural damping ratio is illustrated: as the structural damping ratio increases, the lobes shift slightly to the left and the asymptotic stability boundary shifts up dramatically. The effect of the structural natural frequency is illustrated in [Figure 35.7](#): as the structural natural frequency increases, the lobes shift to the right but the magnitude remains the same.

This section presented an analytical method to generate stability lobe diagrams for turning operations. The limiting depth-of-cut in a turning operation is given by

$$d_{\text{lim}} = \frac{A_R}{2P} (1 + \kappa^2)$$

where A_R is the real part of $-1/g(j\omega_c)$, $g(j\omega_c)$ is the structural transfer function evaluated at the chatter frequency, ω_c , $\kappa = A_I/A_R$, and A_I is the imaginary part of $-1/g(j\omega_c)$. The corresponding spindle speed is

$$N_s = \frac{60\omega_c}{\varepsilon + 2l\pi}$$

where $l = 0, 1, 2, \dots$ is the stability lobe number and

$$\varepsilon = \cos^{-1} \left(\frac{\kappa^2 - 1}{\kappa^2 + 1} \right)$$

35.3 Chatter in Face-Milling Operations

A schematic of a face-milling operation is shown in Figure 35.8. In milling operations, multiple teeth may be in contact with the part simultaneously, the feed naturally varies as a function of the tooth angle even when structural vibrations are not present, and each tooth enters and leaves contact with the part every spindle revolution. The depth-of-cut is the chip thickness in the z direction and is assumed to be constant, since the machine tool and part structures are typically much stiffer in the z direction than in the x and y directions.

The instantaneous feed of the i th tooth, illustrated in Figure 35.9, is

$$f_i(t) = f_t \cos[\theta_i(t)] + \Delta x(t) \cos[\theta_i(t)] + \Delta y(t) \sin[\theta_i(t)] \quad (35.30)$$

where

$$\Delta x(t) = \{x_t(t) - x_t(t - T_t)\} - \{x_p(t) - x_p(t - T_t)\} \quad (35.31)$$

$$\Delta y(t) = \{y_t(t) - y_t(t - T_t)\} - \{y_p(t) - y_p(t - T_t)\} \quad (35.32)$$

The term $f_t \cos[\theta_i(t)]$ in Equation 35.30 represents the feed due to the distance the part advances relative to the cutting tool each tooth rotation and is known as the static feed. The terms $\Delta x(t) \cos[\theta_i(t)]$

FIGURE 35.8 Face milling operation schematic: current pass (solid line), previous pass (dotted line), and depth-of-cut in z direction.

FIGURE 35.9 Modulation in feed due to structural vibrations in a face-milling operation: current pass (solid line) and previous pass (dotted line).

and $\Delta y(t) \sin[\theta_i(t)]$ in Equation 35.30 represent the feed due to tool and part vibrations in the x and y directions, respectively, at the tooth angle $\theta_i(t)$, and are known as the dynamic feed.

The machining forces in the x and y directions, respectively, are

$$\begin{aligned} F_x(t) = & df_t \sum_{i=1}^{N_t} \left\{ -P_T \cos(\psi_r) \cos^2[\theta_i(t)] + P_C \cos[\theta_i(t)] \sin[\theta_i(t)] \right\} \sigma[\theta_i(t)] \\ & + d\Delta x(t) \sum_{i=1}^{N_t} \left\{ -P_T \cos(\psi_r) \cos^2[\theta_i(t)] + P_C \cos[\theta_i(t)] \sin[\theta_i(t)] \right\} \sigma[\theta_i(t)] \\ & + d\Delta y(t) \sum_{i=1}^{N_t} \left\{ -P_T \cos(\psi_r) \sin[\theta_i(t)] \cos[\theta_i(t)] + P_C \sin^2[\theta_i(t)] \right\} \sigma[\theta_i(t)] \end{aligned} \quad (35.33)$$

$$\begin{aligned} F_y(t) = & df_t \sum_{i=1}^{N_t} \left\{ -P_T \cos(\psi_r) \cos[\theta_i(t)] \sin[\theta_i(t)] - P_C \cos^2[\theta_i(t)] \right\} \sigma[\theta_i(t)] \\ & + d\Delta x(t) \sum_{i=1}^{N_t} \left\{ -P_T \cos(\psi_r) \cos[\theta_i(t)] \sin[\theta_i(t)] - P_C \cos^2[\theta_i(t)] \right\} \sigma[\theta_i(t)] \\ & + d\Delta y(t) \sum_{i=1}^{N_t} \left\{ -P_T \cos(\psi_r) \sin^2[\theta_i(t)] - P_C \cos[\theta_i(t)] \sin[\theta_i(t)] \right\} \sigma[\theta_i(t)] \end{aligned} \quad (35.34)$$

where

$$\sigma[\theta_i(t)] = \begin{cases} 1 & \text{if } \theta_{en} \leq \theta_i(t) \leq \theta_{ex} \\ 0 & \text{if } \theta_{en} > \theta_i(t) > \theta_{ex} \end{cases} \quad (35.35)$$

The function $\sigma[\theta_i(t)]$ determines if the i th tooth is in contact with the part at the tooth angle, $\theta_i(t)$. The first terms in Equation 35.33 and Equation 35.34 are the machining forces acting on the tool in the x and y directions, respectively, due to the static feed. The second terms in Equation 35.33 and Equation 35.34 are the machining forces acting on the tool in the x and y directions, respectively, due to the dynamic feed resulting from structural vibrations in the x direction. The third terms in Equation 35.33 and Equation 35.34 are the machining forces acting on the tool in the x and y directions, respectively, due to the dynamic feed resulting from structural vibrations in the y direction.

The dynamic portion of the face milling force process model may be written compactly as

$$\begin{bmatrix} \Delta F_x(t) \\ \Delta F_y(t) \end{bmatrix} = dA(t) \begin{bmatrix} \Delta x(t) \\ \Delta y(t) \end{bmatrix} = d \begin{bmatrix} A_{11}(t) & A_{12}(t) \\ A_{21}(t) & A_{22}(t) \end{bmatrix} \begin{bmatrix} \Delta x(t) \\ \Delta y(t) \end{bmatrix} \quad (35.36)$$

where

$$A_{11}(t) = \sum_{i=1}^{N_t} \left\{ -P_T \cos(\psi_r) \cos^2[\theta_i(t)] + P_C \cos[\theta_i(t)] \sin[\theta_i(t)] \right\} \sigma[\theta_i(t)] \quad (35.37)$$

$$A_{12}(t) = \sum_{i=1}^{N_t} \left\{ -P_T \cos(\psi_r) \sin[\theta_i(t)] \cos[\theta_i(t)] + P_C \sin^2[\theta_i(t)] \right\} \sigma[\theta_i(t)] \quad (35.38)$$

$$A_{21}(t) = \sum_{i=1}^{N_t} \left\{ -P_T \cos(\psi_r) \cos[\theta_i(t)] \sin[\theta_i(t)] - P_C \cos^2[\theta_i(t)] \right\} \sigma[\theta_i(t)] \quad (35.39)$$

$$A_{22}(t) = \sum_{i=1}^{N_t} \left\{ -P_T \cos(\psi_r) \sin^2[\theta_i(t)] - P_C \cos[\theta_i(t)] \sin[\theta_i(t)] \right\} \sigma[\theta_i(t)] \quad (35.40)$$

These coefficients modulate the instantaneous feed as the tooth angular displacement changes. The summation from $i = 1$ to N_t represents the contribution to this modulation for each of the N_t teeth. Note the matrix $A(t)$ is time-varying and periodic with the tooth-passing period, T_t . For chatter analysis, the matrix $A(t)$ is typically expanded in a Fourier series using the zeroth term (Minis and Yanushevsky, 1993; Budak and Altintas, 1998a). The zeroth term of the Fourier expansion of the force process matrix $A(t)$ is

$$A^0 = \frac{N_t}{2\pi} \begin{bmatrix} A_{11}^0 & A_{12}^0 \\ A_{21}^0 & A_{22}^0 \end{bmatrix} \quad (35.41)$$

where

$$A_{11}^0 = \frac{1}{2} \left[-P_T \cos(\psi_r) \left\{ \theta + \frac{1}{2} \sin(2\theta) \right\} + P_C \sin^2(\theta) \right]_{\theta=\theta_{en}}^{\theta=\theta_{ex}} \quad (35.42)$$

$$A_{12}^0 = \frac{1}{2} \left[-P_T \cos(\psi_r) \sin^2(\theta) + P_C \left\{ \theta - \frac{1}{2} \sin(2\theta) \right\} \right]_{\theta=\theta_{en}}^{\theta=\theta_{ex}} \quad (35.43)$$

$$A_{21}^0 = \frac{1}{2} \left[-P_T \cos(\psi_r) \sin^2(\theta) - P_C \left\{ \theta + \frac{1}{2} \sin(2\theta) \right\} \right]_{\theta=\theta_{en}}^{\theta=\theta_{ex}} \quad (35.44)$$

$$A_{22}^0 = \frac{1}{2} \left[-P_T \cos(\psi_r) \left\{ \theta - \frac{1}{2} \sin(2\theta) \right\} - P_C \sin^2(\theta) \right]_{\theta=\theta_{en}}^{\theta=\theta_{ex}} \quad (35.45)$$

The dynamic force process is now approximated by the linear, time-invariant relationship:

$$\begin{bmatrix} \Delta F_x(t) \\ \Delta F_y(t) \end{bmatrix} = dA^0 \begin{bmatrix} \Delta x(t) \\ \Delta y(t) \end{bmatrix} \quad (35.46)$$

The tool and part vibrations, respectively, are related to the machining forces by

$$\begin{bmatrix} x_t(s) \\ y_t(s) \end{bmatrix} = G_t(s) \begin{bmatrix} F_x(s) \\ F_y(s) \end{bmatrix} = \begin{bmatrix} G_{t11}(s) & G_{t12}(s) \\ G_{t21}(s) & G_{t22}(s) \end{bmatrix} \begin{bmatrix} F_x(s) \\ F_y(s) \end{bmatrix} \quad (35.47)$$

$$\begin{bmatrix} x_p(s) \\ y_p(s) \end{bmatrix} = -G_p(s) \begin{bmatrix} F_x(s) \\ F_y(s) \end{bmatrix} = -\begin{bmatrix} G_{p11}(s) & G_{p12}(s) \\ G_{p21}(s) & G_{p22}(s) \end{bmatrix} \begin{bmatrix} F_x(s) \\ F_y(s) \end{bmatrix} \quad (35.48)$$

where $G_t(s)$ and $G_p(s)$ are the transfer functions relating the tool structural and part structural vibrations, respectively, to the machining forces. The negative sign in Equation 35.48 is due to the fact that the forces acting on the part are equal in magnitude and opposite in direction to the machining forces given in Equation 35.33 and Equation 35.34. Since

$$\begin{bmatrix} F_x(t) \\ F_y(t) \end{bmatrix} - \begin{bmatrix} F_x(t - T_t) \\ F_y(t - T_t) \end{bmatrix} = \begin{bmatrix} \Delta F_x(t) \\ \Delta F_y(t) \end{bmatrix} - \begin{bmatrix} \Delta F_x(t - T_t) \\ \Delta F_y(t - T_t) \end{bmatrix}$$

the structural vibrations can be related to the machining forces by

$$\begin{bmatrix} \Delta x \\ \Delta y \end{bmatrix} = (1 - e^{-sT_t}) [G_t(s) + G_p(s)] \begin{bmatrix} \Delta F_x(s) \\ \Delta F_y(s) \end{bmatrix} \quad (35.49)$$

The machine tool and part vibrations are assumed to occur at a chatter frequency, ω_c , when a marginally stable depth-of-cut is taken. Assuming the steady-state solution is a harmonic function at a chatter

frequency, ω_c , and substituting for the structural vibrations, Equation 35.49 becomes

$$\begin{bmatrix} \Delta F_x \\ \Delta F_y \end{bmatrix} e^{j\omega_c t} = \frac{dN_t}{2\pi} (1 - e^{j\omega_c T_t}) G^0(j\omega_c) \begin{bmatrix} \Delta F_x \\ \Delta F_y \end{bmatrix} e^{j\omega_c t} \quad (35.50)$$

where the matrix G^0 is

$$G^0(j\omega_c) = \frac{2\pi}{N_t} A^0 [G_t(j\omega_c) + G_p(j\omega_c)] \quad (35.51)$$

Equation 35.50 is now solved based on the method presented by Budak and Altintas (1998a, 1998b) to determine the stability lobe diagram. The characteristic equation of Equation 35.50 is

$$\det \left[I_2 - \frac{dN_t}{2\pi} (1 - e^{j\omega_c T_t}) G^0(j\omega_c) \right] = 0 \quad (35.52)$$

where I_2 is the 2×2 identity matrix. The solution of Equation 35.52 yields the limiting stable depth-of-cut. The inverse of the eigenvalue of G^0 is defined as

$$\Lambda(j\omega_c) = \Lambda_R(j\omega_c) + j\Lambda_I(j\omega_c) = -\frac{dN_t}{2\pi} (1 - e^{j\omega_c T_t}) \quad (35.53)$$

Expanding the exponential term in Equation 35.53 and noting that the depth-of-cut must be a real number, the limiting stable depth-of-cut may be written as

$$d_{\lim} = -\frac{\pi \Lambda_R}{N_t} (1 + \kappa^2) \quad (35.54)$$

where the parameter κ is defined by the transcendental equation

$$\kappa = \frac{\Lambda_I}{\Lambda_R} = \frac{\sin(\omega_c T_t)}{1 - \cos(\omega_c T_t)} \quad (35.55)$$

Equation 35.55 is solved for the tooth-passing period of the l th stability lobe and the tooth-passing period is related to the spindle speed to yield

$$N_s = \frac{60\omega_c}{N_t[\pi - 2\varphi + 2l\pi]}, \quad l = 0, 1, 2, \dots \quad (35.56)$$

where, again, $\varphi = \tan^{-1}(\kappa)$. A chatter frequency is selected and the limiting stable depth-of-cut is calculated from Equation 35.54 corresponding to the spindle speed on the l th lobe as given by Equation 35.56.

35.3.1 Example 2

The cutting and thrust pressures in a face-milling operation are given by $P_C = 2.0 \text{ kN/mm}^2$ and $P_T = 0.8 \text{ kN/mm}^2$, respectively, and the lead angle is 45° . The part is assumed to be perfectly rigid and the tool structural dynamics for the x and y directions are given by Equation 35.57 and Equation 35.58, respectively. The nominal parameters are $\theta_{\text{en}} = -45^\circ$, $\theta_{\text{ex}} = 45^\circ$, $N_t = 4$, $k_x = 14 \text{ kN/mm}$, $k_y = 17 \text{ kN/mm}$, $\zeta_x = 0.15$, $\zeta_y = 0.1$, $\omega_x = 3000 \text{ rad/sec}$, and $\omega_y = 4000 \text{ rad/sec}$. Stability lobe diagrams are generated for the nominal parameters and $N_t = 1, 2$, and 8 teeth. Next, stability lobe diagrams are generated for the nominal parameters and $\theta_{\text{ex}} = 30^\circ, 60^\circ$, and 75° . The first 15 lobes are included for all stability lobe diagrams.

$$\ddot{x}_t(t) + 2\zeta_x \omega_x \dot{x}_t(t) + \omega_x^2 x_t(t) = \frac{\omega_x^2}{k_x} F_x(t) \quad (35.57)$$

$$\ddot{y}_t(t) + 2\zeta_y \omega_y \dot{y}_t(t) + \omega_y^2 y_t(t) = \frac{\omega_y^2}{k_y} F_y(t) \quad (35.58)$$

The effect of the number of teeth is illustrated in Figure 35.10: as the number of teeth increases, the lobes shift to the left and the asymptotic stability borderline decreases. In Figure 35.11, the effect of the exit angle is illustrated: as the exit angle increases, the asymptotic stability borderline decreases.

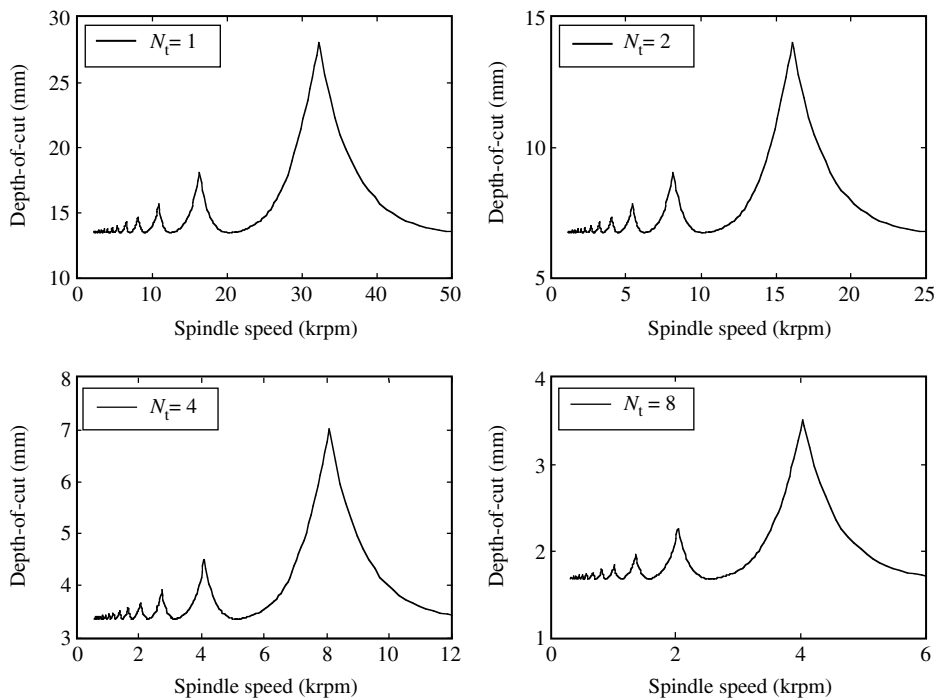

FIGURE 35.10 Stability lobe diagrams for Example 2, with $N_t = 1, 2, 4,$ and 8 .

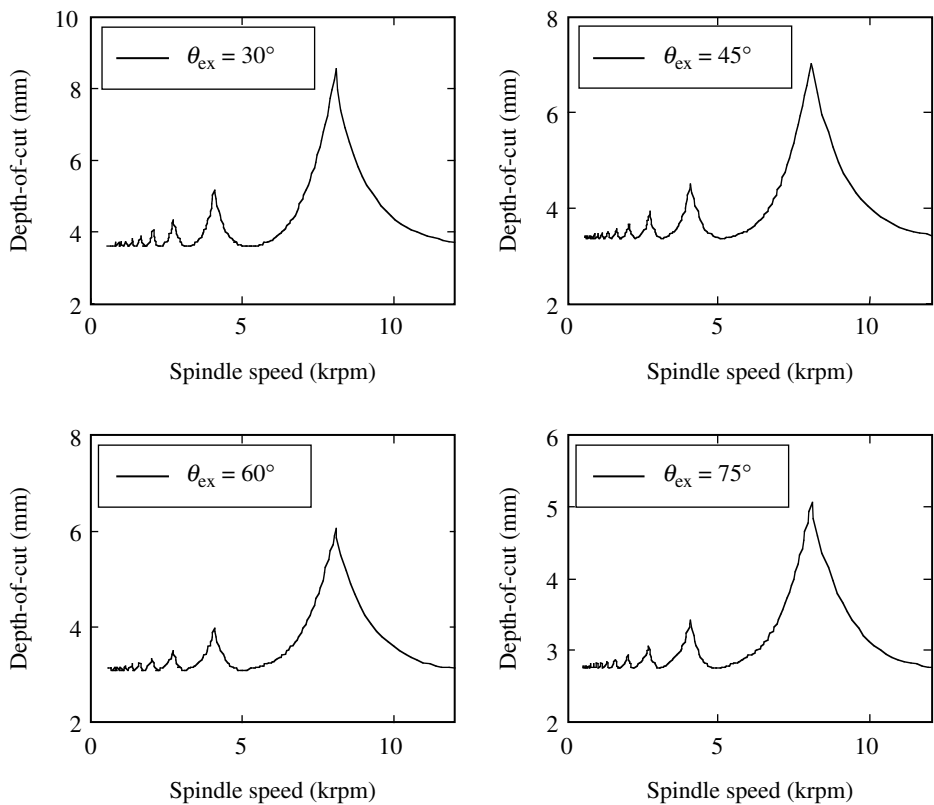

FIGURE 35.11 Stability lobe diagrams for Example 2, with $\theta_{ex} = 30^\circ, 45^\circ, 60^\circ,$ and 75° .

This section presented an analytical method to generate stability lobe diagrams for face-milling operations. The limiting depth-of-cut in a face-milling operation is given by

$$d_{\text{lim}} = -\frac{\pi A_R}{N_t}(1 + \kappa^2)$$

where N_t is the number of teeth, A_R is the inverse eigenvalue of $(2\pi/N_t)A^0[G_t(j\omega_c) + G_p(j\omega_c)]$, A^0 is the zeroth term of the Fourier expansion of the force process matrix, $G_t(j\omega_c)$ and $G_p(j\omega_c)$ are the transfer functions relating the tool structural and part structural vibrations, respectively, to the machining forces evaluated at the chatter frequency ω_c , $\kappa = A_I/A_R$, and A_I is the imaginary part of $(2\pi/N_t)A^0[G_t(j\omega_c) + G_p(j\omega_c)]$. The corresponding spindle speed is

$$N_s = \frac{60\omega_c}{N_t[\pi - 2 \tan^{-1}(\kappa) + 2l\pi]}$$

where $l = 0, 1, 2, \dots$ is the stability lobe number.

35.4 Time-Domain Simulation

Time-domain simulation (Tlusty and Ismail, 1981, 1983; Tlusty, 1986; Tsai et al., 1990; Lee and Liu, 1991a, 1991b; Smith and Tlusty, 1993; Elbestawi et al., 1994; Tarn and Li, 1994; Weck et al., 1994) is an alternative method for determining regenerative chatter. In a time-domain simulation, the machining forces and structural vibrations are simulated in the time domain for a specific set of process parameters and the resulting signals (i.e., forces and displacements) are examined to determine if chatter is present. The analyses presented above for the turning and face-milling operations assume that the tool always maintains contact with the part and that the cutting and thrust pressures are independent of the process parameters. Further, the face milling analysis approximated the time-varying force process matrix, $A(t)$, by the zeroth term of its Fourier expansion. With time domain simulations, nonlinear effects may be directly incorporated into the simulation; thus, more accurate stability prediction is possible. The disadvantage of time-domain simulations is the extreme computational cost that is required. For a specific spindle speed, several simulations must be conducted at different depths-of-cut; thus, the stability boundary for that spindle speed is determined iteratively. This procedure is repeated for a range of spindle speeds to construct a complete stability lobe diagram.

For turning operations, the machining force is calculated using Equation 35.1, the feed is calculated using Equation 35.2, and the tool displacement is calculated using Equation 35.4. For face-milling operations, the feed is calculated using Equation 35.30, the machining forces in the x and y directions are calculated using Equation 35.33 to Equation 35.35, and the tool and part displacements, respectively, are calculated using Equation 35.47 and Equation 35.48. To calculate the machining forces in the face-milling operation, the angular displacement of each tooth is required. The angular displacement of the i th tooth is

$$\theta_i(t) = \frac{2\pi}{60} N_s t + \frac{2\pi}{N_t}(i - 1) \quad (35.59)$$

The feed and force equations are static, while the structural displacement equations are dynamic and must be solved via a numerical integration technique. A sufficiently small time step must be utilized in the numerical integrations to account for the small system time constants associated with the large structural frequencies.

35.4.1 Example 3

The feed force for a turning operation is given by $F(t) = 0.6df^{0.7}(t)$. The structural dynamics are given by Equation 35.26 with the following parameters: $\omega_n = 600$ Hz, $\zeta = 0.2$, and $k = 12$ kN/mm.

FIGURE 35.12 Time-domain simulations for Example 3 with $f_{\text{nom}} = 0.1$ mm.

A time-domain simulation of the system including the effect of the tool disengaging from the part is constructed, and simulations for $N_s = 10,000$ rpm, $d = 8$ mm, and $f_{\text{nom}} = 0.1$ mm are conducted. The simulation is repeated for $f_{\text{nom}} = 0.2$ mm. For both simulations, the time history of the feed force and the tool displacement are plotted.

To account for the phenomenon of the tool disengaging from the part, the feed in Equation 35.2 must be modified as follows:

$$f(t) = \begin{cases} f_{\text{nom}} + z(t) - f_p(t - T) & \text{if } f_{\text{nom}} + z(t) - f_p(t - T) \geq 0 \\ 0 & \text{if } f_{\text{nom}} + z(t) - f_p(t - T) < 0 \end{cases} \quad (35.60)$$

where

$$f_p(t) = \begin{cases} z(t) & \text{if } f_{\text{nom}} + z(t) - f_p(t - T) \geq 0 \\ -f_{\text{nom}} + f_p(t - T) & \text{if } f_{\text{nom}} + z(t) - f_p(t - T) < 0 \end{cases} \quad (35.61)$$

If the feed at the current time is calculated to be negative, then the cutting tool has disengaged from the part and the feed is zero. The term $f_p(t)$ accounts for feed due to structural vibrations at the previous spindle rotation, even when the cutting tool disengages from the part. The results for $f_{\text{nom}} = 0.1$ mm and $f_{\text{nom}} = 0.2$ mm are shown in Figure 35.12 and Figure 35.13, respectively. As the nominal feed is increased, chatter is suppressed.

35.4.2 Example 4

The cutting and thrust forces in a face-milling operation are given by $F_C(t) = 1.4df^{0.6}(t)$ and $F_T(t) = 0.4df^{0.8}(t)$, respectively. The lead angle is 45° , the entry angle is -60° ; the exit angle is 60° , the number of teeth is four, and the feed per tooth is $f_t = 0.15$ mm. The part is assumed to be perfectly rigid, and tool structural dynamics for the x and y directions are given by Equation 35.58 and Equation 35.59, respectively. A time-domain simulation is developed to determine the limiting stable depth-of-cut for spindle speeds of 1000 and 32,000 rpm. For both spindle speeds, the system is simulated for a depth-of-cut 10% below the limiting stable depth-of-cut and for a depth-of-cut 10% above the limiting stable depth-of-cut. The cutting force, thrust force, x tool displacement, and y tool displacement are plotted.

FIGURE 35.13 Time-domain simulations for Example 3 with $f_{\text{nom}} = 0.2$ mm.

The nonlinear effect of tooth disengagement is included:

$$\ddot{x}_t(t) + 2(0.15)(3000)\dot{x}_t(t) + 3000^2 x_t(t) = \frac{3000^2}{15} F_x(t) \quad (35.62)$$

$$\ddot{y}_t(t) + 2(0.1)(4000)\dot{y}_t(t) + 4000^2 y_t(t) = \frac{4000^2}{17} F_y(t) \quad (35.63)$$

To account for the phenomenon of the tool disengaging from the part, the feed in Equation 35.30 must be modified as follows:

$$f_i(t) = \begin{cases} f_{ci}(t) - f_{pi}(t - T_t) & \text{if } f_{ci}(t) \geq 0 \\ 0 & \text{if } f_{ci}(t) < 0 \end{cases} \quad (35.64)$$

FIGURE 35.14 Time-domain simulation for Example 4 with $N_s = 1000$ rpm and $d = 2.025$ mm.

FIGURE 35.15 Time-domain simulation for Example 4 with $N_s = 1000$ rpm and $d = 2.475$ mm.

where

$$f_{ci}(t) = f_t \cos[\theta_i(t)] + \{x_t(t) - x_p(t)\} \cos[\theta_i(t)] + \{y_t(t) - y_p(t)\} \sin[\theta_i(t)] \quad (35.65)$$

$$f_{pi}(t) = \begin{cases} \{x_t(t - T_t) - x_p(t - T_t)\} \cos[\theta_i(t)] + \{y_t(t - T_t) - y_p(t - T_t)\} \sin[\theta_i(t)] & \text{if } f_{ci}(t) \geq 0 \\ -f_t \cos[\theta_i(t)] + f_{pi}(t - T_t) & \text{if } f_{ci}(t) < 0 \end{cases} \quad (35.66)$$

Note that $\theta_i(t) = \theta_{i+1}(t - T_t)$ and $i - 1 \rightarrow N_t$ if $i = 1$. The term $f_{pi}(t)$ represents the contribution to the instantaneous feed when the previous tooth was at the same angular location as the i th tooth. If the tooth and part are in contact, this contribution is due to the tool and part vibrations. If the tooth and part are not in contact, this contribution is the previous contribution added to the static portion and the instantaneous feed is set to zero. Through time-domain simulations, the limiting stable depth-of-cut for

FIGURE 35.16 Time-domain simulation for Example 4 with $N_s = 32,000$ rpm and $d = 3.105$ mm.

FIGURE 35.17 Time-domain simulation for Example 4 with $N_s = 32,000$ rpm and $d = 3.795$ mm.

$N_s = 1000$ rpm is found to be 2.25 mm and the limiting depth-of-cut for $N_s = 32,000$ rpm is found to be 3.45 mm. The results are shown in Figure 35.14 to Figure 35.17. The system is stable in Figure 35.14 and Figure 35.16, while instability is evidenced in Figure 35.15 and Figure 35.17 by the force in the y direction saturating at 0 kN.

This section presented the technique of time-domain simulation as an alternative means to analyze regenerative chatter. Time-domain simulations are the direct numerical simulations of the force process and structural vibrations. A process parameter is changed iteratively from simulation to simulation to determine the critical value at which chatter occurs. A sufficiently small time step must be utilized in the numerical integrations to account for the small system time constants associated with the large structural frequencies.

35.5 Chatter Detection

Regenerative chatter is easily detected by an operator due to the loud, high-pitched noise it produces and the distinctive “chatter marks” it leaves on the part surface. However, automatic detection is required for intelligent manufacturing (Cho and Ehmann, 1988; Delio et al., 1992). At the onset of chatter, process signals (e.g., force, vibration) contain significant energy at the chatter frequency. It is a well-known fact that the chatter frequency will be close to a dominant structural frequency. The most common method to detect the presence of chatter is to threshold the frequency signal of a process signal. To analyze the frequency content of a signal, a Fourier transform, or fast Fourier transform, is performed. If the frequency content of the resulting signal near a dominant chatter frequency is above a threshold value, then chatter is determined to be present. It should be noted that machining process signals also contain significant energy at the tooth-passing frequency. If the dominant structural frequencies and tooth-passing frequency are sufficiently separated, then the tooth-passing frequency may be ignored when determining the presence of chatter. If the dominant structural frequencies and tooth-passing frequency are close, then the signal must be filtered at the tooth-passing frequency using a notch filter. Also, forced vibrations, such as those resulting from the impact between the cutting tool and part, must not be allowed to falsely trigger the chatter

detection algorithm. These thresholding algorithms all suffer from the lack of an analytical method of selecting a threshold value. This value is typically selected empirically and will not be valid over a wide range of cutting conditions and machining operations.

35.5.1 Example 5

An experimental face-milling operation, a complete description of which is given in Landers (1997), is conducted with a spindle speed of 1500 rpm and a tool with four teeth. The dominant structural frequencies are 334, 414, 653, and 716 Hz. The machining force F_z is sampled at a frequency of 2000 Hz, and the time-domain signal is transformed into the frequency domain via a Fourier transform using 80 points (i.e., one spindle revolution). The power spectral density of the force signal is shown for depths-of-cut of 1.0 and 1.5 mm in Figure 35.18 and Figure 35.19, respectively. In Figure 35.18, there is significant energy at 100 Hz, which is the tooth-passing frequency. There is also significant energy at 750 Hz due to structural vibrations; however, the system did not chatter, as evidenced by the lack of chatter marks on the part and a high-pitched sound during machining. In Figure 35.19, there is significant energy at 665 Hz as well as 100 Hz. Chatter was evidenced by the chatter marks left on the part surface and the high-pitched sound during machining. The results demonstrate that the chatter frequency is 665 Hz, which is near the dominant structural frequency of 653 Hz. Note that the power spectral density at the frequency of 0 Hz is ignored in Figure 35.18 and Figure 35.19. This component is stronger than the components at all other frequencies since the machining force F_z fluctuates about a static, nonzero value. In this application, a thresholding algorithm may ignore the low frequencies where the tooth-passing frequency is strong; however, if the operation were to be performed at a higher spindle speed, say 7500 rpm, or the number of teeth were increased from 4 to 20, the tooth-passing frequency would be 500 Hz, close to the structural frequencies. In this case, the force signal would have to be filtered at the tooth-passing frequency.

FIGURE 35.18 Power spectral density of F_z in a face-milling operation with $d = 1.0$ mm.

FIGURE 35.19 Power spectral density of F_z in a face-milling operation with $d = 1.5$ mm.

This section presented techniques to detect the occurrence of regenerative chatter. The phenomenon of regenerative chatter is easily detected by an operator due to the loud, high-pitched noise it produces and the distinctive “chatter marks” it leaves on the part surface. The most common method to detect the presence of chatter is to threshold the frequency signal of a process signal. In this case, one must be careful to separate out the spindle rotation and tooth-passing frequencies.

35.6 Chatter Suppression

Most machining process plans are derived from handbooks or from a database. Since these plans do not consider the physical machine that will be used, chatter-free operations cannot be guaranteed. Thus, multiple iterations, where the feed or spindle speed are adjusted using the operator's experience, are typically required. The tool position may also be adjusted (e.g., the depth-of-cut may be decreased) to suppress chatter and, while this is guaranteed to be effective due to the presence of the asymptotic stability borderline, this approach is typically not employed since part program must be rewritten to add multiple passes, thereby drastically decreasing productivity. The stability lobe diagram can be used as a tool to plan chatter-free machining operations and productivity can be greatly increased by selecting the process parameters to lie in a pocket between two lobes. A cutting tool design methodology (Altintas et al., 1999) has also been proposed for milling tools where the pitch is slightly adjusted such that the teeth are not evenly spaced. The variable pitch has the effect of changing the phase difference between successive teeth vibrations and, if designed properly, will suppress chatter. These design techniques are very sensitive to parameter variations and model uncertainty, and may not be used reliably for a large range of operating conditions. This section will describe methods for automatic chatter suppression.

35.6.1 Spindle-Speed Selection

For the stability lobe diagram generated from a system modeled as having a one-dimensional structure, it is seen that the maximum depths-of-cut are located at the tooth-passing frequencies (i.e., the number of teeth multiplied by the spindle speed) corresponding to the dominant structural frequency and integer fractions thereof. If the dominant structural frequency is known, it may be used as an aid in selecting spindle speeds; however, the structural dynamics are often unknown and may be determined only through costly testing. Further, structural dynamics change drastically over time.

It is known, however, that during chatter, the dominant frequency seen in the cutting-process output is close to a dominant structural frequency. This fact is used in Smith and Delio (1992) to suppress chatter automatically. The following steps are taken:

1. Implement a chatter detection routine to determine the presence of chatter.
2. If chatter is detected, determine the chatter frequency, ω_c . This will be the frequency at which the process signal has the greatest energy.
3. Set the new spindle speed to be $N_s = \omega_c / [N_t(N + 1)]$, where N is the smallest positive integer such that the new spindle speed does not violate the maximum spindle speed constraint.
4. Repeat Steps 1 to 3 until the chatter has been suppressed.

The equation $N_s = \omega_c / [N_t(N + 1)]$ may be interpreted as selecting the tooth-passing frequency, or an integer fraction thereof, corresponding to the approximate dominant structural frequency. Note that if the depth-of-cut is too large and the maximum spindle speed is too small, this technique will not be effective and the feed or depth-of-cut must be adjusted, or the spindle speed must be continuously varied.

35.6.2 Example 6

The feed force for a turning operation is given by Equation 35.1, and the structural dynamics are given by Equation 35.26. The system parameters are $P = 0.75 \text{ kN/mm}^2$, $f_{\text{nom}} = 0.1 \text{ mm}$, $\omega_n = 750 \text{ Hz}$, $\zeta = 0.1$, and $k = 15 \text{ kN/mm}$. The depth-of-cut is 5 mm. The spindle speed that should be selected to suppress chatter if the chatter frequency is 725 Hz, when the spindle speed is not constrained, is determined. The spindle speed that should be selected to suppress chatter if the maximum spindle speed is 15,000 rpm is also determined. The system is simulated for a spindle speed of 10,000 rpm for ten spindle revolutions and then for ten spindle revolutions for the spindle

FIGURE 35.20 Time-domain simulations using spindle speed selection with $N_s = 43,500$ rpm.

speed calculated when the spindle speed is not constrained. The simulation is then repeated for the spindle speed calculated when the spindle speed is constrained. Feed force and tool displacement are plotted for both cases.

For a chatter frequency of 725 Hz, the optimal spindle speed is $60(725) = 43,500$ rpm. Other possible spindle speeds are $43,500/2 = 21,750$ rpm, $43,500/3 = 14,500$ rpm, $43,500/4 = 10,875$ rpm, and so on. Therefore, when the maximum spindle speed is 15,000 rpm, a spindle speed of 14,500 rpm is used. The time domain simulations are in Figure 35.20 and Figure 35.21. The results illustrate that a depth-of-cut of 5.3 mm is stable at 43,500 rpm, but not at 14,500 rpm. Therefore, if the spindle speed is limited to 15,000 rpm, spindle-speed selection may not be used to suppress the chatter present in the machining operation.

FIGURE 35.21 Time-domain simulations using spindle speed selection with $N_s = 14,500$ rpm.

35.6.3 Feed and Depth-of-Cut Selection

When chatter occurs, operators will sometimes increase the feedrate via the feedrate override button on the machine tool control panel. This has the effect of increasing the feed, assuming the spindle speed remains constant. When linear chatter analysis techniques are employed, the force process gains are linearized about the nominal feed, and stability does not appear to be affected by the nominal feed. However, the stability results are only valid for a small region about the nominal feed. It is well known that there is a nonlinear relationship between the machining forces and the feed of the form $F = P(f)df$. The pressure can be expressed in the form $P(f) = Kf^\alpha$ where $\alpha < 0$; thus, the pressure decreases as the feed increases. Since the stable depth-of-cut is inversely proportional to the pressure, the stability limit will increase as the feed increases, assuming the spindle speed remains constant. An illustration of this phenomenon was shown in Example 3: when the feed was increased from 0.1 to 0.2 mm, chatter was suppressed. While increasing the feed can suppress chatter, the sensitivity of chatter to feed is limited and other adverse phenomenon, such as tooth chippage, may occur.

Another method to suppress chatter is to decrease the depth-of-cut (Weck et al., 1975). This method is guaranteed to work as evidenced by stability lobe diagrams. However, this method is typically not preferred as it dramatically decreases operation productivity by increasing the total number of tool passes that are required to complete the operation.

35.6.4 Spindle-Speed Variation

Spindle speed variation (SSV) is another technique that has shown the ability to suppress chatter (Inamura and Sata, 1974; Lin et al., 1990). The spindle speed is varied about some nominal value, typically in a sinusoidal manner. Although SSV is a promising technique, the theory required to guide the designer in the selection of suitable amplitudes and frequencies is in its infancy (Radulescu et al., 1997a, 1997b; Sastry et al., 2002). Also, in some cases, SSV may create chatter that would not occur when using a constant spindle speed.

FIGURE 35.22 Time-domain simulations using spindle-speed variation with $A = 0.1$ and $\Omega = 20$ Hz.

FIGURE 35.23 Time-domain simulations using spindle-speed variation with $A = 0.25$ and $\Omega = 20$ Hz.

35.6.5 Example 7

The feed force for a turning operation is given by Equation 35.1 and the structural dynamics are given by Equation 35.26. The system parameters are $P = 0.75 \text{ kN/mm}^2$, $f_{\text{nom}} = 0.1 \text{ mm}$, $\omega_n = 750 \text{ Hz}$, $\zeta = 0.1$, and $k = 15 \text{ kN/mm}$. The depth-of-cut is 5 mm. The system is simulated for a nominal spindle speed of $N_{\text{nom}} = 10,000 \text{ rpm}$ for 10 spindle revolutions and then for 30 spindle revolutions for the spindle speed calculated from Equation 35.67 for the following three cases: $A = 0.1$ and $\Omega = 20 \text{ Hz}$, $A = 0.25$ and $\Omega = 20 \text{ Hz}$, and $A = 0.25$ and $\Omega = 160 \text{ Hz}$. Feed force and tool displacement are plotted for all three cases.

$$N_s(t) = N_{\text{nom}}[1 + A \sin(\Omega t)] \quad (35.67)$$

FIGURE 35.24 Time-domain simulations using spindle-speed variation with $A = 0.25$ and $\Omega = 160$ Hz.

The time-domain simulations are in [Figure 35.22](#) to [Figure 35.24](#) for the respective cases. The results illustrate that SSV may be utilized to suppress chatter; however, the amplitude and frequency of the spindle speed vibration must be carefully chosen.

This section presented several techniques to suppress regenerative chatter. The three major techniques to suppress chatter are spindle-speed selection, feed selection, and SSV. In spindle-speed selection, the spindle speed is adjusted to be a multiple of the chatter frequency to place the spindle speed in a pocket of the stability lobe diagram. In feed selection, the feed is increased to suppress chatter. In SSV, the spindle speed is varied in a sinusoidal manner to decrease the phase difference between the current and previous tooth passes.

35.7 Case Study

A case study of regenerative chatter for a face-milling operation is now presented. Further details are presented in Landers (1997). The machine tool is a three-axis vertical milling machine ([Figure 35.25](#)). Each axis has a linear encoder with a resolution of $10\text{ }\mu\text{m}$ mounted on it. The axis motors (186 W) drive pulleys that rotate leadscrews and provide motion to the linear axes. The spindle (2240 W) drives the face mill (Carboloy R/L220.13-02.00-12, 50 mm diameter). The tool holds four carbide inserts (Carboloy SEAN 42AFTN-M14 HX, 45° lead angle). The part is 6061 aluminum. The spindle is run open-loop. A Kistler 9293 piezoelectric three-component dynamometer was utilized for force process modeling and chatter detection. The x and y channels have a natural frequency of 4.5 kHz, rigidity of $0.7\text{ kN}/\mu\text{m}$, and range of -20 to 20 kN . The z channel has a natural frequency of 5 kHz, rigidity of $7\text{ kN}/\mu\text{m}$, and range of -100 to 200 kN . A Bently Nevada 3000 Series Type 190 proximity transducer was utilized to measure the static stiffnesses of the structural components. The sensor gain is 8 V/mm , the response is flat to 10 kHz, and the range is 1.02 mm . A Kistler Quartz Model #802A accelerometer (resonant frequency 36.7 kHz) was utilized to measure the dynamic characteristics of the structural components.

The cutting and thrust pressures, respectively, are

$$P_C = 0.29f^{-0.25}d^{-0.13}\left(\frac{V}{1000}\right)^{-0.72} \quad (35.68)$$

$$P_T = 0.16f^{-0.40}d^{-0.41}\left(\frac{V}{1000}\right)^{-0.58} \quad (35.69)$$

The transfer function matrices, respectively, between the tool structure and machining forces, and the part structure and machining forces are modeled as

$$\begin{bmatrix} x_t(s) \\ y_t(s) \end{bmatrix} = \begin{bmatrix} \frac{(4500^2/14)}{s^2 + 2(0.07)(4500)s + 4500^2} & 0 \\ 0 & \frac{(4100^2/14)}{s^2 + 2(0.11)(4100)s + 4100^2} \end{bmatrix} \begin{bmatrix} F_x(s) \\ F_y(s) \end{bmatrix} \quad (35.70)$$

$$\begin{bmatrix} x_p(s) \\ y_p(s) \end{bmatrix} = - \begin{bmatrix} \frac{(2600^2/9.5)}{s^2 + 2(0.09)(2600)s + 2600^2} & 0 \\ 0 & \frac{(2100^2/9.5)}{s^2 + 2(0.22)(2100)s + 2100^2} \end{bmatrix} \begin{bmatrix} F_x(s) \\ F_y(s) \end{bmatrix} \quad (35.71)$$

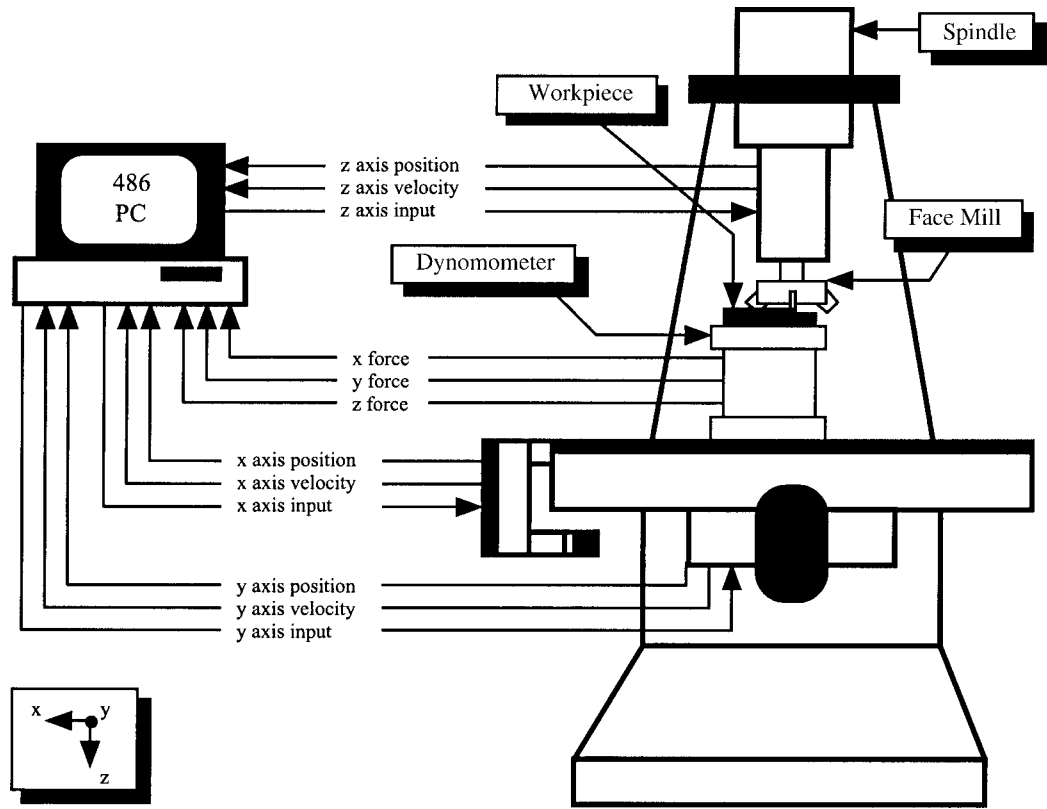

FIGURE 35.25 Three-axis vertical machine tool schematic.

Using the machining force and structural models, a stability lobe diagram was constructed using time domain simulations. Experimental data were collected by adjusting the depth-of-cut in increments of 0.1 mm until chatter occurred. The time-domain simulations and the experimental data are plotted in Figure 35.26. The cutting conditions were $f_t = 0.10$ mm/tooth, $N_t = 4$ teeth, $\theta_{en} = -90^\circ$, and $\theta_{ex} = 90^\circ$. The chatter detection methodology for this system was described in Example 5.

Spindle-speed adjustment is typically a more productive chatter suppression option. However, the machine tool in this case study is not equipped with automatic spindle speed control and, thus, the depth-of-cut is adjusted to suppress chatter. When chatter is detected, the chatter suppressor rewrites the part program to accommodate one additional tool pass (Figure 35.27). Therefore, the new operation depth-of-cut is

FIGURE 35.26 Stability lobe diagram for a face-milling operation — time-domain simulations (empty boxes) and experimental points (filled circles).

$$d_n = \frac{d_p}{1 + N_c} \tag{35.72}$$

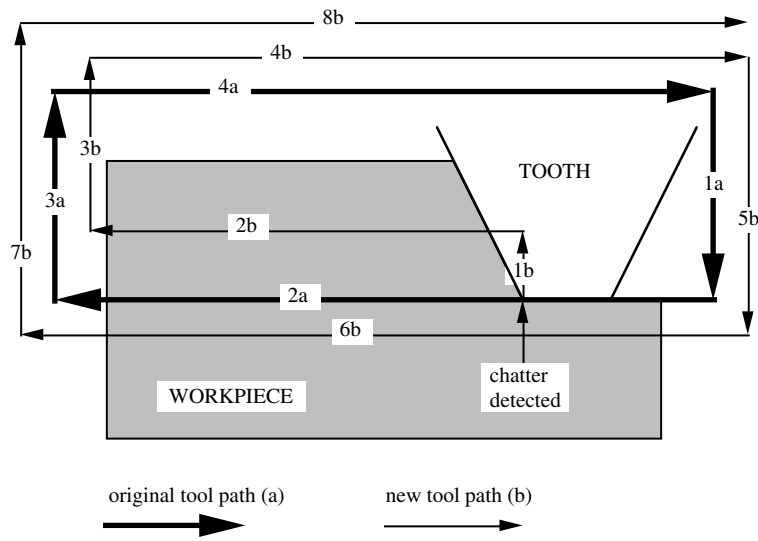

FIGURE 35.27 Original tool path (a) is rewritten when chatter occurs. New tool path (b) contains an additional tool pass.

where d_p is the previous operation depth-of-cut and N_c is the number of times the chatter suppression routine has been invoked. The new value may be well below the stability limit; however, making all passes an equal depth-of-cut provides a good balance between productivity and the search for a stable depth-of-cut. Results of this controller are presented in Landers and Ulsoy (1998, 2001).

Nomenclature

Symbol	Quantity	Symbol	Quantity
d	depth-of-cut (mm)	T	spindle rotational period (sec)
d_{lim}	limiting stable depth-of-cut (mm)	T_t	tooth rotational period (sec)
f	feed (mm)	x_p	part structural displacement in x direction (mm)
f_t	feed per tooth (mm)	x_t	cutting tool structural displacement in x direction (mm)
F	machining force (kN)	y_p	part structural displacement in y direction (mm)
F_C	cutting force (kN)	y_t	cutting tool structural displacement in y direction (mm)
F_T	thrust force (kN)	z	cutting tool structural displacement in z direction (mm)
F_x	force acting on cutting tool in x direction (kN)	θ	tooth angle (rad)
F_y	force acting on cutting tool in y direction (kN)	θ_{en}	tooth entry angle (rad)
F_z	force acting on cutting tool in z direction (kN)	θ_{ex}	tooth exit angle (rad)
k	structural stiffness (kN/mm)	ω_c	chatter frequency (rad/sec)
N_s	spindle speed (rpm)	ω_n	structural natural frequency (rad/sec)
N_t	number of teeth	ψ_r	lead angle (rad)
P	machining pressure (kN/mm ²)	ζ	structural damping ratio
P_C	cutting pressure (kN/mm ²)		
P_T	thrust pressure (kN/mm ²)		
t	time (sec)

Summary

This chapter gives an overview on the subject of fluid-induced vibration in an ocean environment. The main objective is to show how the fluid forces on an offshore structure due to current and random waves are modeled. The chapter is divided into three sections. The first section describes the ocean environment, especially the currents and random waves. The second section is dedicated to obtaining fluid forces utilizing the results from the first section and the third section gives some examples to show how the results from the first two sections can be used in practice. In the first section, the concept of spectral density is introduced. For a given spectrum, methods to obtain a sample time series are given. In the second section, the forces that the fluid can exert on a body are discussed. The regimes in which inertia, drag, or diffraction forces are dominant are shown in terms of the ratio of the wave height to the structural diameter and the ratio of the structural diameter to the wavelength. The Morison equation is extended to the case of a moving inclined cylinder. The Morison equation requires the use of experimentally determined fluid coefficients such as added mass, inertia, and drag coefficients. Plots of these fluid coefficients for various values of the fluid parameters are reproduced here. The vortex shedding force is discussed briefly. In the third section, four examples are given to show how fluid forces affect the static and dynamics of ocean structures, how the significant wave height can be chosen to represent the condition in a certain area for a long time, and how the time series can be constructed from a given spectrum. Finally, the available numerical codes for modeling slender flexible bodies in fluids are listed.

36.1 Description of the Ocean Environment

In modeling offshore structures, one needs to account for the forces exerted by the surrounding fluid. In-depth studies are given in Kinsman (1965), Sarpkaya and Isaacson (1981), Wilson (1984), Chakrabarti (1987), and Faltinsen (1993). The vibration characteristics of a structure can be significantly altered when it is surrounded by water. For example, damping by the fluid (or the added mass) lowers the natural

frequency of vibration. When considering the dynamics of an offshore structure, one must also consider the forces due to the surrounding fluid. The two important sources of fluid motion are ocean waves and ocean currents.

Most steady large currents are generated by the drag of the wind passing over the surface of the water, and they are confined to a region near the ocean surface. Tidal currents are generated by the gravitational attraction of the sun and the moon, and they are most significant near coasts. The ultimate source of the ocean circulation is the uneven radiation heating of the Earth by the Sun.

Isaacson (1988) suggested an empirical formula for the current velocity in the horizontal direction as a function of depth:

$$U_c(x) = (U_{\text{tide}}(d) + U_{\text{circulation}}(d)) \left(\frac{x}{d} \right)^{1/7} + U_{\text{drift}}(d) \left(\frac{x - d + d_0}{d_0} \right) \quad (36.1)$$

where U_{drift} is the wind-induced drift current, U_{tide} is the tidal current, $U_{\text{circulation}}$ is the low-frequency long-term circulation, x is the vertical distance measured from the ocean bottom, d is the depth of the water, and d_0 is the smaller of the depth of the thermocline and 50 m. The value of U_{tide} is obtained from tide tables, and U_{drift} is about 3% of the 10 min mean wind velocity at 10 m above the sea level.

It should be noted that these currents evolve slowly compared with the time scales of engineering interests. Therefore, they can be treated as a quasisteady phenomenon. Waves, on the other hand, cannot be treated as a steady phenomenon. The underlying physics that govern wave dynamics are too complex and, therefore, waves must be modeled stochastically. The subsequent section discusses the concept of the spectral density, available ocean wave spectral densities, a method to obtain the spectral density from wave time histories, methods to obtain a sample time history from a spectral density, the short-term and long-term statistics, and a method to obtain fluid velocities and accelerations from wave elevation using linear wave theory.

36.1.1 Spectral Density

Here, we will consider only surface gravity waves. Let us first consider a regular wave in order to familiarize ourselves with the terms that are used to describe a wave. The wave surface elevation is denoted as $\eta(x, t)$ and can be written as $\eta(x, t) = A \cos(kx - \omega t)$, where k is the wave number, and ω is the angular frequency. Figure 36.1 shows the surface elevation at two time instances ($t = 0$ and $t = \tau$) and the surface elevation at a fixed location ($x = 0$). A is the amplitude, H is the wave height or the distance between the maximum and minimum wave elevation or twice the amplitude, and T is the period given by $T = 2\pi/\omega$.

In practice, waves are not regular. Figure 36.2 shows a schematic time history of an irregular wave surface elevation. The wave height and frequency are not easy to find. Therefore, we rely on a statistical description for the wave elevation such as the wave spectral density. The spectral density tells us how the energy of the system is distributed among frequencies. The random surface elevation $\eta(t)$ can be thought of as a summation of regular waves with different frequencies. The surface elevation $\eta(t)$ is related to its Fourier transform $X(\omega)$ by

$$\eta(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} X(\omega) \exp(-i\omega t) d\omega$$

FIGURE 36.1 Regular wave.

Suppose that the energy of the system is proportional to $\eta^2(t)$ so that we can write the energy as

$$E = \frac{1}{2} C \eta^2(t)$$

where C is the proportionality constant.

Let us assume that the expected value of the energy is given by

$$E\{E\} = \frac{1}{2} C E\{\eta^2(t)\}$$

where $E\{\eta^2(t)\}$ is the mean square of $\eta(t)$. If $\eta(t)$ is an *ergodic process* (see Chapter 5 and Chapter 30), then the mean square of $\eta(t)$ can be approximated by the time average over a long period of time:

$$E\{\eta^2(t)\} = \lim_{T_s \rightarrow +\infty} \frac{1}{T_s} \int_{-T_s/2}^{T_s/2} \eta^2(t) dt = \lim_{T_s \rightarrow +\infty} \frac{1}{T_s} \frac{1}{2\pi} \int_{-\infty}^{\infty} |X(\omega)|^2 d\omega \quad (36.2)$$

where we have used Parseval's theorem

$$\int_{-\infty}^{\infty} \eta^2(t) dt = \frac{1}{2\pi} \int_{-\infty}^{\infty} |X(\omega)|^2 d\omega \quad (36.3)$$

where

$$|X(\omega)|^2 = X(\omega)X^*(\omega), \quad X(\omega) = \int_{-\infty}^{\infty} \eta(t) \exp(-i\omega t) dt, \quad X^*(\omega) = \int_{-\infty}^{\infty} \eta(t) \exp(i\omega t) dt$$

We define the power spectral density (or simply the spectrum) as (see Chapter 5 and Chapter 30)

$$S_{\eta\eta}(\omega) \equiv \frac{1}{2\pi T_s} |X(\omega)|^2 \quad (36.4)$$

so that $E\{\eta^2(t)\}$ is given by

$$E\{\eta^2(t)\} = \int_{-\infty}^{\infty} S_{\eta\eta}(\omega) d\omega \quad (36.5)$$

For a zero-mean process, $E\{\eta^2(t)\}$ is also the variance σ_η^2 . The spectral density has units of $\eta^2 t$. Where η is the wave elevation, the spectral density has a unit of $m^2 \text{ sec}$.

It can also be shown that $S_{\eta\eta}(\omega)$ is related to the autocorrelation function, $R(\tau)$, by the Wiener–Khinchine relations (Wiener, 1930; Khinchine, 1934):

$$S_{\eta\eta}(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{\eta\eta}(\tau) \exp(-i\omega\tau) d\tau, \quad R_{\eta\eta}(\tau) = \int_{-\infty}^{\infty} S_{\eta\eta}(\omega) \exp(i\omega\tau) d\omega \quad (36.6)$$

It should be noted that, in some textbooks, the factor $1/2\pi$ appears in the second equation instead of the first. Figure 36.3 shows some important pairs of $S_{\eta\eta}(\omega)$ and $R_{\eta\eta}(\tau)$.

There are a few properties of the spectral density that readers should become familiar with. The first property is that the spectral density function of a real-valued stationary process is both real and symmetric. That is, $S_{\eta\eta}(\omega) = S_{\eta\eta}(-\omega)$ (Equation 36.4). Secondly, the area under the spectral density is equal to $E\{\eta^2(t)\}$ (Equation 36.5) and is also equal to $R_{\eta\eta}(0) = \sigma_\eta^2 - \mu_\eta^2$, where σ_η^2 is the variance and μ_η^2 is the mean of $\eta(t)$. In most cases, we only consider a zero-mean process so that the area under the spectral density is just σ_η^2 . If the process does not have a zero mean, the mean can be subtracted from it so that the process has a zero mean.

For ocean applications, a one-sided spectrum in terms of cycles per second (cps) or hertz is often used. We will denote the one-sided spectrum with a superscript “o”. The one-sided spectrum can be obtained from the two-sided spectrum by

$$S_{\eta\eta}^o(\omega) = 2S_{\eta\eta}(\omega), \quad \omega \geq 0$$

FIGURE 36.2 Time history of random wave.

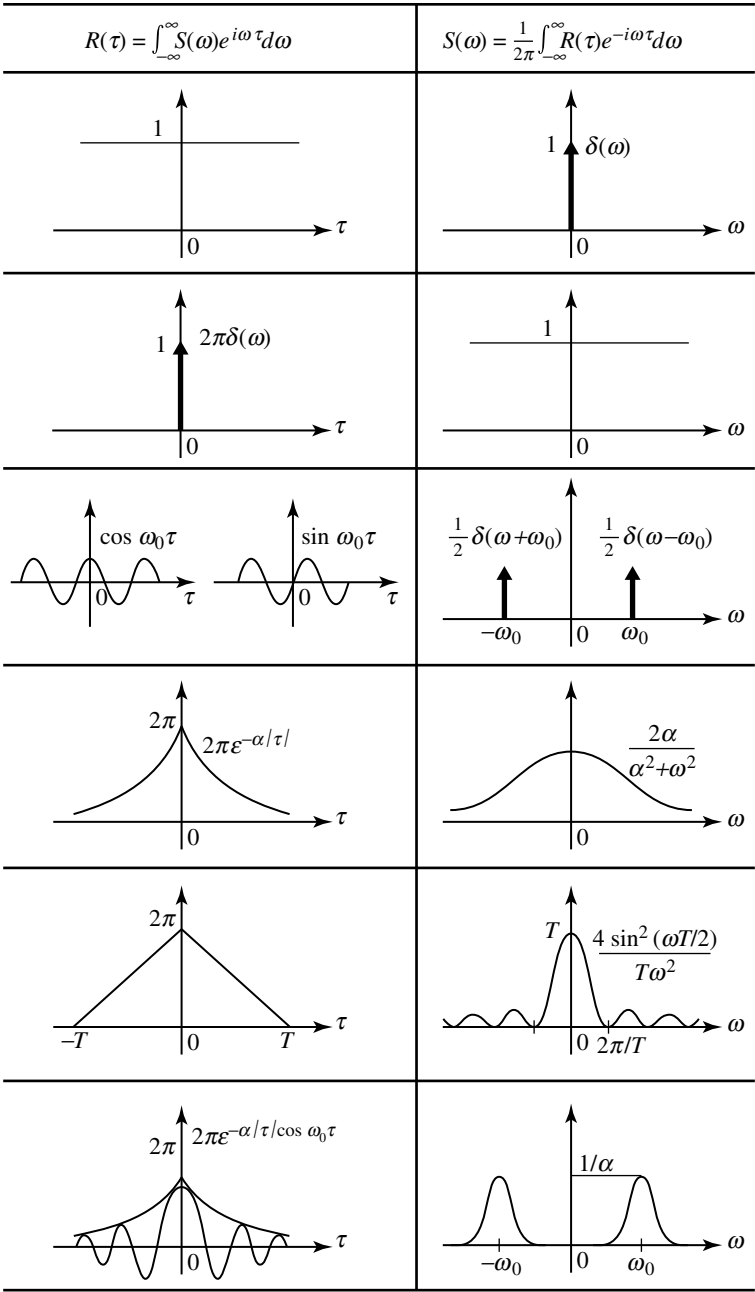

FIGURE 36.3 Relationship between the autocorrelation function and the power spectral density.

The two-sided spectrum in terms of ω can be transformed to the spectrum in terms of f (where $\omega = 2\pi f$) by

$$S_{\eta\eta}(f) = 2\pi S_{\eta\eta}(\omega), \quad f, \omega \geq 0$$

Then, the two-sided spectrum in terms of ω can be transformed to the one-sided spectrum in terms of cps (or hertz) by

$$S_{\eta\eta}^o(f) = 4\pi S_{\eta\eta}(\omega), \quad f, \omega \geq 0$$

It should be noted that the spectral density that we have defined here is the *amplitude half-spectrum*. The amplitude, height, and height double spectra are related to the amplitude half-spectrum by

$$S^A(\omega) = 2S(\omega), \quad S^H(\omega) = 8S(\omega), \quad S^{2H}(\omega) = 16S(\omega)$$

36.1.2 Ocean Wave Spectral Densities

In this section, we will discuss spectral density models to describe a random sea. An excellent review of existing spectral density models is given in [Chapter 4](#) of Chakrabarti (1987).

The ocean wave spectrum models are semiempirical formulas. That is, they are derived mathematically but the formulation requires one or more experimentally determined parameters. The accuracy of the spectrum depends significantly on the choice of these parameters.

In formulating spectral densities, the parameters that influence the spectrum are *fetch limitations*, *decaying vs. developing seas*, *water depth*, *current*, and *swell*. The fetch is the distance over which a wind blows in a wave-generating phase. Fetch limitation refers to the limitation on the distance due to some physical boundaries so that full wave development is prohibited. In a developing sea, the sea has not yet reached its stationary state under a stationary wind. In contrast, a wind has blown for a sufficient time in a fully developed sea, and the sea has reached its stationary state. In a decaying sea, the wind has dropped off from its stationary value. Swell is the wave motion caused by a distant storm and persists even after the storm has died down or moved away.

The Pierson–Moskowitz (P–M) spectrum (Pierson and Moskowitz, 1964) is the most extensively used spectrum for representing a fully developed sea. It is a one-parameter model in which the sea severity can be specified in terms of the wind velocity. The P–M spectrum is given by

$$S_{\eta\eta}^o(f) = \frac{8.1 \times 10^{-3} g^2}{\omega^5} \exp\left(-0.74 \left(\frac{g}{U_{w,19.5 \text{ m}}}\right)^4 \omega^{-4}\right)$$

where g is the gravitational constant and $U_{w,19.5 \text{ m}}$ is the wind speed at a height of 19.5 m above the still water. The P–M spectrum is also called the wind-speed spectrum because it requires wind data. It can also be written in terms of the modal frequency ω_m as

$$S_{\eta\eta}^o(f) = \frac{8.1 \times 10^{-3} g^2}{\omega^5} \exp\left(-1.25 \left(\frac{\omega_m}{\omega}\right)^4\right) \quad (36.7)$$

Note that the modal frequency is the frequency at which the spectrum is the maximum.

In some cases, it may be more convenient to express the spectrum in terms of significant wave height rather than the wind speed or modal frequency. For a narrowband Gaussian process¹, the significant wave height is related to the standard deviation by $H_s = 4\sigma_\eta$. The standard deviation is the square root of the area under the spectral density, $\int_{-\infty}^{\infty} S_{\eta\eta}(\omega) d\omega = \sigma_\eta^2$. Then, the spectrum can be written as

$$S_{\eta\eta}^o(f) = \frac{8.1 \times 10^{-3} g^2}{\omega^5} \exp\left(-\frac{0.0324 g^2}{H_s^2} \omega^{-4}\right) \quad (36.8)$$

and the peak frequency and the significant wave height are related by

$$\omega_m = 0.4 \sqrt{g/H_s} \quad (36.9)$$

The P–M spectrum is applicable for deep water, unidirectional seas, fully developed and local-wind-generated seas with unlimited fetch, and was developed for the North Atlantic. The effect of swell is not accounted for. Although it was developed for the North Atlantic, the spectrum is valid for other locations. However, the limitation that the sea is fully developed may be too restrictive because it cannot model the

¹See Section 36.1.5 for details.

effect of waves generated at a distance. Therefore, we consider a two-parameter spectrum, such as the Bretschneider spectrum, in order to model a sea that is not fully developed as well as a fully developed sea.

The Bretschneider spectrum (Bretschneider, 1959, 1969) is a two-parameter spectrum in which both the sea severity and the state of development can be specified. The Bretschneider spectrum is given by

$$S_{\eta\eta}^o(f) = 0.169 \frac{\omega_s^4}{\omega^5} H_s^2 \exp\left(-0.675 \left(\frac{\omega_s}{\omega}\right)^4\right)$$

where $\omega_s = 2\pi/T_s$ and T_s is the significant period. The sea severity can be specified by H_s and the state of development can be specified by ω_s . It can be shown that the relationship $\omega_s = 1.167\omega_m$ (equivalent to $\omega_s = 1.46/\sqrt{H_s}$) renders the Bretschneider spectrum and the P-M spectrum equivalent. Figure 36.4 shows the Bretschneider spectra for $H_s = 4$ m. When $\omega_s = 0.731$ rad/sec, the P-M and the Bretschneider spectra are identical. It should be noted that the developing sea will have a slightly higher modal frequency than the fully developed sea, and can be described by ω_s greater than $1.46/\sqrt{H_s}$.

Other two-parameter spectral densities that are often used are the International Ship Structures Congress (ISSC) and the International Towing Tank Conference (ITTC) spectra. The ISSC spectrum is written in terms of the significant wave height and the mean frequency, where the mean frequency is given by

$$\bar{\omega} = \sqrt{\frac{\int_0^\infty \omega S(\omega) d\omega}{\int_0^\infty S(\omega) d\omega}} = 1.30\omega_m$$

Thus, the ISSC spectrum is given by

$$S_{\eta\eta}^o(f) = 0.111 \frac{\bar{\omega}^4}{\omega^5} H_s^2 \exp\left(-0.444 \left(\frac{\bar{\omega}}{\omega}\right)^4\right)$$

The ITTC spectrum is based on the significant wave height and the zero crossing frequency and is given by

$$S_{\eta\eta}^o(f) = 0.0795 \frac{\omega_z^4}{\omega^5} H_s^2 \exp\left(-0.318 \left(\frac{\omega_z}{\omega}\right)^4\right)$$

where the zero crossing frequency, ω_z , is given by

$$\omega_z = \sqrt{\frac{\int_0^\infty \omega^2 S(\omega) d\omega}{\int_0^\infty S(\omega) d\omega}} = 1.41\omega_m$$

The Bretschneider, ITTC, and ISSC spectra are called two-parameter spectra, and they can be written as

$$S_{\eta\eta}^o(f) = \frac{A}{4} \frac{\bar{\omega}^4}{\omega^5} H_s^2 \exp\left(-A \left(\frac{\bar{\omega}}{\omega}\right)^4\right)$$

with A and $\bar{\omega}$ given in Table 36.1.

FIGURE 36.4 Bretschneider spectrum with various values of ω_s .

TABLE 36.1 Two-Parameter Spectrum Models

$$S_{\eta\eta}^o(\omega) = (A/4)H_s^2\bar{\omega}^4/\omega^5 \exp(-A(\omega/\bar{\omega})^{-4})$$

Model	A	$\bar{\omega}$
Bretschneider	0.675	ω_s
ITTC	0.318	ω_z
ISSC	0.4427	$\bar{\omega}$

The spectra that we have discussed so far do not allow us to generate spectra with two peaks to represent local or distant storms or to specify the sharpness of the peaks. The Ochi–Hubble (O–H) spectrum (Ochi and Hubble, 1976) is a six-parameter spectrum with the form:

$$S_{\eta\eta}^o(\omega) = \frac{1}{4} \sum_{i=1}^2 \frac{((4\lambda_i + 1)\omega_{mi}^4/4)^{\lambda_i}}{\Gamma(\lambda_i)} \frac{H_{si}^2}{\omega^{4\lambda_i+1}} \exp\left(-\left(\frac{4\lambda_i + 1}{4}\right)\left(\frac{\omega_{mi}}{\omega}\right)^4\right)$$

where $\Gamma(\lambda_i)$ is the Gamma function, H_{s1} , ω_{m1} , and λ_1 are the significant wave height, modal frequency, and shape factor for the lower frequency components, respectively, and H_{s2} , ω_{m2} , and λ_2 are those for the higher frequency component. Assuming that the entire spectrum is that of a narrow band, the equivalent significant wave height is given by

$$H_s = \sqrt{H_{s1}^2 + H_{s2}^2}$$

For $\lambda_1 = 1$ and $\lambda_2 = 0$, the spectrum reduces to the P–M spectrum. With the assumption that the entire spectrum is narrowband, the value of λ_1 is much higher than λ_2 . The O–H spectrum represents unidirectional seas with unlimited fetch. The sea severity and the state of development can be specified by H_{si} and ω_{mi} , respectively. In addition, λ_i can be selected to control the frequency width of the spectrum. For example, a small λ_i (wider frequency range) describes a developing sea, and a large λ_i (narrower frequency range) describes a swell condition. Figure 36.5 shows the O–H spectrum with $\lambda_1 = 2.72$, $\omega_{m1} = 0.626$ rad/sec, $H_{s1} = 3.35$ m, $\lambda_2 = 2.72$, $\omega_{m2} = 1.25$ rad/sec, and $H_{s2} = 2.19$ m.

Finally, another spectrum that is commonly used is the Joint North Sea Wave Project (JONSWAP) spectrum developed by Hasselmann et al. (1973). It is a fetch-limited spectrum because the growth over a limited fetch is taken into account. The attenuation in shallow water is also taken into account. The JONSWAP spectrum is written as

$$S_{\eta\eta}^o(\omega) = \frac{\alpha g^2}{\omega^5} \exp\left(-1.25\left(\frac{\omega_m}{\omega}\right)^4\right) \gamma^{\exp(-(\omega - \omega_m) / 2\tau^2 \omega_m^2)}$$

where γ is the peakedness parameter and τ is the shape parameter. The peakedness parameter γ is the ratio of the maximum spectral energy to the maximum spectral energy of the corresponding P–M spectrum. That is, when $\gamma = 7$, the peak spectral energy is seven times that of the P–M spectrum.

$$\gamma = \begin{cases} 7.0 & \text{for very peaked data} \\ 3.3 & \text{for mean of selected JONSWAP data} \\ 1.0 & \text{for P–M spectrum} \end{cases}$$

$$\tau = \begin{cases} 0.07 & \text{for } \omega \leq \omega_m \\ 0.09 & \text{for } \omega > \omega_m \end{cases}$$

$$\alpha = 0.076(\bar{X})^{-0.22} \text{ or } 0.0081 \text{ if fetch independent}$$

$$\bar{X} = gX/U_w^2$$

$$X = \text{fetch length (nautical miles)}$$

$$U_w = \text{wind speed (knots)}$$

$$\omega_m = 2\pi \times 3.5(g/U_w)\bar{X}^{-0.33}$$

FIGURE 36.5 Ochi–Hubble spectrum.

Figure 36.6 shows the JONSWAP spectrum when $\alpha = 0.0081$ and $\omega_m = 0.626$ rad/sec for three peakedness parameters.

36.1.3 Approximation of Spectral Density from Time Series

From the time history of the wave elevation, the spectral density function can be obtained by two methods.

The first method is to use the autocorrelation function $R_{\eta\eta}(\tau)$, which is related to the spectral density function $S_{\eta\eta}(\omega)$ by the Wiener–Khinchine relations (Equation 36.6).

The autocorrelation $R_{\eta\eta}(\tau)$ is the expected value of $\eta(t)\eta(t + \tau)$ or $R_{\eta\eta}(\tau) = E\{\eta(t)\eta(t + \tau)\}$, where t is an arbitrary time and τ is the time lag. For a weakly stationary process, the autocorrelation is a function of the time lag only.

Assuming that the process is ergodic, the autocorrelation function for a given time history of length T_s can be approximated as

$$\hat{R}_{\eta\eta}(\tau) = \lim_{T_s \rightarrow \infty} \frac{1}{T_s - \tau} \int_0^{T_s - \tau} \eta(t)\eta(t + \tau) dt \quad \text{for } 0 < \tau < T_s$$

Note that the superscript \wedge is used to emphasize that the variable is an approximation based on a sample time history of length T_s . The spectral density is then obtained by taking the Fourier cosine transform of $\hat{R}_{\eta\eta}(\tau)$,

$$\hat{S}_{\eta\eta}(\omega) = \frac{1}{\pi} \int_0^{T_s} \hat{R}_{\eta\eta}(\tau) \cos \omega\tau d\tau \quad (36.10)$$

The second method for obtaining the spectral density function is to use the relationship between the spectral density and the Fourier transform of the time series. They are related by

$$\hat{S}_{\eta\eta}(\omega) = \lim_{T_s \rightarrow \infty} \frac{1}{2\pi T_s} |\hat{X}(\omega)\hat{X}^*(\omega)| \quad (36.11)$$

where $\hat{X}(\omega)$ is given by

$$\hat{X}(\omega) = \int_0^{T_s} \eta(t) \exp(-i\omega t) dt$$

and $\hat{X}^*(\omega)$ is the complex conjugate given by

$$\hat{X}^*(\omega) = \int_0^{T_s} \eta(t) \exp(i\omega t) dt$$

In order to obtain the Fourier transforms of the time series (see Chapter 2, Chapter 10, Chapter 21, and Appendix 2A), the discrete Fourier transform (DFT) or the fast Fourier transform (FFT) procedure can be used. For detailed descriptions of how this is done, see Appendix 1 in Tucker (1991). Nowadays, spectral analysis is almost always carried out via FFTs because it is easier to use and faster than the formal method via correlation function.

It should be noted that the length of the sample time history only needs to be long enough so that the limits converge. Taking a longer sample will not improve the accuracy of the estimate. Instead, one should take many samples or break one long sample into many parts. For n samples, the spectral densities

FIGURE 36.6 JONSWAP spectrum for $\gamma = 1.0, 3.3$, and 7.0 .

are obtained for each sample time history using either Equation 36.10 or Equation 36.11, and they are averaged to give the estimate.

The determination of the spectral density from wave records depends on the details of the procedure such as the length of the record, sampling interval, degree and type of filtering and smoothing, and time discretization.

36.1.4 Generation of Time Series from a Spectral Density

In a nonlinear analysis, the structural response is found by a numerical integration in time. Therefore, one needs to convert the wave elevation spectrum into an equivalent time history. The wave elevation can be represented as a sum of many sinusoidal functions with different angular frequencies and random phase angles. That is, we write $\eta(t)$ as

$$\eta(t) = \sum_{i=1}^N \cos(\omega_i t - \varphi_i) \sqrt{2S_{\eta\eta}(\omega_i)\Delta\omega_i} \quad (36.12)$$

where φ_i is a uniform random number between 0 and 2π , ω_i are discrete sampling frequencies, $\Delta\omega_i = \omega_i - \omega_{i-1}$, and N is the number of partitions. Recall that the area under the spectrum is equal to the variance, σ_η^2 . The incremental area under the spectrum, $S_{\eta\eta}(\omega_i)\Delta\omega_i$, can be denoted as σ_i^2 such that the sum of all the incremental area equals the variance of the wave elevation or $\sigma_\eta^2 = \sum_{i=1}^N \sigma_i^2$. The time history can be written as

$$\eta(t) = \sum_{i=1}^N \cos(\omega_i t - \varphi_i) \sqrt{2}\sigma_i$$

The sampling frequencies, ω_i , can be chosen at equal intervals such that $\omega_i = i\omega_1$. However, the time history will then have the lowest frequency of ω_1 and will have a period of $T = 2\pi/\omega_1$. In order to avoid this unwanted periodicity, Borgman (1969) suggested that the frequencies are chosen so that the area under the spectrum curve for each interval is equal or $\sigma_i^2 = \sigma^2 = \sigma_\eta^2/N$. The time history is written as

$$\eta(t) = \sqrt{\frac{2}{N}}\sigma_\eta \sum_{i=1}^N \cos(\bar{\omega}_i t - \varphi_i) \quad (36.13)$$

where $\bar{\omega}_i = (\omega_i + \omega_{i-1})/2$. The discrete frequencies, ω_i , are chosen such that the area between the interval $0 < \omega < \omega_i$ is equal to i/N of the total area under the curve between the interval $0 < \omega < \omega_N$ or

$$\int_0^{\omega_i} S_{\eta\eta}(\omega) d\omega = \frac{i}{N} \int_0^{\omega_N} S_{\eta\eta}(\omega) d\omega \quad \text{for } i = 1, \dots, N$$

where it is assumed that the area under the spectrum beyond ω_N is negligible. If $\eta(t)$ is a narrowband Gaussian process, the standard deviation can be replaced by $\sigma_\eta = H_s/4$, and the time history can be written as

$$\eta(t) = \frac{H_s}{4} \sqrt{\frac{2}{N}} \sum_{i=1}^N \cos(\bar{\omega}_i t - \varphi_i)$$

Shinozuka (1972) proposed that the sampling frequencies, $\bar{\omega}_i$, in Equation 36.13 should be randomly chosen according to the density function, $f(\omega) \equiv S_{\eta\eta}^o(\omega)/\sigma_\eta^2$. This is equivalent to performing an integration using the Monte Carlo method. The random frequencies ω distributed according to $f(\omega)$ can be obtained from uniformly distributed random numbers, x , by $\omega = F^{-1}(x)$, where $F(\omega)$ is the cumulative distribution of $f(\omega)$.

The random frequencies obtained this way are used in Equation 36.13 to generate a sample time series. It should be noted that many sample time histories should be obtained and averaged to synthesize a time history for use in numerical simulations.

36.1.5 Short-Term Statistics

In discussing wave statistics, we often use the term *significant wave* to describe an irregular sea surface. The significant wave is not a physical wave that can be seen but rather a statistical description of random waves. The concept of significant wave height was first introduced by Sverdrup and Munk (1947) as the average height of the highest one third of all waves. Usually, ships co-operate in programs to find sea statistics by reporting a rough estimate of the storm severity in terms of an observed wave height.

This observed wave height is consistently very close to the significant wave height.

Stationarity and ergodicity are two assumptions that are made in describing short-term waves statistics. These assumptions are valid only for “short” time intervals — approximately two hours or the duration of a storm — but not for weeks or years. The wave elevation is assumed to be weakly stationary so that its autocorrelation is a function of time lag only. As a result, the mean and the variance are constant, and the spectral density is invariant with time. Therefore, the significant wave height and the significant wave period are constant when we consider short-term statistics. In this case, the individual wave height and wave period are the stochastic variables. We then need to determine certain statistics for the analysis and design of offshore structures when we consider short time intervals.

Consider a sample time history of a zero-mean random process, as shown in Figure 36.7. The questions that we ask are how often is a certain level (e.g., z in the figure) exceeded, and how are the maxima distributed? Likewise, we can ask when we can expect to see that a certain level is exceeded for the first time, and what are the values of the peaks of a random process? The first question is important when a structure may fail due to a one-time excessive load, and the second question is important when a structure may fail due to cyclic loads.

It is found that the rate at which a random process $X(t)$ crosses Z with a positive slope (zero up-crossing) may be calculated from

$$\nu_{z^+} = \int_0^\infty \nu f_{X\dot{X}}(z, \nu) d\nu$$

where $f_{X\dot{X}}(x, \dot{x})$ is the joint probability density function of X and $\dot{X}(t)$. The expected time of the first up-crossing is then the inverse of the crossing rate or

$$E\{T\} = 1/\nu_{z^+}$$

The probability density function of the maxima, A , can be calculated from

$$f_A(a) = \frac{\int_{-\infty}^0 -\omega f_{X\ddot{X}}(a, 0, \omega) d\omega}{\int_{-\infty}^0 -\omega f_{X\ddot{X}}(0, \omega) d\omega}$$

where $f_{X\dot{X}\ddot{X}}(x, \dot{x}, \ddot{x})$ is the joint probability density function of X , \dot{X} , and \ddot{X} .

If $X(t)$ is a Gaussian process, then we can write the joint probability density functions as

$$f_{X\dot{X}}(x, \dot{x}) = \frac{1}{2\pi\sigma_X\sigma_{\dot{X}}} \exp\left[-\frac{1}{2}\left(\frac{x}{\sigma_X}\right)^2 - \frac{1}{2}\left(\frac{\dot{x}}{\sigma_{\dot{X}}}\right)^2\right], \quad -\infty < x < \infty, \quad -\infty < \dot{x} < \infty$$

and

$$f_{X\dot{X}\ddot{X}}(x, \dot{x}, \ddot{x}) = \frac{1}{(2\pi)^{3/2}|M|^{1/2}} \exp\left[-\frac{1}{2}(\{x\} - \{\mu_X\})^T [M]^{-1} (\{x\} - \{\mu_X\})\right]$$

FIGURE 36.7 A sample time history.

where

$$[M] = \begin{bmatrix} \sigma_X^2 & 0 & \sigma_{\dot{X}}^2 \\ 0 & \sigma_{\dot{X}}^2 & 0 \\ \sigma_{\dot{X}}^2 & 0 & \sigma_{\ddot{X}}^2 \end{bmatrix} \quad \text{and} \quad \{x\} - \{\mu_X\} = \begin{bmatrix} x - \mu_X \\ \dot{x} - \mu_{\dot{X}} \\ \ddot{x} - \mu_{\ddot{X}} \end{bmatrix}$$

Then, for a stationary Gaussian process, the up-crossing rate is given by

$$\begin{aligned} \nu_z^+ &= \int_0^\infty f_{\dot{X}\ddot{X}}(Z, \dot{x}) \dot{x} \, d\dot{x} = \frac{1}{2\pi\sigma_X\sigma_{\dot{X}}} \exp\left[-\frac{1}{2}\left(\frac{Z}{\sigma_X}\right)^2\right] \int_0^\infty \exp\left[-\frac{1}{2}\left(\frac{\dot{x}}{\sigma_{\dot{X}}}\right)^2\right] \dot{x} \, d\dot{x} \\ &= \frac{\sigma_{\dot{X}}}{2\pi\sigma_X} \exp\left[-\frac{1}{2}\left(\frac{Z}{\sigma_X}\right)^2\right] \end{aligned} \quad (36.14)$$

and the probability density function of maxima is given by the Rice density function (Rice, 1954)

$$f_A(a) = \frac{\sqrt{1-\alpha^2}}{\sqrt{2\pi}\sigma_\eta} \exp\left[-\frac{1}{2} \frac{\alpha^2}{\sigma_\eta^2(1-\alpha^2)}\right] + a \frac{\alpha}{\sigma_\eta^2} \Phi\left(\frac{a\alpha}{\sigma_\eta\sqrt{\alpha^2-1}}\right) \exp\left(-\frac{1}{2} \frac{a^2}{\sigma_\eta^2}\right) \quad \text{for } -\infty < a < \infty$$

where $\Phi(x)$ is the cumulative distribution function of standard normal random variable

$$\Phi(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^x \exp(-z^2/2) dz$$

and α is the irregularity factor equivalent to the ratio of the number of zero up-crossings (number of times that $\eta[t]$ crosses zero with a positive slope) to the number of peaks. α ranges from 0 to 1, and it is also equal to

$$\alpha = \frac{\sigma_\eta^2}{\sigma_\eta^2 \sigma_\eta^2}$$

If $X(t)$ is a broadband process, $\alpha = 0$ and the Rice distribution is reduced to the Gaussian probability density function given by

$$f_A(a) = \frac{1}{\sqrt{2\pi}\sigma_\eta} \exp\left[-\frac{1}{2} \frac{a^2}{\sigma_\eta^2}\right] \quad \text{for } -\infty < a < \infty$$

If $X(t)$ is a narrowband process, it is guaranteed that it will have a peak whenever $\eta(t)$ crosses its mean. In this case, the irregularity factor is close to unity, and the Rice distribution is reduced to the Rayleigh probability density function given by

$$f_A(a) = \frac{a}{\sigma_\eta^2} \exp\left[-\frac{1}{2} \frac{a^2}{\sigma_\eta^2}\right] \quad \text{for } 0 < a < \infty$$

In other words, the amplitudes of a narrowband stationary Gaussian process are distributed according to the Rayleigh distribution.

Figure 36.8 shows the Rice distribution for various values of α . Note that the Rice distribution includes both positive and negative maxima except when $\alpha = 1$, in which case all the maxima are positive. The positive maxima are the local maxima that occur above the mean of $X(t)$, and the negative maxima are the local maxima that occur below the mean, as shown in Figure 36.7. In some cases, the negative maxima may not mean

FIGURE 36.8 Rice distribution for maxima.

much physically. In those cases, we can use the truncated Rice distribution, where only the positive portion of $f_A(a)$ is used. $f_A(a)$ is normalized by the area under the probability density for positive maxima (Longuet-Higgins, 1952; Ochi, 1973):

$$f_A^{\text{trunc}}(a) = \frac{f_A(a)}{\int_0^\infty f_A(a) da}, \quad a \geq 0$$

The truncated Rice distribution is shown in Figure 36.9.

If $X(t)$ is the wave elevation, its maxima, A , are the amplitudes of the wave elevation. The wave height, $H = 2A$, is then distributed according to

$$f_H(h) = f_A(H/2) \frac{dA}{dH} = \frac{h}{4\sigma_\eta^2} \exp\left[-\frac{1}{2} \frac{h^2}{4\sigma_\eta^2}\right] \quad \text{for } 0 < h < \infty$$

For any given wave, the probability that the height is less than h (the cumulative distribution) is

$$F_H(h) = 1 - \exp\left[-\frac{1}{2} \frac{h^2}{4\sigma_\eta^2}\right] \quad \text{for } 0 < h < \infty$$

If $\eta(t)$ is a stationary narrowband process so that the peaks are distributed according to the Rayleigh distribution, we find that the root-mean-square wave height, $\sqrt{E\{H^2\}}$, is given by

$$\sqrt{E\{H^2\}} = \int_0^\infty h^2 f_H(h) dh = 2\sqrt{2}\sigma_\eta$$

In addition, it can be shown that the average and the significant wave heights are given by

$$H_0 \equiv E\{H\} = \sqrt{2\pi}\sigma_\eta, \quad H_s \equiv E\{H_{1/3}\} = 4\sigma_\eta \quad (36.15)$$

where $E\{H_{1/3}\}$ means that it is the expectation of the highest one third of the waves.

36.1.6 Long-Term Statistics

Because offshore structures are designed for long life spans, we must also consider long-term wave statistics. Previously, when we considered the short-term statistics, the significant wave height and spectrum were assumed to be invariant with time. This assumption is valid only over time periods of days at most. For longer time periods, the significant wave height has its own statistics and is a random variable.

When one uses short-term statistics to describe long-term events, improbable events seem unjustifiably probable. For example, let us consider the probability that the wave height, distributed according to the Rayleigh distribution, exceeds a certain extreme value. Let us assume that the mean period of this wave is 10 sec and the probability that the height of any given wave is greater than 300 ft is 10^{-10} . The value is small and the occurrence of a 300 ft wave seems improbable. However, the probability that the height will exceed 300 ft at least once in 10 years (3×10^8 sec) is given by

$$1 - (1 - 10^{-10})^{3 \times 10^8 / 10} = 0.997$$

FIGURE 36.9 Truncated Rice distribution.

Thus, the statistical description states that it is almost certain that the wave height will exceed 300 ft at least once in 10 years. This prediction is a shortcoming of the short-term statistics since waves of this magnitude do not arrive at this probability.

In order to compute the probability that a wave height will exceed a certain extreme value, we require statistics for these extreme events. The actual maximum amplitude in a sequence of random amplitudes is a random variable itself. It has a probability distribution with mean value, standard deviation and other statistical properties. In fact, the distributions of these maximum values are called the extreme value distributions (EVDs). Gumbel (1958) obtained three methods of extrapolation known as three asymptotes. They are the Gumbel, Fretchet, and Weibull distributions. We will discuss the Gumbel and Weibull distributions in the next section. For the moment, we will discuss the concept of the N -year storm.

In long-term statistics, we often speak of an N -year storm. It means that, for any given year, the probability that we will have an N -year storm is

$$p = \frac{1}{N}$$

It follows that the probability that we will have m storms in n years is given by

$$\Pr\{mN\text{-year storms in } n \text{ years}\} = {}_n P_m \left(\frac{1}{N}\right)^m \left(1 - \frac{1}{N}\right)^{n-m}$$

where ${}_n P_m$ is the permutation given by

$${}_n P_m = \frac{n!}{(n-m)!}$$

The probability that we will have at least one N -year storm in n years is

$$\Pr\{\text{at least one } N\text{-year storms in } n \text{ years}\} = 1 - \left(1 - \frac{1}{N}\right)^n$$

For a large N , the probability can be approximated as $1 - \exp(n/N)$. It should be noted that the probability that we will have exactly one N -year storm in N years is not one, but

$$\Pr\{\text{one } N\text{-year storm in } N \text{ years}\} = \left(1 - \frac{1}{N}\right)^{N-1}$$

As $N \rightarrow \infty$, we find that

$$P = 1/e \approx 0.3679$$

The probability that we will have at least one N -year storm in N years is

$$\Pr\{\text{at least one } N\text{-year storms in } n \text{ years}\} = 1 - \left(1 - \frac{1}{N}\right)^N$$

As $N \rightarrow \infty$, we find that

$$P = 1 - 1/e \approx 0.6321 \quad (36.16)$$

36.1.6.1 Weibull Distribution

The Weibull distribution fits probabilities of extremes quite satisfactorily. In long-term statistics, the significant wave height follows the Weibull distribution closely. The probability density and the cumulative distribution are given by

$$f(h) = \frac{m}{\beta} \left(\frac{h-\gamma}{\beta}\right)^{m-1} \exp\left(-\left(\frac{h-\gamma}{\beta}\right)^m\right), \quad F(h) = 1 - \exp\left(-\left(\frac{h-\gamma}{\beta}\right)^m\right) \text{ for } \gamma < h \quad (36.17)$$

where m is called the shape parameter. Manipulating the cumulative distribution, we can write

$$\ln(-\ln\{1 - F(h)\}) = m\{\ln(h - \gamma) - \ln(\beta)\}$$

where the left-hand side is known from data. If we let $y = \ln(-\ln\{1 - F(h)\})$ and $x = \ln(h - \gamma)$, y is a straight line with slope of m and a y -intercept of $-m \ln \beta$:

$$y = mx - m \ln \beta$$

Suppose we have significant wave height data over a long period of time, and our goal is to find the Weibull parameters, γ , β , and m that best fit the distribution of the significant wave heights. These parameters can be determined by the least-squares method or using the Weibull paper. Using the latter method, we first guess γ so that the discrete points (x, y) or $(\ln(h - \gamma), \ln(-\ln\{1 - F(h)\}))$ form a straight line. The slope of this line is m , and the value of y when the line intersects the y axis is $-m \ln \beta$. This method will be illustrated in Section 36.3.3.

The Gumbel distribution is given by

$$\begin{aligned} f(h) &= \alpha \exp(-\alpha(h - \beta)) \exp\{\exp[-\alpha(h - \beta)]\} \\ F(h) &= \exp\{-\exp[-\alpha(h - \beta)]\} \quad \text{for } -\infty < h < \infty \end{aligned} \quad (36.18)$$

When $\ln[-\ln F(h)]$ is plotted against h , the result is a line with a slope of $-\alpha$ and y intercept of $\alpha\beta$.

Another distribution that may be used is the lognormal distribution given by (Jasper, 1954)

$$f(h) = \frac{1}{\sqrt{2\pi}\sigma h} \exp\left[-\frac{1}{2} \frac{(\ln h - \mu)^2}{\sigma^2}\right], \quad F(h) = \Phi\left(\frac{\ln h - \mu}{\sigma}\right) \quad \text{for } 0 \leq h \quad (36.19)$$

36.1.6.2 Wave Velocities via Linear Wave Theory

The wave velocities that correspond to the wave elevation given in Equation 36.12 can be obtained by *linear wave theory*. Linear wave theory, also called *airy wave theory*, *sinusoidal wave theory*, and *small-amplitude theory*, is the simplest wave theory. It is also the most important wave theory because it forms the basis for the probabilistic spectral description of waves.

Linear wave theory assumes that the wave height is small compared with the wavelength and wave depth. In addition, fluid particles are assumed to follow a circular orbit. The readers should refer to Kinsman (1965) and LeMehaute (1976) for detailed descriptions.

In linear wave theory, the surface elevation is given by

$$\eta(y, t) = A \cos(\omega t - ky) \quad (36.20)$$

which is a plane wave traveling to the right in Figure 36.10. Linear wave theory relates this sinusoidal surface elevation to the wave velocities given by

$$w_y(x, y, t) = A\omega \frac{\cosh kx}{\sinh kd} \cos(\omega t - ky), \quad w_x(x, y, t) = A\omega \frac{\sinh kx}{\sinh kd} \sin(\omega t - ky) \quad (36.21)$$

where k , ω , and A are wave number, angular frequency, and amplitude of a surface wave, respectively. The velocities vary with time, horizontal coordinate y , and depth x measured from the ocean floor. The wave velocities are sinusoidal in y and t , but exponentially decrease with the distance from the surface.

FIGURE 36.10 A schematic of a simple sinusoidal wave shown at two different times.

The frequency ω is related to the wave number k by the dispersion relation given by

$$\omega^2 = gk \tanh kd$$

where d is the water depth. For deep water, $\tanh kd$ approaches unity and the frequency is given by

$$\lim_{d \rightarrow \infty} \omega^2 = gk$$

For the surface elevation given in Equation 36.12, the surface elevation and the wave velocities are given by

$$\begin{aligned} \eta(y, t) &= \sum_{i=1}^N \cos(\omega_i t - k_i y - \varphi_i) \sqrt{2S_{\eta\eta}(\omega_i) \Delta\omega_i} \\ w_y(x, y, t) &= \sum_{i=1}^N \omega_i \frac{\cosh k_i x}{\sinh k_i d} \cos(\omega_i t - k_i y - \varphi_i) \sqrt{2S_{\eta\eta}(\omega_i) \Delta\omega_i} \\ w_x(x, y, t) &= \sum_{i=1}^N \omega_i \frac{\sinh k_i x}{\sinh k_i d} \sin(\omega_i t - k_i y - \varphi_i) \sqrt{2S_{\eta\eta}(\omega_i) \Delta\omega_i} \end{aligned} \quad (36.22)$$

The wave accelerations can be obtained by differentiating the wave velocities with respect to time. Sample time histories of the wave velocity and acceleration can be obtained using either Borgman's or Shinozuka's method.

36.1.7 Summary

In this section, the concept of spectral density is introduced. It is then shown how the concept is used to describe the ocean wave heights. The spectral density or spectrum is related to the autocorrelation function by the Wiener–Khinchine relations:

$$\begin{aligned} S_{\eta\eta}(\omega) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{\eta\eta}(\tau) \exp(-i\omega\tau) d\tau \\ R_{\eta\eta}(\tau) &= \int_{-\infty}^{\infty} S_{\eta\eta}(\omega) \exp(-i\omega\tau) d\omega \end{aligned}$$

In addition, the spectral density function of a real-valued stationary process is also real and symmetric, or

$$S_{\eta\eta}(\omega) = S_{\eta\eta}(-\omega) \quad (36.23)$$

and the area under the spectral density is given by

$$\int_{-\infty}^{\infty} S_{\eta\eta}(\omega) d\omega = R_{\eta\eta}(0) = \sigma_{\eta}^2 - \mu_{\eta}^2 \quad (36.24)$$

If the spectral density is given only for $\omega \geq 0$, then this one-sided spectrum is related to the two-sided spectrum by

$$S_{\eta\eta}^o(\omega) = 2S_{\eta\eta}(\omega), \quad \omega \geq 0$$

When the frequency is given in Hertz instead of in rad/sec, the spectra are related by

$$S_{\eta\eta}(f) = 2\pi S_{\eta\eta}(\omega), \quad \omega \geq 0$$

The spectra that are often used to describe wave heights are the P–M, Bretschneider, ITTC, ISSC, O–H, and JONSWAP spectra. The most widely used spectrum is the P–M spectrum, which is a single parameter spectrum. The P–M spectrum is applicable for deep water, unidirectional seas, fully developed and local-wind-generated sea with unlimited fetch, and was originally developed for the North Atlantic. The single parameter for this spectrum can be expressed as the wind velocity at 19.5 m above sea level or the significant wave height that specifies the sea severity. When it is written

in terms of the significant wave height, it is given by

$$S_{\eta\eta}^o(f) = \frac{8.1 \times 10^{-3} g^2}{\omega^5} \exp\left(-\frac{0.0324 g^2}{H_s^2} \omega^{-4}\right)$$

Bretschneider, ITTC, and ISSC spectra are two-parameter spectra in which the state of development as well as the sea severity can be specified. The O–H spectrum is a six-parameter spectrum that allows us to represent local and distant storm effects and to specify sharpness of the peaks as well as to specify the sea severity and the state of development. The JONSWAP spectrum allows us to account for growth over a limited fetch.

For a given ocean spectrum, a sample time history can be obtained by

$$\eta(t) = \sqrt{\frac{2}{N}} \sigma_\eta \sum_{i=1}^N \cos(\bar{\omega}_i t - \varphi_i)$$

In Borgman's method, the sampling frequencies $\bar{\omega}_i = (\omega_i + \omega_{i-1})/2$ are chosen so that the area between ω_{i-1} and ω_i are equal. In Shinozuka's method, the sampling frequencies are chosen randomly. The traditional method of choosing the sampling frequency at even intervals is not recommended.

When a relatively short interval of time is considered, for example, about two hours or the duration of a storm, it can be assumed that the spectrum and its statistics are invariant with time. In this case, the distribution of local maxima or peaks of a stationary Gaussian process is described by the Rice distribution. The Rice distribution can be reduced to the Rayleigh distribution when the process is narrowband and to the Gaussian distribution when the process is broadband. In the long-term statistics, the spectrum and its statistics may vary with time. In this case, the term “*N*-year storm” is often used to indicate the sea severity, and the significant wave heights closely follow the Weibull distribution.

Finally, the wave velocities and accelerations are related to the wave velocities using linear wave theory.

36.2 Fluid Forces

The following is a list of several types of forces that the fluid can exert on a body:

1. *Drag force.* This is due to the pressure difference between the downstream and upstream flow region. It can be thought of as the force required to hold a body stationary in a fluid of constant velocity. The drag force is proportional to the square of the velocity of the fluid relative to the structure.
2. *Inertia force.* This is the force exerted by the fluid while it accelerates and decelerates as it passes the structure. It is also the force required to hold a rigid structure in a uniformly accelerating flow, and it is proportional to the fluid acceleration. The concept of the inertia force in an inviscid flow was first formulated by Lamb (1945).
3. *Added mass.* As the body accelerates or decelerates in a stationary fluid, the body carries a certain amount of the surrounding fluid along with it. This entrained fluid is called the *added, apparent, or virtual mass*. In order to accelerate the body, additional force is required to accelerate or decelerate the added mass.
4. *Diffraction force.* This is due to the scattering of an incident wave on the surface of the structure. It is important when the body is large compared with the wavelength of the incident wave.
5. *Froude–Kryloff force.* This is the pressure force on the structure due to the incident wave, assuming that the structure does not exist and does not interfere with the incident wave.
6. *Lift force.* This is due to nonsymmetrical separation of the fluid or due to vortices that are shed in a nonsymmetrical way. The component of the force perpendicular to the flow direction is the lift force.

7. *Wave slamming force.* This is due to a single occasional wave with a particularly high amplitude and energy, and it may be important at the free surface. Sarpkaya and Isaacson (1981) reviewed the research on slamming of water against circular cylinders. Miller (1977, 1980) found that the peak wave slamming force on a rigidly held horizontal circular cylinder is proportional to the square of the horizontal water particle velocity.

36.2.1 Wave Force Regime

Previously, we discussed various types of forces caused by waves and currents. In some cases, one type of force may be dominant. Hogben (1976) gave a literature review of the fluid force in various regimes. The load regime of importance can be demonstrated for the case of a vertical cylinder in Figure 36.11 in terms of H/D and $\pi D/\lambda$, where H is the wave height, D is the cylinder diameter, and λ is the wavelength. When linear wave theory is used, H/D is related to the Keulegan–Carpenter number by

$$K = \pi H/D$$

The Keulegan–Carpenter number gives a measure of the importance of drag force relative to the inertia force. The term $\pi D/\lambda$ is called the diffraction parameter, and it determines the importance of the diffraction effect. As H/D increases, the drag force becomes more important and the inertia force becomes less important. As $\pi D/\lambda$ increases, the diffraction force becomes important.

Using linear wave theory, the maximum drag force to the maximum inertia force can be written as

$$\frac{f_{\text{drag}}}{f_{\text{inertia}}} = \frac{1}{2\pi} \frac{H}{D} = \frac{K}{2\pi^2}$$

From the last relation, we find that the drag force is 5% of the inertial force when $H/D = 0.314$. The Morison equation may be used for $D/\lambda < 0.2$ and $f_{\text{drag}}/f_{\text{inertia}} > 0.1$ or thereabouts. It should be noted that Figure 36.11 is valid only near the surface. The drag force is predominant for a cylinder that extends from the bottom to the near surface, so that the Morison equation may be used.

For example, consider a fixed jacket platform with legs with a diameter of 10 m and bracings with a diameter of 0.8 m. For a 10-year storm with $\lambda = 100$ m and $H = 8$ m, the ratios H/D and D/λ for the leg are 0.8 and 0.1, respectively. Similarly, the ratios H/D and D/λ for the bracings are 10 and 0.08, respectively. Figure 36.11 shows that the inertia force is dominant for the legs, and both inertia and the drag forces are important for the bracings.

FIGURE 36.11 Load regimes near surface.

36.2.2 Wave Forces on Small Structures — Morison Equation

The added mass, M_A , can be written as

$$M_A = C_A M_{\text{disp}}$$

where C_A is called the *added mass coefficient* and M_{disp} is the mass of the fluid displaced by the structure. For a cylinder with a diameter, D , and height, h , the displaced fluid mass is $\pi D^2 h/4$. It should be noted that the added mass is a tensor quantity. That is, we can speak of the added mass force in the x_i direction due to the acceleration of the body in the x_j direction, denoted as M_{ij}^A . M_{ij}^A is symmetric so that the added mass force in the x_i direction due to the acceleration in the x_j direction is equal to the added mass force in the x_j direction due to the acceleration in the x_i direction. The off-diagonal terms are not zero if the cross-section is not symmetric.

Similarly, the inertia force can be written as

$$F_M = C_M M_{\text{disp}} \dot{w} \quad (36.25)$$

where the proportionality constant, C_M , is called the *inertia coefficient*.

It should be noted that the added mass and the inertia effects are often neglected for a body vibrating in air since the displaced air mass is negligible.

The drag force is proportional to the square of the fluid velocity, w , the density of the fluid, ρ , and the area of the body projected onto the plane perpendicular to the flow direction, A_f ,

$$F_D = \frac{1}{2} C_D \rho A_f w |w|$$

where C_D is the *drag coefficient*. The absolute value sign is used to ensure that the drag force always acts in the direction of the flow. For a cylinder with a diameter D and height h , the projected area A_f is Dh .

For a body with nonzero velocity, the drag force is given by

$$F_D = \frac{1}{2} C_D \rho A_f (w - v) |w - v| \quad (36.26)$$

where $w - v$ is the velocity of the fluid relative to the body.

Morison et al. (1950) combined the inertia and drag terms (Equation 36.25 and Equation 36.26) so that the fluid force on a body is given by

$$f = \frac{1}{2} C_D \rho A_f w |w| + C_M M_{\text{disp}} \dot{w}$$

For a cylinder, the fluid force per unit length can be written as

$$f = \frac{1}{2} C_D \rho D w |w| + C_M \rho \pi \frac{D^2}{4} \dot{w}$$

For a moving cylinder with velocity v , the Morison force is given by

$$f = \frac{1}{2} C_D \rho D (w - v) |w - v| + C_M \rho \pi \frac{D^2}{4} \dot{w}$$

36.2.2.1 Inclined Cylinder

Let us now consider the inclined cylinder shown in [Figure 36.13](#). The direction of the flow makes an angle of θ with the cylinder. Often, only the fluid force in the normal direction is considered. The normal component is given by

$$f^n = \frac{1}{2} C_D \rho D (w^n - v^n) |w^n - v^n| + C_M \rho \pi \frac{D^2}{4} \dot{w}^n \quad (36.27)$$

where the superscript is used for the normal component. The term, $w^n - v^n$, is the normal component of the relative velocity of the fluid with respect to the structure. Suppose that fluid is flowing to the right,

and the cylinder is also moving to the right, as shown in Figure 36.12. The normal components of the fluid and cylinder velocities are

$$w^n = |w| \cos \theta, \quad v^n = |v| \cos \theta$$

In three dimensions, it may be difficult to picture what the normal component should be. Here, we can find the normal component using the formula

$$(w^n - v^n)\vec{n} = \vec{t} \times (\vec{w} - \vec{v}) \times \vec{t} \quad (36.28)$$

where \vec{t} is the unit vector tangent to the cylinder and \vec{n} is the unit vector normal to the cylinder.

Note that the normal direction depends on the direction of the flow as well as the inclination of the cylinder.

In some cases, the tangential drag force may be included, and it can be written as

$$f^t = \frac{1}{2} C_T \rho D (w^t - v^t) |w^t - v^t| \quad (36.29)$$

where C_T is the tangential drag coefficient. Note that C_T is usually a very small number.

The normal component of the fluid force is more dominant than the tangential component. It may seem strange that the fluid force does not act in the direction of the fluid motion. Instead, the force is predominantly in the normal direction defined by Equation 36.28. In Section 36.3.1, we will demonstrate what this means by considering a towing cable.

36.2.2.1.1 Determination of Fluid Coefficients

The drag, inertia, and added mass coefficients must be obtained by experiment. However, for a long cylinder, C_M approaches its theoretical limiting value (uniformly accelerated inviscid flow) of 2, and C_A approaches unity (Lamb, 1945; Wilson, 1984). In reality, the inertia and drag coefficients are functions of at least three parameters (Wilson, 1984):

$$C_M = C_M(\text{Re}, K, \text{cylinder roughness})$$

$$C_D = C_D(\text{Re}, K, \text{cylinder roughness})$$

where Re is the Reynolds number and K is the Keulegan–Carpenter number given by

$$\text{Re} \equiv \frac{\rho_f U D}{\mu}, \quad K \equiv \frac{U T}{D} \quad (36.30)$$

where ρ_f is the density of the fluid, U is the free stream velocity, D is the diameter of the structure, μ is the dynamic or absolute viscosity, and T is the wave period.

Sarpkaya looked at the variation of these hydrodynamic coefficients extensively and obtained the plots shown in Figure 36.13 to Figure 36.15 (Sarpkaya, 1976; Sarpkaya et al., 1977). Figure 36.13 shows the inertia and drag coefficients for a smooth cylinder as a function of K for various values of Re and the reduced frequency β , defined by $\beta = \text{Re}/K$. From this figure, we find that for low Re and β , the inertial coefficient decreases and the drag coefficient increases at about $10 < K < 15$. It is found that the drop and the increase in these coefficients are due to shedding vortices, which also exert forces perpendicular to the structure and the flow.

Figure 36.14 and Figure 36.15 show the inertia and drag coefficients for a rough cylinder, whose roughness is measured by k/D . Figure 36.14a shows a drop in the drag coefficient for Re between 10^4 and 10^5 , and this is called the “drag crisis.” For a larger Re , the drag coefficient stays constant. As the surface becomes rougher, the drop occurs at lower Re and the drag coefficients for the larger Re increases.

Figure 36.14 to Figure 36.16 can be used to obtain proper values of the drag and inertia coefficients for fluid with known Re , Keulegan–Carpenter number, and cylinder roughness.

FIGURE 36.12 Inclined cylinder.

FIGURE 36.13 Drag and inertia coefficients as functions of K for various values of Re and β . (Source: Sarpkaya, 1976, *Proceedings of the Eighth Offshore Technology Conference*. With permission.)

36.2.3 Vortex-Induced Vibration

When the flow passes around a fixed cylinder, for a very low Re ($0 < Re < 4$), the flow separates and reunites smoothly. When the Re is between 4 and 40, eddies are formed and are attached to the downstream side of cylinder. They are stable and there is no oscillation in the flow. For a flow with a Reynolds number greater than about 40, the fluid near the cylinder starts to oscillate due to shedding vortices. These shedding vortices exert an oscillatory force on the cylinder in the direction perpendicular to both the flow and the structure. The frequency of oscillation is related to the nondimensionalized parameter, the Strouhal number, defined by

$$St = \frac{f_v D}{U} \quad (36.31)$$

where f_v is the frequency of oscillation, U is the steady velocity of the flow, and D is the diameter of the cylinder. For circular cylinders, the Strouhal number stays roughly at 0.22 for laminar flow ($10^3 < Re < 2 \times 10^5$) and 0.3 for turbulent flow (Patel, 1989).

The lift force due to these shedding vortices can be written as

$$f_L = \frac{1}{2} C_L \rho A_f U^2 \cos 2\pi f_v t \quad (36.32)$$

where C_L is the lift coefficient, which is also a function of Re , K , and the surface roughness. The experimental data of the lift coefficients show considerable scatter with typical values ranging from 0.25 to 1. For smooth cylinders, the lift coefficient approaches about 0.25 as Re and K increase.

FIGURE 36.14 Drag and inertia coefficients for a rough cylinder as functions of Re for various values of cylinder roughness (as measured by k/D) for $K = 20$. (Source: Sarpkaya et al., 1977, *Proceedings of the Ninth Offshore Technology Conference*. With permission.)

It should be noted that the vortex forces are not generally correlated on the entire cylinder length. That is, the phase of the vortex shedding forces varies over the length. The correlation length — the length over which vortex shedding is synchronized — for a stationary cylinder is about three to seven diameters for laminar flow. If sectional forces are randomly phased, the net effect will be small. The total force on a cylinder of length L will be only a fraction of Lf_L . This fraction is called the joint acceptance and depends on the ratio of the correlation length to the total length.

When the flow passes by a cylinder that is free to vibrate, the shedding frequency is also controlled by the movement of the cylinder. When the shedding frequency is close to the first natural frequency of the cylinder (± 25 to 30% of the natural frequency [Sarpkaya and Isaacson, 1981]), the cylinder takes control of the vortex shedding. The vortices will shed at the natural frequency instead of at the frequency determined by the Strouhal number. This is called lock-in or synchronization, which is a result of nonlinear interaction between the oscillation of the body and the action of the fluid. Figure 36.16 shows the shedding frequency, as a function of flow velocity in the presence of a structure. f_1 and f_2 are the natural frequencies of the structure.

The amplitude of the structural response and the range of the fluid velocity over which the lock-in phenomenon persists are functions of a reduced damping parameter — the ratio of the damping force to the exciting force (Vandiver, 1985, 1993). If the reduced damping parameter is small, the lock-in can persist over a greater range of flow velocity.

FIGURE 36.15 Drag and inertia coefficients for a rough cylinder as functions of Re for various values of cylinder roughness (as measured by k/D) for $K = 60$. (Source: Sarpkaya et al., 1977, *Proceedings of the Ninth Offshore Technology Conference*. With permission.)

The existing models for vortex-induced oscillation for a rigid cylinder include single-degree-of-freedom models and coupled models. The single-DoF models assume that the effect of vortex shedding is an external forcing function, which is not affected by the motion of the body. The coupled models assume that the equations that govern the motion of the structure and the lift coefficients are coupled so that the fluid and the structure affect each other (Billah, 1989).

36.2.4 Summary

Some of the fluid forces are discussed briefly, and the regimes where inertia, drag, and diffraction forces are important are shown as functions of the ratio of the structural diameter to the wave

FIGURE 36.16 An example of fluid elastic resonance.

length, D/λ , and the ratio of the wave height to the structural diameter, H/D . The wave forces on small structures are modeled by the Morison equation, and it is valid for $D/\lambda < 0.2$ and $H/D > 0.63$ or thereabouts. The Morison equation includes the effects of added mass, inertia, and drag. The added mass is simply

$$M_A = C_A M_{\text{disp}}$$

For a cylinder with transverse velocity, v , the normal and the tangential components of the drag and the inertia forces are given by

$$\begin{aligned} f^n &= \frac{1}{2} C_D \rho D (w^n - v^n) |w^n - v^n| + C_M \rho \pi \frac{D^2}{4} \dot{w}^n \\ f^t &= \frac{1}{2} C_T \rho D (w^t - v^t) |w^t - v^t| \end{aligned}$$

The fluid coefficients are at least functions of three parameters: the Reynolds number, the Keulegan–Carpenter number, and the cylinder roughness. The plots of these coefficients are reproduced in [Figure 36.13](#) to [Figure 36.15](#).

The frequency of the lift force that is exerted by shedding vortices is closely related to the Strouhal number given by

$$St = \frac{f_v D}{U}$$

The lift force due to these shedding vortices can be written as

$$f_L = \frac{1}{2} C_L \rho A_f U^2 \cos 2\pi f_v t$$

If the structure is free to vibrate, then lock-in or synchronization may occur when the shedding frequency is close to the structure's natural frequency. The structure takes control of the vortex shedding. Many nonlinear models are available to capture this phenomenon.

36.3 Examples

Four examples are given in this section. The first example illustrates the roles of the normal and the tangential components of the drag force in the static configuration of a towing cable. The second example shows how the equation of motion of an articulated tower can be formulated in the presence of surrounding fluid. The third example shows how to choose a single significant wave height to represent a certain condition from significant wave height data over a long period of time. The final example shows how to reconstruct time series data from a given spectrum.

36.3.1 Static Configuration of a Towing Cable

For the purpose of ocean surveillance, oceanographic or geographic measurements, or ocean exploration, marine cables with instrument packages or Remotely Operated Vehicles are often towed behind ships or submarines. For example, the goal of the VENTS program by the National Oceanic and Atmospheric Administration (NOAA) is to conduct research on the impacts and consequences of submarine volcanoes and hydrothermal venting on the global ocean. In attempts to locate and map the distributions of hydrothermal plumes in the Mid-Ocean Ridge system, an instrument package called a CTD (Conductivity, Temperature and Depth Sensors) is towed behind a ship.

Let us consider a cable and a body towed behind a ship at a constant velocity with no current as shown in Figure 36.17. What kind of shape will the cable take? What will be the distance between the ship and the towed body?

We immediately recognize that this is equivalent to having a stationary ship with a steady current in the opposite direction. The equation of motion is given by

$$\sum \vec{F} = m\vec{a}(s, t) = \vec{0} = \frac{\partial}{\partial s}(T\vec{t}) + f^n\vec{n} + f^t\vec{t} + mg\vec{k}$$

where m is the mass of the cable per unit length, $\vec{a}(s, t)$ is the acceleration of the cable, s is the coordinate along the cable, T is the tension which is a function of s , $(\vec{t}, \vec{n}, \vec{b})$ is the set of unit vectors of the curvilinear coordinate system, \vec{k} is the unit vector downward in the direction of gravity, g is the gravitational acceleration, f^n is the normal drag force, and f^t is the tangential drag force. The added mass and the inertial terms are zero because the fluid acceleration and the cable acceleration are zero. The normal and tangential drag forces are given in Equation 36.27 and Equation 36.29. In our case, they are given by

$$f^n = C_D \rho \frac{D}{2} U^2 \cos^2 \theta, \quad f^t = -C_T \rho \frac{D}{2} U^2 \sin^2 \theta$$

The corresponding scalar equations are given by

$$\begin{aligned} \frac{dT}{ds} - C_T \rho \frac{D}{2} U^2 \sin^2 \theta - mg \cos \theta &= 0 \\ -T \frac{d\theta}{ds} + C_D \rho \frac{D}{2} U^2 \cos^2 \theta - mg \sin \theta &= 0 \end{aligned} \quad (36.33)$$

where θ is the angle that the tangential vector makes with the vertical and measured positive clockwise. Note that we have used $\partial \vec{t} / \partial s = (-\partial \theta / \partial s) \vec{n}$ and $\vec{k} = -\cos \theta \vec{t} - \sin \theta \vec{n}$. Equation 36.33 shows that the tangential components of the external forces act to increase the tension, while the normal components cause the towline to bend. Because the normal component of the drag force is much larger than the tangential component, most of the fluid force is used to turn the cable.

From the force diagram (in Figure 36.17), the angle that the cable makes with the vertical where it is connected to the towed body is given by

$$T(0) \cos \theta(0) = W, \quad T(0) \sin \theta(0) = \text{Drag}$$

Once we know the weight and the drag force on the towed body, the tension and the angle at $s = 0$ can be found. If the drag is negligible compared with the weight, then the cable must be near vertical and the tension must be equal to the weight of the towed body at $s = 0$:

$$T(0) \approx W \quad \text{and} \quad \theta(0) \approx 0$$

For now, let us assume that this is the case. Then, with these initial conditions, the system of ordinary differential equations (Equation 36.33) can be solved numerically for $T(s)$ and $\theta(s)$. For example,

FIGURE 36.17 Towed system in equilibrium and the forces acting on the towed body.

even very simple finite difference equations will work. A set of equations

$$T_{i+1} = T_i + \left(mg \cos \theta_i - C_T \rho \frac{D}{2} U^2 \sin^2 \theta_i \right) \Delta s \quad (36.34)$$

$$\theta_{i+1} = \theta_i - \left(mg \sin \theta_i + C_D \rho \frac{D}{2} U^2 \cos^2 \theta_i \right) \Delta s / T_i \quad (36.35)$$

where $T_i = T(i\Delta s)$, are used here, and it works very well for $\Delta s = 0.05$.

The Cartesian coordinates, x and y , are related to θ by

$$\frac{dx}{ds} = \sin \theta \quad \text{and} \quad \frac{dy}{ds} = \cos \theta$$

and can also be obtained by integrating them numerically.

Figure 36.18 shows the results when $mg = 1.5$ N/m, $C_D \rho D U^2 / 2 = 10$ N/m, $C_T \rho D U^2 / 2 = 0.1$ N/m, $W = 100$ N, and the cable is 100 m long. Care is taken so that the ship is located at $x = 0$ and $y = 0$.

It is interesting to note that θ approaches a critical value, and the shape gradually becomes linear toward the ship. Mathematically, $d\theta/ds$ becomes zero. This is when the drag force is completely balanced by the normal component of the cable weight. The angle at which this occurs, θ_{cr} , can be obtained from the second governing equation and

$$mg \sin \theta_{cr} = -f^n, \quad \frac{\sin \theta_{cr}}{\cos \theta_{cr}} = C_D \rho \frac{D}{2} U^2 \frac{1}{mg}$$

In our case, $\theta_{cr} = 1.184$ rad, and this value agrees with Figure 36.18.

FIGURE 36.18 The equilibrium configuration of a towed cable and the angle that the cable makes with the vertical when $mg = 1.5$ N/m, $C_D \rho D U^2 / 2 = 10$ N/m, $C_T \rho D U^2 / 2 = 0.1$ N/m, and $W = 100$ N.

36.3.2 Fluid Forces on an Articulated Tower

Offshore structures are used in the oil industry as exploratory, production, oil storage, and oil landing facilities. They are designed to be self-supporting and sufficiently stable for offshore activities such as drilling and production of oil. An articulated tower as seen in Figure 36.19 is an example of an offshore platform that consists of a base, shaft, universal joint that connects the base and the shaft, ballast chamber, buoyancy chamber, and deck. The ballast chambers provide the extra weight so that the tower's bottom stays on the ocean floor, and the buoyancy chamber adds the necessary buoyancy so that the tower does not fall.

An articulated tower can be effectively modeled as a rigid inverted pendulum, where the deck is modeled as a point mass, the shaft as a uniform rigid bar, and the buoyancy chamber by a point buoyancy. In two dimensions, motion of the tower can be described with a single DoF (Chakrabarti and Cottor, 1979; Bar-Avi, 1996). The equation of motion in terms of the tower's deflection angle is obtained by summing the moment about the point O in Figure 36.20 and is given by

$$I \frac{d^2 \theta}{dt^2} = \sum M_O = mg \frac{L}{2} \sin \theta + MgL \sin \theta - Bl \sin \theta + \int_0^L f^n x dx$$

where I is the mass moment of inertia about the point O given by $I = mL^2/3 + ML^2$, m is the mass of the shaft, g is the gravitational acceleration, L is the length of the shaft, M is the point mass at the top, B is the buoyancy provided by the buoyancy chamber, l is its moment arm, f^n is the normal fluid force per unit length, and x is the coordinate along the shaft from O.

The fluid force per unit length in the normal direction is given by

$$f^n = C_D \rho \frac{D}{2} (w^n - v^n) |w^n - v^n| + C_M \rho \pi \frac{D^2}{4} \dot{w}^n - C_A \rho \pi \frac{D^2}{4} a^n$$

where the last term is the force in the normal direction due to the added mass. v^n and a^n are the velocity and the acceleration of the body in the normal direction and are given by

$$v^n = x \frac{d\theta}{dt} \quad \text{and} \quad a^n = x \frac{d^2 \theta}{dt^2}$$

FIGURE 36.19 Schematic of an articulated tower.

FIGURE 36.20 Free-body diagram.

If we assume that the surrounding fluid is stationary, then the normal velocity and the acceleration of the fluid (w and \dot{w}) are zeros. Thus, the moment due to the fluid force is given by

$$\begin{aligned}\int_0^L f^n x \, dx &= \int_0^L \left(-C_D \rho \frac{D}{2} x^2 \left(\frac{d\theta}{dt} \right)^2 \text{sign} \left(\frac{d\theta}{dt} \right) + C_A \rho \pi \frac{D^2}{4} x \frac{d^2 \theta}{dt^2} \right) x \, dx \\ &= -C_D \rho \frac{D}{2} \frac{L^4}{4} \left(\frac{d\theta}{dt} \right)^2 \text{sign} \left(\frac{d\theta}{dt} \right) + C_A \rho \pi \frac{D^2}{4} \frac{L^3}{3} \frac{d^2 \theta}{dt^2}\end{aligned}$$

and the equation of motion is given by

$$\left(m \frac{L^2}{3} + ML^2 + C_A \rho \pi \frac{D^2}{4} \frac{L^3}{3} \right) \frac{d^2 \theta}{dt^2} = \left(mg \frac{L}{2} + MgL - Bl_b \right) \sin \theta - C_D \rho \frac{D}{2} \frac{L^4}{4} \text{sign} \left(\frac{d\theta}{dt} \right) \left(\frac{d\theta}{dt} \right)^2$$

Note that the normal fluid drag force adds directly to the restoring moment in the case of a rigid bar. The equation of motion can be solved numerically once the initial conditions ($\theta[0]$ and $d\theta/dt[0]$) are given.

The equation of motion can be simplified if we assume that the angle of rotation θ is small. More specifically, if we assume that θ^2 is negligible when compared with 1, then we find that²

$$\sin \theta \approx \theta$$

The equation of motion can be simplified to

$$\left(m \frac{L^2}{3} + ML^2 + C_A \rho \pi \frac{D^2}{4} \frac{L^3}{3} \right) \frac{d^2 \theta}{dt^2} - \left(mg \frac{L}{2} + MgL - Bl_b \right) \theta + C_D \rho \frac{D}{2} \frac{L^4}{4} \text{sign} \left(\frac{d\theta}{dt} \right) \left(\frac{d\theta}{dt} \right)^2 = 0$$

which resembles the equation for a linear oscillator with a nonlinear damping term. Note that the system becomes unstable when the stiffness term (the coefficient of θ) becomes negative. This occurs when the buoyancy is not sufficient or

$$B < \frac{1}{l_b} \left(mg \frac{L}{2} + MgL \right)$$

36.3.3 Distribution of Significant Wave Heights — Weibull and Gumbel Distributions

The National Buoy Data Center (NBDC) run by NOAA collects ocean data such as wind, current, wave, pressure, and temperature data in various locations and the records are made public. Let us say that we are to design an articulated tower (in Section 36.3.2) in one of these locations where the data are available. The first task is to characterize the environment. Using all of the information that is collected is inefficient and impractical. Instead, we are interested in choosing a single number that can represent typical and extreme situations such as 10- and 50-year storms. For now, let us only consider random waves. We are then interested in finding the significant wave heights representing 10- and 50-year storms.

From NBDC data for a buoy outside Monterey Bay, the number of occurrences for ranges of significant wave heights is constructed in Table 36.2. The measurements were taken every hour for about 12 years. We first construct the corresponding Weibull distribution using the method described in Section 36.1.6. We first guess γ so that a pair of $\ln(-\ln\{1 - F(h)\})$ and $\ln(h - \gamma)$ form a

²This is called the small angle assumption.

TABLE 36.2 Number of Occurrences of Various Sea States

Significant Wave Height, h (m)	Number of Occurrences	Sum
< 1	2,367	2,367
1–2	46,353	48,720
2–3	3,4285	83,005
3–4	1,3181	96,186
4–5	3,813	99,999
5–6	716	100,715
6–7	145	100,860
7–8	32	100,892
8–9	8	100,900
9–10	2	100,902
Total	100,902	

straight line. Figure 36.21 shows that the pair yields nearly a straight line when $\gamma \approx 0.84$. The slope and the γ intercept of this line are 1.6 and -0.78 , respectively. The Weibull parameters are then $m = 1.6$ and $\beta = 1.6$.

Similarly, we can find the corresponding Gumbel probability density function by plotting pairs of $(h, \ln(-\ln\{F(h)\}))$ to form a line. For the data shown in Table 36.2, the line has a slope of -1.52 and γ intercept of 2.84 so that $\alpha = -1.52$ and $\beta = 1.87$.

Figure 36.22 shows the Weibull probability density and the cumulative distribution (Equation 36.17) in solid lines, the Gumbel probability density and the cumulative distribution in dotted lines (Equation 36.18), and the discrete probability density and the cumulative distribution derived from Table 36.2 in symbols.

FIGURE 36.21 Plots of $(\ln(h - \gamma), \ln[-\ln\{1 - F(h)\}])$ for various values of γ .

FIGURE 36.22 Weibull approximations of the probability density and cumulative distribution of significant wave heights measured in the outer Monterey Bay area. The symbols are the values given in Table 36.2.

TABLE 36.3 Comparison of Representative Significant Wave Heights for Long-Term Predictions from Gumbel and Weibull Distributions

	5-Year (m)	10-Year (m)	50-Year (m)
Weibull	7.84	8.15	8.79
Gumbel	8.83	9.33	10.4

The next step is to find a significant wave height that can represent an N -year storm, h_N . The probability that we will not have an N -year storm in any given year is $1 - 1/N$ and is equivalent to the probability that the significant wave height will not exceed h_N in the same year. The probability that $h < h_N$ in a single measurement is $F(h_N)$, and the probability that $h < h_N$ in every measurement taken in a year is $F(h_N)^{24 \times 365}$. Then, we have

$$1 - \frac{1}{N} = F(h_N)^{24 \times 365}$$

Table 36.3 shows significant wave heights that represent 5-, 10-, and 50-year storms obtained using the Weibull and Gumbel distributions.

The Gumbel probability distribution gives higher significant wave heights. For this particular set of data, the Weibull distribution seems to fit the data better (Figure 36.22), and the Weibull distribution is the most often used distribution in the offshore industry.

36.3.4 Reconstructing Time Series for a Given Significant Wave Height

Previously, we found significant wave heights that could represent 5-, 10-, and 25-year storms for a given site. Recall that the significant wave height can entirely characterize the Pierson–Moskowitz spectra. Once the spectral density is determined, a sample time history of the wave profile, $\eta(t)$, can be determined using either Borgman's or Shinozuka's method (Section 36.1.4). Here, Shinozuka's method is used to generate the random wave elevations.

Let us first find the random frequencies distributed according to $S_{\eta\eta}^o(\omega)/\sigma_\eta^2$. The P–M spectrum in terms of the significant wave height is given by Equation 36.8.

$$S_{\eta\eta}^o(\omega) = 0.7795\omega^{-5} \exp\left(-\frac{3.118}{H_s^2}\omega^{-4}\right)$$

The variance is given by

$$\sigma_\eta^2 = \int_0^\infty S_{\eta\eta}^o(\omega) d\omega = \frac{H_s^2}{16}$$

The probability density and the cumulative distribution functions are given by

$$f(\omega) = S_{\eta\eta}^o(\omega)/\sigma_\eta^2 = \frac{12.472}{H_s^2}\omega^{-5} \exp\left(-\frac{3.118}{H_s^2}\omega^{-4}\right), \quad F(\omega) = 1 - \exp\left(-\frac{3.118}{H_s^2}\omega^{-4}\right)$$

The inverse of the cumulative distribution function is given by

$$F^{-1}(x) = \left(-\frac{H_s^2}{3.118} \ln(1-x)\right)^{-1/4}$$

The random frequencies distributed according to $f(\omega)$ can be obtained from uniformly distributed random numbers x from 0 and 1. Table 36.4 shows uniform random numbers between

TABLE 36.4 Generation of Random Frequencies Distributed According to $f(\omega)$ from Uniform Random Numbers

Uniform Random Numbers $0 < x < 1$	Random Frequencies ω Distributed According to $f(\omega)$
0.950	$(-19.713 \ln[1 - 0.950])^{-1/4} = 0.360$
0.231	$(-19.713 \ln[1 - 0.231])^{-1/4} = 0.662$
0.606	$(-19.713 \ln[1 - 0.606])^{-1/4} = 0.483$
\vdots	\vdots

FIGURE 36.23 Wave elevation and velocities.

0 and 1 and the random frequencies distributed according to $f(\omega)$ ³. The significant wave height of 7.84 m is used.

We can obtain 100 in this way, and the wave elevation is also obtained using Equation 36.13. The random phase φ_i is obtained by multiplying uniform random numbers (different from the ones used to generate the random frequencies) by 2π .

Figure 36.23 shows the surface elevation as a function of time, the corresponding wave velocities at the water surface (Section 36.1.7) as functions of time, and the wave velocities at $t = 0$ as functions of the water depth. Note that the wave velocities decay with depth.

³The uniform random numbers can be generated by the MATLAB rand function.

36.3.5 Available Numerical Codes

Many numerical codes are available for modeling the dynamics of slender structures such as risers, tether, umbilicals, and mooring lines. The first example in this section was solved by a numerical code, WHOI Cable, developed at Woods Hole Oceanographic Institution. WHOI Cable is a time-domain program that can be used for analyzing the dynamics of towed and moored cable systems in both two and three dimensions. It takes into account bending and torsion as well as extension.

Comparative studies investigating flexible risers were carried out by ISSC Committee V7 from computer programs developed by 11 different institutions in the period between 1988 and 1991, and the results were reported by Larsen (1992). More recently, Brown and Mavrakos (1999) conducted a comparative study on the dynamic analysis of suspended wire and chain mooring lines and reported results from 15 different numerical codes. The participants included engineering consultancies, and academic and research institutions involved in marine technology. Some of the time-domain programs that were included in the comparative study are MODEX by Chalmers University of Technology, FLEXAN-C by Institut Français du Pétrole, DYWIDAG 95 by MARIN, R.FLEX by MARINTEK, CABLEDYN by National Technical University of Athens, DMOOR by Noble Denton Consultancy Services Ltd, VORCAFLEX by Orcina Ltd Consulting Engineers, ANFLEX by Petrobras SA, TDMOOR-DYN by University College London, FLEXRISER by Zentech International. Some of these programs are available to academic institutions and government laboratories at no cost.

Acknowledgments

The author wishes to express gratitude for the funding from the Woods Hole Oceanographic Institution and the Department of Mechanical Engineering at Texas Tech University.

Summary

In this chapter, the basic characteristics of sound and sound propagation are described. Levels and decibels, which represent the magnitude of sound waves, are defined and explained.

37.1 Introduction

Sound is related to vibration, and is described as a propagating perturbation through a fluid, which is air or water in most cases. A very wide variety of noise sources exists. Each source is peculiar to its generation mechanism, which may cover a wide range of phenomena including fluid mechanics and the vibration of structures. Sound is perceived by the ear of the listener as a pressure wave superimposed upon the ambient air pressure. The *sound pressure* is the incremental variation about the ambient atmospheric pressure. Generally, it is detected by a microphone and expressed as oscillatory electric signal output from an audio measurement instrument. We shall present a mathematical description of these pressure waves that are known as sound. The field of acoustics concerns sound and vibration, and is treated in Chapter 37 to [Chapter 45](#) of this book.

37.2 Sound Wave Characteristics

The characteristics of a sound wave are described by a pressure oscillation of a pure tone. A “pure tone” is a sinusoidal pressure wave of a specific frequency and amplitude, propagating at a velocity determined by the temperature and pressure of the medium (air).

Let us consider a hypothetical sound field in a duct with constant cross-sectional area, as shown in [Figure 37.1a](#). A reciprocating piston at the left end emits the sound wave and it propagates toward the right-side end along the indicated axis. It is detected by a microphone at the right end. [Figure 37.1b](#) shows the instantaneous pressure distribution in a duct at time $t = t_0$. [Figure 37.1c](#) shows the pressure variation of the time history detected by the microphone at $x = x_0$.

The wavelength, λ , is the distance between successive two peaks in the waveform in Figure 37.1b. Wavelength is related to the frequency, f , and the velocity of wave propagation, c , by

$$\lambda = \frac{c}{f} \quad (\text{ft or m}) \quad (37.1)$$

The period, T , of the sinusoidal wave is the time interval required for one complete cycle, as depicted in Figure 37.1b. The period, T , is related to the frequency, f , by

$$T = \frac{1}{f} \quad (\text{sec}) \quad (37.2)$$

37.2.1 Velocity of Sound

The velocity of sound is identical to the velocity of wave propagation, c , and in air it is given by

$$c = \sqrt{\frac{\gamma p_0}{\rho}} \quad (\text{ft/sec or m/sec}) \quad (37.3)$$

where γ denotes the ratio of specific heat, p_0 denotes the ambient or equilibrium pressure, and ρ denotes the ambient or equilibrium density. For air, γ is taken as 1.4. Equation 37.3 then becomes

$$c = \sqrt{\frac{1.4 p_0}{\rho}} \quad (\text{ft/sec or m/sec}) \quad (37.4)$$

which can be further simplified by the fact that the ratio p_0/ρ is related to the temperature of the gas. On assuming that the air behaves virtually as an ideal gas, the velocity, c , is related to the absolute temperature in degrees Kelvin (K) by

$$c = 20.05\sqrt{T} \quad (\text{m/sec}) \quad (37.5)$$

where T , the temperature in degrees Kelvin, is

$$T = 273.2^\circ + (^\circ\text{C}) \text{ K} \quad (37.6)$$

Example 37.1

Calculate the velocity of sound, c , giving the temperature of 15°C .

Solution

$$T = 273.2^\circ + 15^\circ = 288.2 \text{ K, then}$$

$$c = 20.05\sqrt{288.2} = 340.4 \text{ m/sec}$$

is obtained. This value means a typical velocity of sound in the air.

FIGURE 37.1 (a) Propagating sound wave in a duct; (b) instantaneous pressure distribution; (c) pressure variation in time history detected by a microphone at $x = x_0$.

37.3 Levels and Decibels

Sound pressure and power are commonly expressed in terms of *decibel levels*. This allows us to use a logarithmic rather than a linear scale. It provides the distinct advantage of allowing accurate computations using small numerical values, while accommodating a wide range of numerical values.

37.3.1 Sound Power Level

Sound power level describes the acoustical power radiated by a given source with respect to the international reference of 10^{-12} W. The sound power level, L_W , is defined as

$$L_W = 10 \log\left(\frac{W}{W_{re}}\right) \text{ (dB)} \quad (37.7)$$

where W denotes sound power in question and $W_{re} = 10^{-12}$ W (reference).

Example 37.2

Determine the sound power level of a small ventilation fan that generates 10 W of sound power.

Solution

$$L_W = 10 \log\left(\frac{W}{W_{re}}\right) = 10 \log\left(\frac{10}{10^{-12}}\right) = 130 \text{ dB}$$

37.3.2 Sound Pressure Level

Sound pressure levels are expressed in decibels, as are sound power levels. The sound pressure level, L_p , is defined as

$$L_p = 10 \log\left(\frac{\bar{p}^2}{p_{re}^2}\right) = 20 \log\left(\frac{\bar{p}}{p_{re}}\right) \text{ (dB)} \quad (37.8)$$

where \bar{p} denotes root-mean-square (RMS) sound pressure in question Pa or N/m² and $p_{re} = 20 \times 10^{-6}$ Pa = 0.0002 μ bar. The pressure of 20×10^{-6} Pa has been chosen as a reference because it has been found that the average young adult can perceive a 10^3 Hz tone at this pressure. This reference is often referred to as the threshold of hearing at 10^3 Hz.

Example 37.3

Giving $L_p = 50$ dB for the Aeolian tone of 200 Hz, determine the RMS pressure of the tone.

Solution

Given L_p as 50 dB, then \bar{p} is determined by using Equation 37.8.

$$50 = 20 \log\left(\frac{\bar{p}}{p_{re}}\right)$$

then

$$\begin{aligned} \bar{p} &= 10^{50/20} p_{re} = 316.2 p_{re} \\ \bar{p} &= 6.32 \times 10^{-3} \text{ Pa} = 0.0632 \mu\text{bar} \end{aligned}$$

Note that this value is very small, contradicting the magnitude of the sensory impression of the human ear.

37.3.3 Overall Sound Pressure Level

The sound pressure level is defined assuming “pure tone” sound. However, practically any real sound contains various components of pure tone sound. Let us consider a set of n components of pure tone, denoted by

$$\begin{cases} p_1(t) = a_1 \sin(2\pi f_1 t + \phi_1) \\ \vdots \\ p_n(t) = a_n \sin(2\pi f_n t + \phi_n) \end{cases} \quad (37.9)$$

$$p(t) = p_1(t) + \cdots + p_n(t) \quad (37.10)$$

If L_p of $p(t)$ is evaluated in RMS pressure, \bar{p} , we have

$$\bar{p} = \left[\lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T p^2(t) dt \right]^{1/2} = \left[\lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T (p_1(t) + \cdots + p_n(t))^2 dt \right]^{1/2} \quad (37.11)$$

Since

$$\lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T p_i(t) p_j(t) dt = 0, \quad i \neq j$$

is valid, \bar{p} is obtained as

$$\bar{p} = \left[\overline{p_1(t)^2} + \cdots + \overline{p_n(t)^2} \right]^{1/2} = \left[\bar{p}_1^2 + \cdots + \bar{p}_n^2 \right]^{1/2} \quad (37.12)$$

where

$$\bar{p}_i^2 \equiv \overline{p_i(t)^2} \equiv \lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T p_i^2(t) dt = \frac{1}{2} a_i^2 \quad (37.13)$$

Let us define $L_{pi} \equiv 10 \log(\bar{p}_i^2/p_{re}^2)$ ($i = 1, 2, \dots, n$). Then the overall sound pressure level, L_p , of $p(t)$ is expressed by

$$L_p \equiv 20 \log \frac{\bar{p}}{p_{re}} = 10 \log \frac{1}{p_{re}^2} (\bar{p}_1^2 + \cdots + \bar{p}_n^2)$$

or L_p is expressed by L_{pi} ($i = 1, 2, \dots, n$) as follows:

$$L_p = 10 \log(10^{L_{p1}/10} + 10^{L_{p2}/10} + \cdots + 10^{L_{pn}/10}) \quad (37.14)$$

Example 37.4

Determine the overall sound pressure level of the combination of three pure tones, the sound pressure levels of which are expressed by

$$L_{p1} = 60 \text{ dB } (f_1 = 250 \text{ Hz}), \quad L_{p2} = 65 \text{ dB } (f_2 = 500 \text{ Hz}), \quad L_{p3} = 55 \text{ dB } (f_3 = 1000 \text{ Hz})$$

Solution

We have $10^{L_{p1}/10} = 10^6$, $10^{L_{p2}/10} = 10^{6.5}$, and $10^{L_{p3}/10} = 10^{5.5}$. Then the overall level, L_p , is determined by using Equation 37.14 as follows:

$$\begin{aligned} L_p &= 10 \log(10^6 + 10^{0.5} \times 10^6 + 10^{-0.5} \times 10^6) \\ &= 10 \log 10^6 (1 + 10^{0.5} + 10^{-0.5}) = 60 + 10 \log 4.479 = 66.5 \text{ dB} \end{aligned}$$

Note that the sum of 65, 60 and 55 dB is just 66.5 dB.

Hearing and
Psychological Effects

S. Akishita
Ritsumeikan University

38.1 Introduction 38-1
38.2 Structure and Function of the Ear 38-1
38.3 Frequency and Loudness Response 38-2
38.4 Hearing Loss 38-4
38.5 Psychological Effects of Noise 38-4
Loudness Interpretation • Noise-Criteria Curves • Sound Level

Summary

In this chapter, first the characteristics of human hearing are discussed, including a brief description of the anatomy and function of the hearing mechanisms. Next, the frequency and loudness responses of the human hearing are explained, and then hearing loss causing permanent damage is described. Finally, the psychological response to noise is discussed by defining the indices, loudness (sones), noise-criteria curves, and sound level.

38.1 Introduction

This chapter considers the characteristics of human hearing. After a brief description of the anatomy and function of the hearing mechanism, those aspects of hearing that are important in noise control are discussed. The perception of sound by the human ear is a complicated process, dependent both on the frequency and pressure amplitude of the sound. We shall consider the structure of the ear and hearing mechanism. We will also briefly discuss various means of measuring the psychological effects of noise.

38.2 Structure and Function of the Ear [1]

The main components of the human ear are depicted in [Figure 38.1\(a\)](#). The ear is commonly divided into three main components: (1) the outer ear, (2) the middle ear, and (3) the inner ear.

The visible portion of the ear is called the *pinna*. Because of its small size compared with the primary wavelengths that we hear, the pinna serves only to produce a small enhancement of the sounds that arrive from the front of the listener as compared to those which arrive from behind; that is, the human sound reception system has a small frontal directivity. The remainder of the outer ear, which consists of the ear canal terminated in the ear drum, forms a resonant cavity at about 3 kHz. This resonant or near-resonant condition allows for a nearly reflection-free termination of the *ear canal* and thus a good impedance match of the *ear drum* to the air in which the sound wave was propagated.

The middle ear consists of three small *ear bones*, the hammer, anvil, and stirrup. The middle ear serves as an impedance transformer, which matches the low impedance of the air in which sound travels and in

FIGURE 38.1 (a) Main components of the human ear; (b) functional diagram of the ear.

which the ear drum is located to the high impedance of the lymphatic fluid of the *cochlea* beyond the *oval window*. Without this impedance-matching transformation, a mismatch would occur, resulting in a loss of approximately 30 dB.

In the inner ear, the cochlea is the main component where the actual reception of sound takes place. The schematic extended structure of the cochlea is depicted in Figure 38.1(b). The cochlea, which is located in extremely hard temporal bone, is divided almost its entire length by the *basilar membrane*. At the end of the cochlea, the two canals are connected by the *helicotrema*, which allows for the flow of the *lymphatic fluid* between the two sections. The basilar membrane, which is about 3 cm long and 0.02 cm wide, has about 24,000 nerve ends terminated in *hair cells* located on the membrane. The motion of the oval window is transmitted to the basilar membrane and its associated sensing cells. This motion is sensed as sound.

38.3 Frequency and Loudness Response

The threshold of hearing, defined for binaural listening, is that sound pressure in the free field which one can just still hear as the signal is decreased. The threshold of hearing, for what is considered normal hearing, is shown in Figure 38.2. As seen from the curve, human hearing is most sensitive in the range of 2000 to 5000 Hz; furthermore, we note that the response in this range is very close to 0 dB, or 20×10^{-6} Pa. At the other end of the scale, there is the threshold of pain, which is usually taken as about 135 to 140 dB. Thus, there is a dynamic range of normal hearing of approximately 140 dB.

FIGURE 38.2 Equal-loudness contour for free-field binaural listening.

One also readily notes from the curve of Figure 38.2 that the threshold of hearing is a function of frequency. For example, with normal hearing, one would just be able to hear a 2000-Hz tone at a 0-dB level. However, one would require a pressure level of about 15 dB to be able to barely hear a 200-Hz tone. Thus, in describing the subjective loudness of sound, it is necessary to consider the characteristics of the human ear. This concept of loudness is quantized by the loudness level.

The *loudness* level of a particular sound is determined by the subjective comparison of the loudness of the sound to that of a 1000-Hz pure tone. The level, measured in *phons*, is equal numerically to the sound pressure level, in dB, of the 1000-Hz tone, which was regarded to be of equal loudness. A set of internationally standardized equal loudness contours is plotted in Figure 38.2. In keeping with the definition of loudness level, note that at 1000-Hz, all the equal loudness contours are equal in phons to the sound pressure level in dB.

Example 38.1

Determine the sound pressure level of a 100-Hz tone with a loudness level of 30 phon.

Solution

From Figure 38.2, we find the sound pressure level to be 44 dB.

38.4 Hearing Loss

Excessive and prolonged noise exposure causes permanent hearing loss. Various theories have been put forth in an effort to characterize and predict the possible damage that might be caused by a given exposure. Absolute proof of any theory concerning such a complex biological phenomenon is virtually impossible to achieve. However, reliable data have been collected, which deal with situations where workers have been continuously exposed to more or less the same noise environment for many years.

It is well established that excessive noise exposure causes permanent hearing damage by destroying the auditory sensor cells. These cells are hair cells located on the basilar membrane. Furthermore, other types of inner ear damage include harm to the auditory neurons, as well as damage to the structure of the organ of Corti. In all, the various theories and data have been taken advantage of establishing the noise-exposure criteria set forth in the noise exposure regulations.

38.5 Psychological Effects of Noise

In this section, certain generally accepted aspects of the psychological effects of noise will be discussed and quantified. Various indexes have been proposed that quantify the psychological effects of noise. However, only a few of indices, *loudness (sones)*, *noise-criteria (NC) curve*, and *sound level*, are introduced in the following presentation.

38.5.1 Loudness Interpretation

As was discussed relating to Figure 38.2, loudness level is measured in phons, and the related quantity, loudness, is measured in *sones*. A sone is defined as the loudness of a 1000 Hz pure tone with a sound pressure level of 40 dB. On recalling the definition of loudness level, or by referring to Figure 38.2, one notes that 40 phon have a loudness equal to 1 sone. This relationship may be simply expressed as

$$S = 2^{(L_L - 40)/10} \text{ sone} \quad (38.1)$$

where S = loudness (sones), L_L = loudness level (phons), or conversely

$$L_L = 33.2 \log S + 40 \text{ phon} \quad (38.2)$$

Example 38.2

Make the following two conversions using the appropriate equation (Equation 38.1 or Equation 38.2): (1) convert 80 phon to sone, (2) convert 100 sone to phon.

Solution

1. To convert phons to sones, use Equation 38.2:

$$S = 2^{(L_L - 40)/10} = 2^{(80 - 40)/10} = 2^4 = 16 \text{ sone}$$

2. To convert sones to phons, use Equation 38.2:

$$L_L = 33.2 \log S + 40 = 33.2 \log 100 + 40 = 66.4 + 40 = 106.4 \text{ phon}$$

How should we determine the “total loudness” (sones), when the sound is composed of multiple frequency components? Probably the most widely used method for establishing the loudness of a complex noise is that developed by Stevens [2]. The method is based on the measurement of the 1-octave, 1/3-octave, or 1/2-octave band pressure levels. The measured band pressure levels are used

FIGURE 38.3 Equal loudness index contour [2].

in conjunction with the equal loudness index contours shown in Figure 38.3 to determine the loudness or loudness level by means of a simple calculation.

A step-by-step outline of the procedure is as follows:

1. Measure the band pressure levels (1-octave, 1/2-octave, or 1/3-octave) over the frequency range of interest. Usually, the range chosen is from about 50 to 10,000 Hz.
2. Enter the center frequency and band pressure level for each band in the contour of Figure 38.3, and determine the loudness index for each band.
3. Calculate the total loudness, S_t , in sones, by using

$$S_t = I_m(1 - K) + K \sum_{i=1}^n I_i \text{ (sone)} \tag{38.3}$$

where S_t = the total loudness (sones), I_m = the largest of the loudness indices, I_i = the loudness indices, including I_m , K = weighting factor for the bands chosen. $K = 0.3$ for 1-octave bands, $K = 0.2$ for 1/2-octave bands, $K = 0.15$ for 1/3-octave bands.

4. If so desired, one may calculate the loudness level in phons using Equation 38.2, or one may convert to loudness level by means of the conversion curve of [Figure 38.3](#).

Example 38.3

A particular complex noise was measured to yield the one-octave band pressure given in the following table

Center Frequency (Hz)	Band Pressure Level (dB)	Loudness Index (sone)
63	66	2.5
125	63	3.2
250	65	4.8
500	70	7.5
1000	73	10.6
2000	76	15.2
4000	81	25.1
8000	79	29.0

Compute the loudness level using the procedure described before.

Solution

As a first step, the loudness indices are determined from Figure 38.3 and recorded in tabular form with the band pressure levels. Next, we note that one-octave bands have been used. Therefore $K = 0.3$ in Equation 38.3, and

$$S_t = I_m(1 - 0.3) + 0.3 \sum_{i=1}^8 I_i$$

From the table above, we find that $I_m = 29.0$ sone and, summing up, find $\sum I_i = 97.9$ sone. Therefore,

$$S_t = 29(1 - 0.3) + 0.3(97.9) = 49.67 \text{ sone}$$

We find that the loudness, $S_t \cong 50$ sone. The loudness level may now be calculated by means of Equation 38.2 as

$$L_L = 33.2 \log S_t + 40 = 33.2 \log 50 + 40 = 96.4 \text{ phon}$$

Therefore, L_L , the loudness level, is 96 phon.

38.5.2 Noise-Criteria Curves

Noise-criteria curves, which are neglected here, were established in 1957 for rating indoor noise. The curves have been utilized as one method of rating background noise level in a room. Each curve specifies the maximum octave-band sound pressure level for a given NC rating. If the octave band levels for a given noise spectrum are known, the rating of that noise in terms of the NC curves is given by plotting the noise spectrum on the set of NC curves to determine the point of highest penetration.

In 1971, some objections to the NC curves led to their modification. The new curves, which are shown in [Figure 38.4](#), are called the *preferred noise-criteria* (PNC) curves. Although these curves differ from the NC curves, they are used in exactly the same manner.

FIGURE 38.4 1971 preferred noise-criteria curves.

Example 38.4

Determine the PNC rating for the octave-band noise spectrum tabulated below.

Center frequency (Hz)	63	125	250	500	1000	2000	4000	8000
Band pressure level (dB)	65	60	60	63	55	50	45	40

Solution

The highest penetration is found at 500 Hz on PNC-60. Hence, the answer is PNC-60.

38.5.3 Sound Level

Sound levels are sound pressure levels that have been weighted according to a particular weighting curve. Three weightings, A, B, and C, and associated sound levels, have been developed as a method to subjectively evaluate the impact of noise upon the human ear, in a proper manner. The frequency response and decibel conversions from a flat response for each of these weightings are given in [Figure 38.5](#) and [Table 38.1](#), respectively.

The A-weighting network is now used almost exclusively in measurements that relate directly to the human response to noise, both from the viewpoint of hearing damage and of annoyance. Such measurements are referred to as *sound level measurements*. Sound level is designated by **L** and the designated unit is the dBA. Similarly, dBB and dBC are used to designate sound level weighted by B weighting and C weighting networks, respectively.

FIGURE 38.5 Frequency response for the A, B, and C weighting networks.

TABLE 38.1 Sound Level Conversion Chart from Flat Response to A Weighting

Frequency (Hz)	A Weighting (dB)
50	-30.2
63	-26.2
80	-22.5
100	-19.1
125	-16.1
160	-13.4
200	-10.9
250	-8.6
315	-6.6
400	-4.8
500	-3.2
630	-1.9
800	-0.8
1,000	0
1,250	+0.6
1,600	+1.0
2,000	+1.2
2,500	+1.3
3,150	+1.2
4,000	+1.0
5,000	+0.5
6,300	-0.1
8,000	-1.1
10,000	-2.5
12,500	-4.3
16,000	-6.6

TABLE 38.2 Octave-Band Sound Pressure Levels

f_c (Hz)	L_{flat} (dB)	ΔL_A (dB)	$L_A = L_{\text{flat}} + \Delta L$ (dB)	I_{iA}
63	74	− 26.2	47.8	0.60×10^5
125	71	− 16.1	54.9	3.09
250	61	− 8.6	52.4	1.74
500	60	− 3.2	56.8	6.31
1000	62	0	62.0	1.585×10^6
2000	60	1.2	61.2	1.318
4000	62	1.0	63.0	1.995
8000	69	− 1.1	67.9	6.166
Sum				12.238×10^6

Note:

- f_c : band center frequency
- L_{flat} : sound pressure level with flat weighting
- ΔL_A : A-weighting level
- I_{iA} : sound pressure intensity with A weighting.

In noise-abatement problems, it is often necessary to convert calculated a 1-octave-band or 1/3-octave-band sound pressure level to a total sound level in dBA. Table 38.1 gives sound level conversion by A weighting from flat response pressure.

Example 38.5

Determine the total A weight sound level, L , of the set of octave-band sound pressure levels given in Table 38.2.

Solution

Refer Table 38.1 for the dB conversion from a flat response level, L_{flat} , for each of the octave bands to a sound pressure intensity with A weighting I_{iA} , and then the sum of I_{iA} . Finally, the total sound level with A weighting $L_{\text{total,A}}$ is given by

$$L_{\text{total,A}} = 10 \log \sum_{i=1}^n I_{iA} = 10 \log 12.238 \times 10^6 = 70.9 \text{ (dB)}$$

Summary

In this chapter, the basic ideas behind the development of noise control criteria and regulations are discussed, taking into consideration that the standards and criteria vary from country to country and depend on governments in power. Legislations in the European Union and regulations in Japan are introduced as typical examples. Some indexes as measures of noise evaluation are described.

39.1 Introduction

In order to protect people from being exposed to excessive noise, different communities have implemented different types of legislative control. While the controls vary in scope, control mechanisms, and technical requirements, and are based on different control philosophies, they are intended to achieve a balance between the demand for a tranquil environment and the need for maintaining economic and social activities. In general, the noise standards vary according to the time of day and the use of the land concerned, with the more stringent standards applied to rest periods and areas where the noise sensitivity is high, such as those with schools and hospitals, and exclusive residential areas. Different countries have adopted different noise standards and regulations to meet their local situations and requirements. This chapter cannot describe all major control criteria and regulations in the world, or even in the major industrialized countries. Only the main issues of legislation on noise emission and reception are briefly introduced in the chapter. More details in the on-going noise control issues are found in Refs. [2,3].

39.2 Basic Ideas behind Noise Policy

Every noise policy originates from the idea of protecting the quality of life from noise pollution of all kinds. When establishing a noise policy, it is useful to consider the distinction between noise *emission* and *immission* (or *reception*) [6]. The former means literally emitting or radiating

sound energy or power from a noise source, whereas the latter means receiving, perceiving, or observing radiated noise, which leads to the extent of the noise exposure at a position near the noise source. Therefore, noise emission is controlled with noise regulation law by the government, whereas noise immission is legislated with environmental quality standards. The measure of the extent describing the former is the “sound power level,” and that describing the latter is the sound pressure level.

The global professional organization on noise control, the International Institute of Noise Control Engineering (I-INCE) recently started its activities to develop a global noise policy [5]. In response to the question “is noise policy a global issue, or is it a local issue?” I-INCE had a common theme presented in special session. It was felt that noise is primarily a global policy issue, but many noise problems can only be solved with the active participation of local authorities. The task of the technical study group is to take a global approach to noise in order to define the requirements for an international noise control policy to be effective, stated as follows:

All vehicles, devices, machinery, and equipment that emit audible sound are manufactured products; most are entered into world trade and many are produced in two or more different countries by companies with worldwide operations. The *noise emission* of these products is an appropriate subject of international agreements and regulations. The *noise immisions* resulting from the operation of these products are growing in severity as traffic flow and the pace of industrialization continues to increase in many parts of the globe.

The technical study group reports the classification of noise areas as follows:

1. OCCUPATION NOISE — noise received at the workplace, indoors and outdoors, caused by all noise sources in the vicinity of the workplace.
2. ENVIRONMENTAL NOISE — noise perceived by individuals in the domestic environment, indoors and outdoors, caused by sources controlled by others.
3. CONSUMER PRODUCT NOISE — noise perceived by users and bystanders of noise generating products over which the individual has some control, including noise in the passenger compartment of vehicles, excluding occupational and environmental noise.

39.3 Legislation

The World Health Organization (WHO) published the historic “Guidelines for Community Noise” in 2000, which has been accepted as the most significant recommendations for noise exposure criteria. The bodies that are responsible for enacting the regulations as law include the Federal Government in the USA, the European Union (EU) in Europe, and the Japanese Government in Japan. In the following, the EU’s legislation on noise immission is shown, as an example of the flow of legislation process [8].

On July 18th, 2002, a European Directive on the assessment and management of environmental noise was published in the *Official Journal of European Communities*. It was required to be implemented in the national legislation of the EU Member States no later than July 18th, 2004. From then on, a program was to start, containing periodic noise mapping, the making of action plans, and information of the public. The directive also has strengthened the position of the European Commission regarding the reduction of noise emission.

In 2002, the development of the European Directive on environmental noise resulted in an approved directive relating to the assessment and management of environmental noise, for which the acronym “DAMEN” is used. According to Article 1 of the DAMEN its objective is to “define a common approach to avoid, prevent or reduce harmful effects, including annoyance, due to exposure to environmental noise.” A rough description of actions in the DAMEN is shown in [Figure 39.1](#). Brief notes are given next to supplement Figure 39.1.

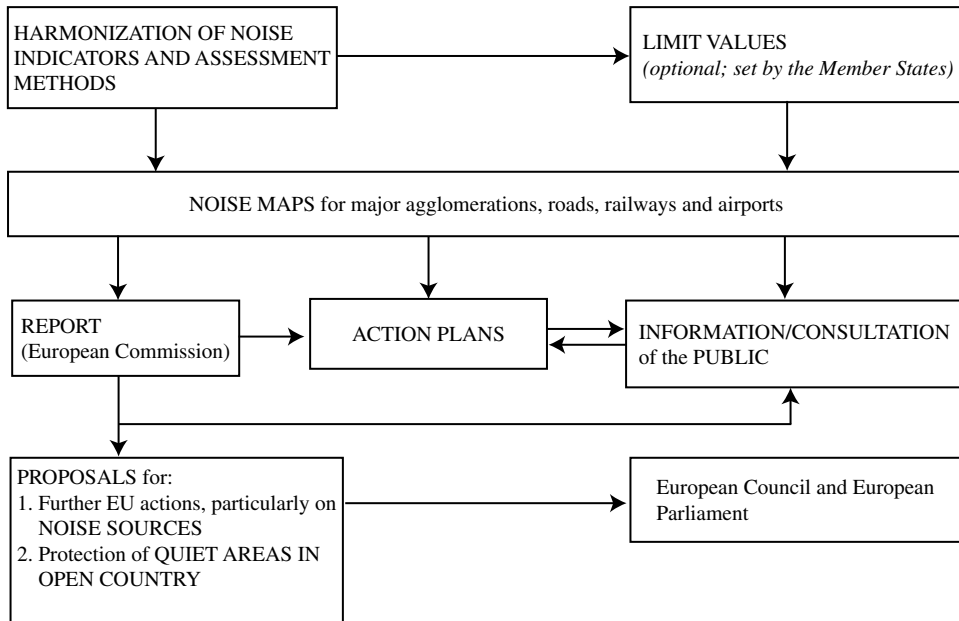

FIGURE 39.1 Overview of the DAMEN. (Source: Wolde, T.T. 2003. The European Union's legislation on noise immission, pp. 4367–4371. In *Proceedings of Inter-noise 2003* (N832). With permission.)

39.3.1 Action Plans

In a case where the mapping results are such that they violate the local or national limit value, or are found unsatisfactory for other reasons, action plans shall be developed for the improvement of the situation. These action plans shall be discussed with the citizens involved. A summary of the action plans shall be sent to the European Commission.

39.3.2 Publication of Data by the European Commission

Every five years, starting in 2009, the Commission shall publish a summary report from the noise maps and the action plans.

39.3.3 Proposal for Further European Union Action

In 2004, the European Commission was to submit a report to the European Parliament and the Council containing a review of existing EU measures relating to sources of environmental noise and present proposals for improvement, if appropriate. In 2009, the European Commission will submit to the European Parliament and the Council a report on the implementation of the directive. That report will in particular assess the need for further EU action and, if appropriate, propose implementing strategies on aspects such as:

- Long-term and medium-term goals for the reduction of the number of persons harmfully affected by environmental noise
- Additional measures on noise emission by specific sources
- The protection of quiet areas on the open country

39.4 Regulation

Noise regulation is executed by local governments once the central government enacts a noise regulation law. The law is considered the “national minimum.” For example, factory noise, construction work noise, and road traffic noise are under the purview of the Noise Control Act, which means the central government is responsible of regulating these kinds of noise. On the other hand, community noise and factory noise are under the purview of the original regulation of local governments. It can be said that local governments are responsible for a great part of the noise policy, although they may not always fully understand the situations concerned. In what follows, an outline of the legal system for environmental noise problem in Japan is given as an example of a typical legal system for noise regulation [6].

In Japan, the “Environmental Quality Standards for Noise” was revised in 1999 after 27 years with the old law. Figure 39.2 outlines of the legal system in Japan.

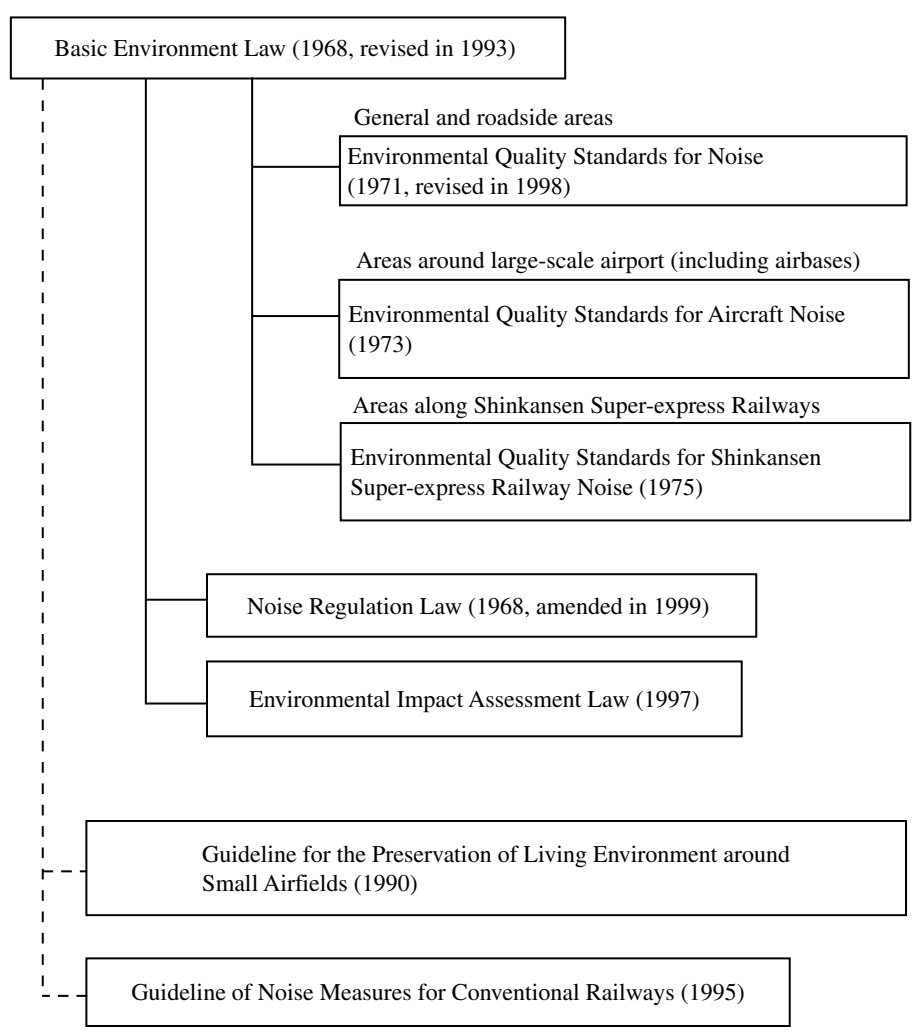

FIGURE 39.2 Legal system for environmental noise in Japan. (Source: Tachibana, H. and Kaku, J. 2003. Acoustic measures for the environmental noise assessment in Japan, pp. 3317–3322. In *Proceedings of Inter-noise 2003* (N1007). With permission.)

Each of these laws and standards is legislated for a specific noise problem (a noise source), and therefore different noise indices are specified according to the respective noise problems. To review this situation from a historical viewpoint, it can be said that each law or standard responds to a specific noise problem promptly, through the use of available measurement technology at that time. However, some laws and standards have become outdated since their establishment, when considering the current situation, international dynamics, and the current acoustic measurement technology.

39.5 Measures of Noise Evaluation

Basically, the A weighting networks are applied to obtain a measure of noise evaluation. As the measures are legislated by governments, they are dependent on the legislative regulations and standards. In what follows, the measure of noise evaluation legislated in Japan is given to show the concepts behind the legislation [6].

In the regulations and standards for environmental noise problems, a variety of noise measures are used. In order to improve these legislative regulations and standards in the future, the present measures shall be reviewed considering the difference between noise emission and immission and the difference between noise measurement and monitoring, and impact assessment and prediction. These measures legislated in Japan are listed and classified in Table 39.1 by considering the difference between noise characteristics.

TABLE 39.1 Assessment Methods Specified in Laws and Standards for Environmental Noises in Japan

Noise Sources	Law and Standards	Noise Indices	Assessment Time
Roads	Environmental Quality Standards for Noise	$L_{Aeq,T}^a$	Daytime (6:00–22:00); nighttime (22:00–6:00)
Shinkansen superexpress railways	Environmental Quality Standards for Shinkansen Superexpress Railways	$L_{A,Smax}^b$	Every event
Conventional railways	Guideline of Noise Measures for Conventional Railways	$L_{Aeq,T}$	Daytime (7:00–22:00); nighttime (22:00–7:00)
Aircrafts	Environmental Quality Standards for Aircrafts Noise	WECPNL ^c	Time weighting
	Guideline for the Preservation of Living Environment around Small Airfields	L_{den}^d	
Construction works	Noise Regulation Law (specific noise sources)	According to time variation:	Not specified; every event
Factories			
Large-scale retail stores	Law concerning the measures by large scale retail stores for preservation of living environment	L_A^e ; $L_{A,Fmax}^f$; L_{A5}^g ; $L_{A,Fmax,5}^h$	

^a $L_{Aeq,T}$ equivalent continuous A-weighted sound pressure level.

^b $L_{A,Smax}$ SLOW maximum value of A-weighted sound pressure level.

^c WECPNL, weighted equivalent continuous perceived noise level(calculated from $L_{A,Smax}$).

^d L_{den} , day/evening/night equivalent continuous A-weighted sound pressure level.

^e L_A , FAST maximum value of A-weighted sound pressure level.

^f $L_{A,Fmax}$, A-weighted sound pressure level.

^g L_{A5} , upper value of the 90% range of A-weighted sound pressure level.

^h $L_{A,Fmax,5}$, upper value of the 90% range of the FAST maximum Aweighted sound pressure level.

Source: Tachibana, H. and Kaku, J. 2003. Acoustic measures for the environmental noise assessment in Japan, pp. 3317–3322. In *Proceedings of Inter-noise 2003* (N1007). With permission.

When considering the consistency between noise measurement and monitoring, and noise prediction for impact assessment, it is most reasonable to use energy based indices such as L_{Aeq} . Of course, L_{Aeq} is not a panacea and some secondary adjustment may be needed for the exact assessment of environmental noise with different characteristics. Nevertheless, the possibility of unification by L_{Aeq} should be considered in the near future in Japan. Although L_{Aeq} is now being widely used for the assessment of aircraft noise in almost all countries, WECPNL is still being used in Japan. WECPNL is very close to L_{Aeq} in concept and it is not difficult to change the assessment index from WECPNL to L_{Aeq} .

The aim of the laws and standards shown in Figure 39.2 is to measure and assess the environmental noise for prevention or maintenance of the present situation. Therefore, any noise index should be appropriately used for each of noise problems, as shown in Table 39.1, which presents assessment methods specified in laws and standards for environmental noise in Japan. In particular, when predicting the future noise situation in environmental impact assessments, the indices should be suitable for theoretical calculation. The statistical noise indices such as the percentile level (L_{A5}) and maximum level ($L_{A,Fmax}$ or $L_{A,Smax}$) specified in the laws and standards have to be predicted statistically. It is difficult to predict these quantities by a simple physical calculation model, in principle. In this respect, the energy-based noise indices such as L_{Aeq} can be easily treated in energy based calculation, and the prediction model becomes simple and clear in physical meaning. In an environmental impact assessment, the predicted results are to be compared with the related laws or standards. In the case of road traffic noise, L_{Aeq} has been adopted in the new environmental quality standards, and therefore prediction has become very simple in theory, founded on energy-based indices.

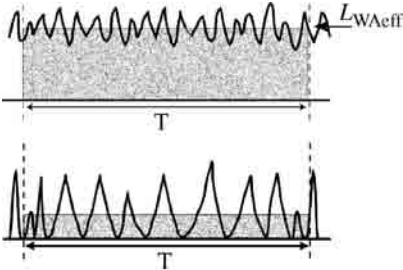

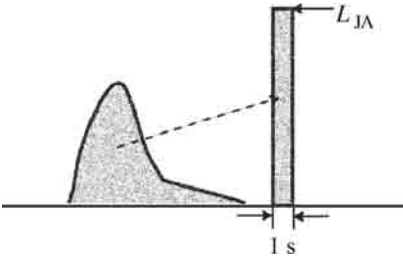

In the prediction of road traffic noise, a motor vehicle as the noise source can be treated as a stationary sound sources of a constant sound power for a limited path. On the other hand, in the case of predicting construction noise, there are many complicated problems because various kinds of machines and equipment with various temporal variations of characteristics must be treated. Therefore, in the construction noise prediction method given in the "Acoustic Society of Japan CN-model 2002" [7], various noise indices for describing the acoustic output of various types of noise sources are specified as given in Table 39.2, which presents classification of noise sources and indices for expressing their acoustic output. Finally, Table 39.3 presents definitions and indices of measurement for acoustical output of noise sources.

TABLE 39.2 Classification of Noise Sources and Indices for Expressing Their Acoustic Output

Temporal Variation	Indices for Expressing Acoustic Output Sign	Terms
Stationary	L_{WA} $L_A(r_0)$	A-weighted sound power level A-weighted sound power level at the reference distance ($r_0 = 1$ m)
Fluctuating randomly and widely	L_{WAeff} $L_{Aeff}(r_0)$ $L_{A,Fmax,5}(r_0)$	Effective A-weighted sound power level Effective A-weighted sound pressure level at the reference distance ($r_0 = 1$ m) 5% value of A-weighted sound pressure level at the reference distance ($r_0 = 1$ m)
Intermittent impulsive	L_{IA} L_{WAeff} $L_{AE}(r_0)$ $L_{A,Fmax}(r_0)$	A-weighted sound energy level Effective A-weighted sound power level Single event sound exposure level at the reference distance ($r_0 = 1$ m) FAST max. of A-weighted sound pressure level at the reference distance ($r_0 = 1$ m)

Summary

This chapter describes some measuring methods for the identification and ranking of noise source that are of benefit in noise control projects. Sound intensity measurement and directional measuring devices such as the mirror–microphone system and microphone array are introduced and their principles and applications are described.

40.1 Sound Intensity Measurement

Every noise control project starts with the identification and ranking of the noise sources. Several methods have been proposed for the purpose and have proved to be useful and widely utilized. In this chapter, sound intensity measurement and directional measuring devices such as the mirror–microphone system and microphone array are introduced and their principles and applications are described. Other useful measurements, such as acoustic holography method [1,2] and spatial transformation of sound fields [3], are described in the literature.

40.1.1 Theoretical Background

Sound intensity is a measure of the magnitude and direction of the flow of sound energy. The instantaneous intensity vector, $\mathbf{I}(t)$, is given by the product of the instantaneous sound pressure, $p(t)$, and the corresponding particle velocity, $\mathbf{u}(t)$, that is, $\mathbf{I}(t) = p(t)\mathbf{u}(t)$.

In practice, the time-averaged intensity, $\bar{\mathbf{I}}$, is more important, and is given by the equation:

$$\bar{\mathbf{I}} = \lim_{T \rightarrow \infty} \frac{1}{T} \int_{-T/2}^{T/2} p(t)\mathbf{u}(t)dt \quad (40.1)$$

The intensity vector denotes the net rate of flow of energy per unit area (watts/m²). Thus, the acoustic power, W , of the source located in a closed surface, S , is given by the integral of the intensity passing through the surface, S , as

$$W = \int_S \bar{\mathbf{I}} \cdot d\mathbf{S} \quad (40.2)$$

Equation 40.2 indicates that the measurement of sound intensity over a surface enclosing a source enables the estimation of its sound power, which shows the usefulness of the sound intensity concept.

40.1.2 Measurement Method

The principle of intensity measurement systems in commercial production employs two closely spaced pressure microphones [4,5], as shown in Figure 40.1.

The particle velocity, $u_r(t)$, in a particular direction, r , can be approximated by integrating over time the difference of sound pressures at two points separated by a distance Δr in that direction:

$$u_r(t) = -\frac{1}{\rho_0} \int_{-\infty}^t \frac{p_2(\tau) - p_1(\tau)}{\Delta r} d\tau \quad (40.3)$$

where p_1 and p_2 are the sound pressure signals from the two microphones. The sound pressure at the center of two microphones is approximated by

$$p(t) = \frac{p_1(t) + p_2(t)}{2} \quad (40.4)$$

Thus, the intensity in the direction r can be calculated as

$$I_r(t) = -\frac{1}{2\rho_0\Delta r} [p_1(t) + p_2(t)] \int_{-\infty}^t [p_2(\tau) - p_1(\tau)] d\tau \quad (40.5)$$

Some commercial intensity analyzers use Equation 40.5 to measure the intensity. Another type of analyzer uses the equation in the frequency domain:

$$I_r(\omega) = -\frac{\text{Im}[G_{12}]}{\omega\rho_0\Delta r} \quad (40.6)$$

where G_{12} is the cross spectrum between the two microphone signals. Equation 40.6 makes it possible to calculate sound intensity with a dual-channel fast fourier transform (FFT) analyzer.

40.1.3 Errors in Measurement of Sound Intensity

The principal systematic error of the two-microphone method is due to the approximation of the pressure gradient by a finite pressure difference. When the incident sound is a plane wave, the ratio of the measured intensity, \hat{I}_r , and the true intensity, I_r , is given by

$$\hat{I}_r/I_r = \frac{\sin(k\Delta r \cos \theta)}{k\Delta r \cos \theta} \quad (40.7)$$

where the angle θ is as defined in Figure 40.1 and k is the wave number. Equation 40.7 indicates that the upper frequency limit is inversely proportional to the distance between the microphones.

Another serious error is caused by the phase mismatch between the two measurement channels. In the calculation of intensity from Equation 40.5, the phase difference, φ , between the two microphone signals, p_1 and p_2 , is very important. Hence, the phase mismatch between the two measurement channels, $\Delta\varphi$, must be much smaller than φ . Since φ increases with frequency, this error is serious in lower frequencies. Other possible errors, such as in the sensitivity of microphones and random errors associated with a given finite averaging time, are usually less serious.

FIGURE 40.1 Microphone arrangement used to measure sound intensity.

40.1.4 Applications

One important application of sound intensity measurement is the determination of the sound power level using Equation 40.2. Furthermore, measurement of the intensity in the very near field of a source surface makes it possible to identify and rank the noise-sources. Plots of the sound intensity measured on a surface near a sound source are useful for investigating noise source distributions. Figure 40.2 shows sound intensity of noise from a wheel of a railway car. An intensity probe is located in the vicinity of the wheel and the normal component of sound intensity is measured by traversing the probe on a plane 100 mm away from the side surface of the wheel. These figures show a free vibration behavior of the wheel at each frequency; the wheel vibrates with one nodal diameter at 700 Hz and with three nodal diameters at 1150 Hz. Visualization by intensity vectors also gives valuable information about a noise source. Figure 40.3 shows the sound intensity vectors at each octave band measured in the vicinity of a railway car running at 120 km/h. These results suggest that the main radiator of rolling noise is the rail at the 500 Hz to 1 kHz band and the wheels at the 2 to 4 kHz band.

FIGURE 40.3 Sound intensity vectors measured in the vicinity of a railway car running at 120 km/h.

40.2 Mirror–Microphone System

40.2.1 Principle of Measurement

A mirror–microphone system consists of a reflector of elliptic or parabolic shape and an omnidirectional microphone located at its focus [6,7]. Figure 40.4 shows the layout of a reflector of elliptic shape, an omnidirectional microphone, and a noise source. Here, S and S' denote the front and back surfaces of the mirror, respectively; $P(\mathbf{r})$ denotes the pressure field on this configuration; $P_i(\mathbf{r})$ denotes the pressure field of free space; \mathbf{r}_m is the position of the microphone; \mathbf{r} is a point on the mirror surface. The normal, \mathbf{n}_0 , directs toward the medium.

Using Green's theorem, the pressure at the microphone position $P(\mathbf{r}_m)$ is obtained by

$$P(\mathbf{r}_m) = P_i(\mathbf{r}_m) + \iint_{(s+s')} P(\mathbf{r}) \frac{\partial}{\partial \mathbf{n}_0} \times \left[\frac{e^{ikR_m}}{4\pi R_m} \right] d^2\mathbf{r} \quad (40.8)$$

where $k = 2\pi f/c_0$ is the wave number, f is the frequency of sound, c_0 is the speed of sound, and $R_m = |\mathbf{r} - \mathbf{r}_m|$ is the distance between the microphone and the mirror surface. If the wavelength is sufficiently smaller than the diameter of the reflector, the pressure field $P(\mathbf{r})$ is approximated by $2P_i(\mathbf{r})$ on the front surface, S , and by zero on the back surface, S' . In such a frequency range, the incident field term $P_i(\mathbf{r}_m)$ can be ignored. With these approximations, assuming that the noise source is a monopole type point source located at a position, \mathbf{r}_s , Equation 40.8 reduces to

$$P(\mathbf{r}_m) = -\frac{m(f)}{8\pi^2} \iint_s \frac{e^{ik(R_m+R_s)}}{R_m R_s} \left(ik - \frac{1}{R_m} \right) \times \cos \theta(\mathbf{r}) d^2\mathbf{r} \quad (40.9)$$

Here, $m(f)$ is the amplitude of the mass-flux rate of the source, $R_s = |\mathbf{r} - \mathbf{r}_s|$ is the distance between the sound source and the mirror surface and the angle $\theta(\mathbf{r})$ is defined in Figure 40.4. When the noise source is located at the far focus of the mirror, the sound pass length $R_m + R_s$ is constant with respect to \mathbf{r} , and a strong signal is obtained. As the noise source is moved away in the direction perpendicular to the mirror axis, the variance of the sound pass length, $R_m + R_s$, due to the position \mathbf{r} increases, and thus the microphone signal drops off due to interference (see Figure 40.5, which we call the “directivity pattern”). The ratio of the peak level to the free field level at the microphone, G , is referred to as the “gain factor.” The spatial resolution of the mirror is characterized by the displacement of the mirror position, w , at which the microphone signal drops off by a given relative amount, such as 3 dB. The quantities G and w

FIGURE 40.4 Layout of a reflector, microphone, and noise source.

FIGURE 40.5 Directivity pattern of a mirror–microphone system.

can be related to the mirror geometries in Figure 40.4 by

$$G \approx 10 \log(CD^4/\lambda^2 B^2) \quad (C = \text{const.}) \quad (40.10)$$

$$w \propto \lambda L/D \quad (40.11)$$

The gain factor, G , increases with frequency at the rate of 6 dB per octave, and the spatial resolution, w , is inversely proportional to the frequency. The lower frequency limit is decided by the size of the mirror. On the other hand, there is no higher frequency limit, except for the capacity of an omnidirectional microphone itself. Thus, measurements with the mirror–microphone system are more suited to a scaled model test.

40.2.2 Applications

The mirror–microphone system has proved useful for identification of a noise source because of its directional property [8–10]. A scan of the source region produces a noise source map. It has an advantage in that the measurement is possible at a far field and it needs only one sensor, but has a disadvantage in that the measuring process is a time-consuming task.

Figure 40.6 shows an example of source maps of aerodynamic noise generated by a one-fifth scale high-speed train model, obtained from measurements by a mirror–microphone system, in a wind tunnel test. The surface of the car model is divided into several noise-source areas and the noise-source distribution in each area is measured by traversing the mirror–microphone system over the surface. The diameter and focal distance of the reflector are 1.7 and 3 m, respectively. Detailed maps of noise-source strength are obtained, which show that aerodynamic noise from high-speed trains is generated in relatively localized areas, namely, the local surface structures. The mirror–microphone system can be used for the measurement of the source distribution of a moving noise source. Figure 40.7 gives a time

FIGURE 40.6 Noise-source distribution of a one-fifth scale Shinkansen car model in a wind tunnel test measured with an elliptic mirror–microphone system.

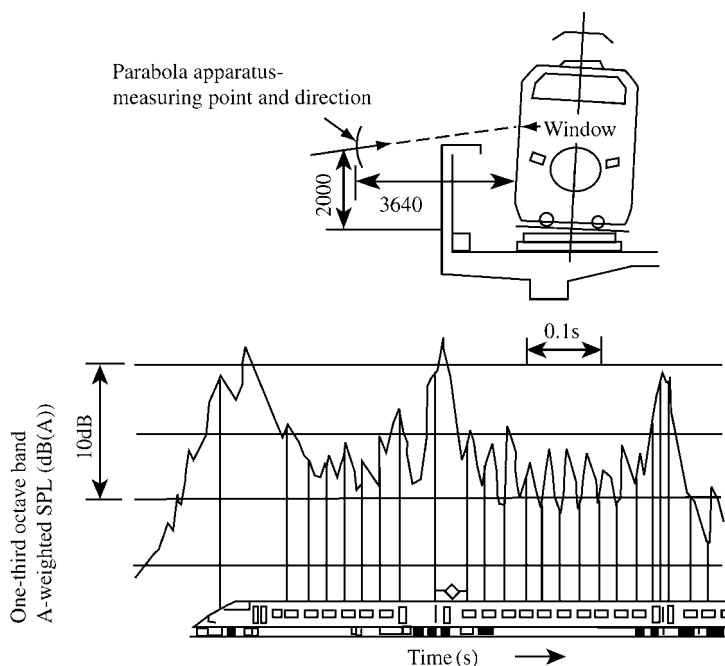

FIGURE 40.7 Time history of the A-weighted one-third octave band ($f_0 = 8$ kHz) sound pressure level measured with a parabolic mirror–microphone system ($D = 1$ m, train speed = 274 km/h).

history of noise from a high-speed train measured with a parabolic mirror–microphone system, the diameter of which is 1 m. Peaks of the time history correspond to pantographs, doors, gaps between cars and the step-up of windows, which shows that they are main noise sources.

40.3 Microphone Array

40.3.1 Principle of Microphone Array

A microphone array [11] consists of several microphones distributed spatially to measure an acoustic field. The time signals from each microphone are added, accounting for the time delay between sound sources and microphones, and a directional output signal can be obtained as a result. The algorithm is called “beamforming.” Now, consider M omnidirectional microphones distributed in a far field of noise sources. The output signal of the array focused to a particular location in the source region, \mathbf{r} , and $z(\mathbf{r}, t)$, is calculated as a sum of delayed and weighted signals of each microphone:

$$z(\mathbf{r}, t) = \sum_{m=1}^M w_m p_m(t - \Delta_m) \quad (40.12)$$

Here, $p_m(t)$ is the signal from the m th microphone, w_m is a weighting factor, and Δ_m is a time delay applied to signal of the m th microphone, as given by

$$\Delta_m = \frac{r_o - r_m}{c_0} \quad (40.13)$$

where r_o and r_m are the distances from the focus point to the reference point o and the m th microphone, respectively. When the focus location coincides with the source location, a strong signal is obtained (see Figure 40.8). If this process is repeated for various focus locations, \mathbf{r} , on the source surface, then a noise-source map can be obtained.

FIGURE 40.8 Principle of a microphone array. Individual time delays are chosen such that signals arriving from a given point will be added up coherently.

40.3.2 Array's Directivity Pattern

The performance of a microphone array is characterized by the spatial resolution and signal-to-noise ratio. For simplicity, consider a linear array of $M = 2N + 1$ microphones spaced equally by d . When a harmonic plane wave is propagating with an incident angle θ , and weighting factors all equal $1/M$, the ratio of the output signal of the array to that of the center microphone is computed using

$$W(\theta) = \frac{1}{M} \frac{\sin((M/2)kd \sin \theta)}{\sin((1/2)kd \sin \theta)} \quad (40.14)$$

where k is the wave number. Figure 40.9 shows the directivity patterns for different values of the product kd based on Equation 40.14. The highest peak appears at $\theta = 0$, which we call a "main lobe," and lower peaks also appear at some locations that are separate from a true source direction, which we call "side lobes." The width of the main lobe decides the performance of the array to separate two closely lying sources (which we call spatial resolution), and the ratio of main lobe to side lobe decides the signal-to-noise ratio of the array. The spatial resolution improves as kd increases, that is, in proportion to the ratio of the array length to the wavelength. However, when $kd = 2\pi$, a peak of the same strength as the true source appears due to a spatial aliasing at $\theta = 90^\circ$, which occurs when $d > \lambda/2$, where λ is the wavelength. Thus, the acoustic frequency, f , is restricted by $f < c_0/2d$, to avoid aliasing.

FIGURE 40.9 Directivity patterns of a linear array for different values of the product kd ($M = 2N + 1 = 9$).

FIGURE 40.10 Time history of sound pressure level for a passing train measured with a linear microphone array located at a point 25 m away from a track (train velocity = 285 km/h).

In the above case of the linear array, the directivity exists only in the direction of the array (one-dimensional). If microphones are arranged in a two-dimensional plane, a two-dimensional directivity can be obtained. Recently, many microphone arrangements have been proposed that obtain better spatial resolution and to reduce side lobes [12–15].

40.3.3 Applications

Microphone arrays have been used for identification of the noise source in various situations, for example, in wind tunnel tests. Many actual examples can be found in published literature [10,16–18]. The measurement with a microphone array has the advantage of much shorter measuring time than that of a mirror–microphone system. Furthermore, the lower frequency limit is not so serious because the size of the apparatus can be easily extended.

Another fundamental example is given now. Nine microphones are arranged equally spaced by $d = \lambda/2$ for each one-third octave band, and their signals are summed without time delay. In this case, the array is focused to a fixed direction, perpendicular to the array axis. Figure 40.10 shows a time history of noise generated by a high-speed train, measured with a linear microphone array located at a point 25 m away from the track. It is found that pantographs, the leading car, and gaps between cars are the main noise sources in this example.

41.1	Introduction	41-1
41.2	Radiation of Sound	41-1
	Point Source • Sources of Finite Volume • Radiation from a Plane Surface • Estimation of Noise-Source Sound Power	

Summary

In this chapter, a mathematical description of sound radiation is briefly presented accompanied by an introduction to sound sources, monopole, and dipole. The modeling of a simple source of noise is discussed, introducing Green's function. As an example of simple sound radiation, the sound field generated by a source embedded in a plane surface is described. Finally, an estimation of noise-source sound power is presented by introducing the power conversion factor of actual machinery.

41.1 Introduction

A careful examination of noise measurement data reveals that there exists a very wide variety of noise sources. Each source is peculiar to its generation mechanism, which can be any of a wide range of phenomena including fluid mechanics and the vibration of structures. However, in analysis, sources are normally simplified to rather simple and typical models in their generation mechanism.

The vibration of a solid body, which may be in contact with the fluid medium, generates sound waves or vibratory forces acting directly on a fluid, will result in the emission of acoustic energy in the medium. In the next section, an expression for an idealized sound source is introduced. We will assume that the fluid medium outside the source region is initially uniform and at rest. Also, we will concentrate on wave propagation in an infinite medium.

Generally, acoustic waves sensed as a sound represent a very small energy density in the medium. Only a very small fraction of the mechanical energy of a source body is converted into acoustic energy. The conversion factor, defined as the ratio of sound power to the mechanical power of the source, is in the order of 10^{-7} to 10^{-5} . Some examples of estimated sound power conversion factor are given for typical common noise sources.

41.2 Radiation of Sound

41.2.1 Point Source

41.2.1.1 Simple Source: Spherical Wave by a Monopole

Propagation of sound pressure wave $p(x, y, z, t)$ is described by the following partial differential equation for a medium where a field point is expressed by orthogonal coordinate system O -xyz, as shown

in Figure 41.1(a):

$$\nabla^2 p - \frac{1}{c^2} \frac{\partial^2 p}{\partial t^2} = 0, \quad (41.1)$$

$$\nabla^2 \equiv \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \right)$$

where c denotes the velocity of sound propagation. If the source region is compact and the generating motion has no preferred direction, it will produce a wave, which spreads spherically outwards. As the medium is assumed infinite in extent, the waveform will depend on the distance, r , from the center of the source. The wave equation in this case is

$$\frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial p}{\partial r} \right) - \frac{1}{c^2} \frac{\partial^2 p}{\partial t^2} = 0 \quad (41.2)$$

When a monopole source of angular frequency ω is assumed, the simplest solution for the outward propagating waveform is expressed as

$$p(r, t) = p_\omega(\mathbf{r}) e^{-i\omega t},$$

$$p_\omega(\mathbf{r}) = \frac{-\omega \rho}{4\pi r} S_\omega e^{ikr}, \quad k = \frac{\omega}{c} = \frac{2\pi}{\lambda} \quad (41.3)$$

where ρ denotes the density of the medium and k denotes the wave number. Here, p_ω is used to denote the sinusoidal component of the sound pressure with angular frequency, ω . The subscript ω on a variable typically indicates the sinusoidal component of a variable, but the variables related to sound energy and sound power, such as w , I , W , do not have the subscript ω even if they mean the sinusoidal component. In this case, the source of sound is taken as a “pulsating globe” of radius a and radial velocity U_ω on the surface. Therefore, the flow outward from the origin, S_ω , is related to U_ω as follows, and as shown in Figure 41.1(a):

$$S_\omega = 4\pi a^2 U_\omega \quad (41.4)$$

We should note that, while a pulsating globe with a finite radius a is assumed as the physical sound source, the sound field by a monopole with infinitesimal small size and finite magnitude, as expressed mathematically in Equation 41.3, is used.

The other quantities related to the spherical wave are described next [1]:

$$\left\{ \begin{array}{ll} u_{r\omega} = \frac{-1}{4\pi r^2} (ikr - 1) S_\omega e^{ik(r-ct)}; & \text{radial velocity} \\ w = \rho \left(\frac{1}{4\pi r^2} \right)^2 |S_\omega|^2 \left[(kr)^2 + \frac{1}{2} \right]; & \text{energy density} \\ I = \rho c \left(\frac{k}{4\pi r} \right)^2 |S_\omega|^2 = \frac{|p|^2}{\rho c}; & \text{energy flux intensity} \\ W = (4\pi r^2) I = \rho c \frac{\pi}{\lambda^2} |S_\omega|^2 = \frac{\rho \omega^2}{4\pi c} |S_\omega|^2; & \text{total power} \end{array} \right. \quad (41.5)$$

FIGURE 41.1 Directivity of monopole and dipole, (a) Spherical sound field by a monopole; (b) Axis-symmetric sound field by a dipole.

We should note that the first term in the parentheses, kr , is negligible in the region where $|kr| \ll 1$ is valid. Hence,

$$w = \frac{\rho}{2} (|S_\omega|/4\pi r^2)^2 = \frac{\rho}{2} u_{r\omega}^2 = \left(\frac{\lambda}{\omega}\right) \frac{I}{4\pi r^2}$$

is reduced. Conversely, when $|kr| \gg 1$ is valid, then $w = \rho(k/4\pi r)^2 |S_\omega|^2 = I/c$ is valid.

41.2.1.2 Simple Source: Plane Wave by an Alternating Piston

Another example of simple sound wave is generated in the one-dimensional field of fluid medium, as shown in Figure 41.1. Let us set the coordinate x along the axis of wave propagation, for example, the axis of duct with a constant cross-sectional area. Then the wave equation is

$$\frac{\partial^2 p}{\partial x^2} - \frac{1}{c^2} \frac{\partial^2 p}{\partial t^2} = 0 \quad (41.6)$$

The solution for a periodic source is given by

$$p(x, t) = p_\omega(x) e^{-i\omega t}, \quad p_\omega(x) = \rho c u_\omega e^{ikx} \quad (41.7)$$

This is known as a *plane wave*, which is generated by the piston motion at the origin, the velocity of which is expressed by

$$u(t) = u_\omega(x) e^{-i\omega t} \quad (41.8)$$

The other quantities related with the plane wave are given below:

$$\begin{cases} u_\omega(x) = u_\omega e^{ikx}, & \text{particle velocity} \\ w = I = \rho c |u_\omega|^2 = |p_\omega|^2 / \rho c^2; & \text{energy density, sound intensity} \\ W = SI \text{ (S; cross-sectional area);} & \text{total power} \end{cases} \quad (41.9)$$

A plane wave is generated in very limited situations, but its utility is rather wide since the sound wave propagating through a duct or duct-like space with a gradually varying cross section is approximated as the plane wave. Network theory is applied to the sound wave propagating through a branch and junction by using the description of a plane wave.

41.2.1.3 Dipole and Multipoles and Their Sound Field

Let us return to the three-dimensional sound field. The second simple solution to Equation 41.1 is the “dipole” sound field. Suppose that a pair of monopoles, close together, opposite in sign, and equal in magnitude, S_ω , are located along the x -axis as shown in Figure 41.1(b). Since only a preferred direction is assigned along the x -axis, the sound field is axisymmetric as represented by

$$p(r, \theta, t) = -k^2 D_\omega \frac{\rho c \cos \theta}{4\pi r} \left(1 + \frac{i}{kr}\right) e^{-i(\omega t - kr)} \quad (41.10)$$

D_ω is defined by

$$D_\omega = S_\omega d \quad (41.11)$$

where d denotes the separation of the monopoles as shown in Figure 41.1(b). Mathematically, d tends to zero, keeping D_ω finite, and the preferred axis is the x -axis. Physically, a sound field is commonly realized by a pair of monopoles with a finite separation that is short compared with the wavelength, λ , as illustrated next with realistic examples.

The characteristic quantities relating with dipole sound field are described below [1]:

$$\left\{ \begin{array}{ll} u_{r\omega} = -\frac{k^2 D_\omega \cos \theta}{4\pi r} \left(1 + \frac{2i}{kr} - \frac{2}{k^2 r^2}\right) e^{-i\omega t + kr}; & \text{radial velocity} \\ u_{\theta\omega} = i\frac{k^2 D_\omega \sin \theta}{4\pi r^2} \left(1 + \frac{i}{kr}\right) e^{-i\omega t + kr}; & \text{peripheral velocity} \\ w = \rho \left(\frac{k^2 |D_\omega|}{4\pi r}\right)^2 \left[\cos^2 \theta + \frac{1}{2} \left(\frac{1}{kr}\right)^2 + \frac{1}{2} \left(\frac{1}{kr}\right)^4 (1 + 3 \cos^2 \theta) \right]; & \text{energy density} \\ I_r = \rho c \left(\frac{k^2 |D_\omega|}{4\pi r}\right)^2 \cos^2 \theta, \quad I_\theta = 0; & \text{sound intensity} \\ W = \frac{\rho \omega^4}{12\pi c^3} |D_\omega|^2; & \text{total power} \end{array} \right. \quad (41.12)$$

We should add the following notes on the dipole sound field.

When $|kr| \gg 1$ is assumed, the second term in parentheses in Equation 41.10 is negligible. Then the directivity for $p(r, \theta, t)$ is expressed by $\cos \theta$. A similar directivity is found on I_r and on $u_{r\omega}$, $u_{\theta\omega}$, and w with the assumption $|kr| \gg 1$.

A pair of dipoles produces a *quadrupole*, a pair of quadrupoles produce an *octopole*, and so on. These are called *multipole* in general. Out of multipoles, the quadrupole is common in representing a sound field generated by mixing fluid flow, especially jet flow. More details on multipoles are found in Ref. [1].

41.2.2 Sources of Finite Volume

41.2.2.1 Description of Sound Field by Green's Function

In order to describe the sound field from distributed sources, source terms are introduced to the right side of Equation 41.1. The partial differential equation with source term is derived from the equation system representing the dynamics of fluid flow with periodic motion at angular frequency ω :

$$\nabla^2 p_\omega + k^2 p_\omega = -m_\omega + \text{div } \mathbf{F}_\omega \quad (41.13)$$

where p_ω denotes the acoustic pressure amplitude according to $p(x, y, z, t) = p_\omega(x, y, z)e^{-i\omega t}$, m_ω denotes the effective monopole source density expressed by $-i\omega \rho s_\omega$, s_ω denotes the generalization of the point source strength, S_ω , of Equation 41.4 for a distributed source, and \mathbf{F}_ω denotes the vector representation of point force-density in the fluid. Introduction of Green's function, g_ω , of angular frequency, ω , satisfying the following equation is useful in general:

$$\nabla^2 g_\omega + k^2 g_\omega = -\delta(x - x_0)\delta(y - y_0)\delta(z - z_0)e^{i\omega t_0} \quad (41.14)$$

Here, $\delta(z)$ denotes the Dirac impulse (delta) function of the variable z ; the coordinate (x_0, y_0, z_0) denotes the position of unit source, r_0 , with periodic angular velocity, ω , and t_0 denotes the time pertaining to the source. The solution of Equation 41.14 is

$$g_\omega(\mathbf{r}, \mathbf{r}_0) = \frac{1}{4\pi R} e^{ikr}, \quad |\mathbf{r} - \mathbf{r}_0| = \sqrt{(x - x_0)^2 + (y - y_0)^2 + (z - z_0)^2} \quad (41.15)$$

where \mathbf{r} denotes the position vector of sound field with coordinates (x, y, z) . The solution of Equation 41.13 is described by using $g_\omega(\mathbf{r}, \mathbf{r}_0)$ as follows:

$$p_\omega(\mathbf{r}) = \iiint [m_\omega(\mathbf{r}_0) - \text{div } \mathbf{F}_\omega(\mathbf{r}_0)] g_\omega(\mathbf{r}, \mathbf{r}_0) dx_0 dy_0 dz_0 \quad (41.16)$$

FIGURE 41.2 Practical monopole sources.

41.2.2.2 Radiation from Vibrating Small Body

A pulsating globe, as the simplest sound source, is rarely realized in the real world. The approximated monopole source required in most measurements is an eight-sided polyhedron, as depicted in Figure 41.2, where a loud speaker is installed on each of the surfaces. The sound field radiated by a thus approximated source is almost the same as that by a pulsating globe at the far field, where $kr \gg 1$ is valid.

In this case, the sound field is represented by Equation 41.16, assuming that $F_\omega(\mathbf{r}_0) = 0$, $m_\omega(\mathbf{r}_0) = -i\omega\rho U_\omega \delta(n)$, and $dx_0 dy_0 dz_0 = dn dS$, where the source $m_\omega(\mathbf{r}_0)$ is distributed on a thin layer of thickness, dn , on the spherical surface element, dS . Substitution of these relationships into Equation 41.16 yields the formula

$$\begin{aligned} p_\omega(\mathbf{r}) &= - \iint_S \frac{i\omega\rho U_\omega}{4\pi R} e^{ikR} dS \\ &= - \frac{i\omega\rho}{4\pi R_0} (4\pi a^2) U_\omega e^{ikR_0} \quad (41.17) \end{aligned}$$

where $\iint_S dS$ means integration on the approximately spherical surface, and then $R \equiv |\mathbf{r} - \mathbf{r}_0| \cong R_0 = \sqrt{x^2 + y^2 + z^2}$ is applied. The final reduction of Equation 41.17 gives the same expression as is deduced from Equation 41.3 and Equation 41.4.

The sound field generated by a monopole source is illustrated in Figure 41.1. This field is unchanged with the presence of a rigid plane AB in Figure 41.3. It is clear, on account of symmetry, that the presence of the rigid plane does not alter the sound field in any way, because only the tangential component of particle velocity is induced on the plane. This utilization of the symmetry and construction of the semi-infinite field is applied to the expression of the sound field generated by the baffled structure, as shown in Figure 41.4.

Let us imagine a sound field generated by an oscillating small body in an infinite medium, as shown in Figure 41.4(a). Since the oscillation is caused by an external force, the sound source is modeled by the force $-\mathbf{F}_\omega(\mathbf{r}_0)$. Therefore, the sound field is described by Equation 41.16, assuming $m_\omega(\mathbf{r}_0) = 0$. After applying a law of vector analysis, such as $g_\omega(\mathbf{r}, \mathbf{r}_0) \text{div } \mathbf{F}_\omega(\mathbf{r}_0) \cdot \text{grad}_0 g_\omega + \text{div}_0(g_\omega \mathbf{F}_\omega)$, the sound field is

FIGURE 41.3 Field of a pulsating spherical source.

FIGURE 41.4 Dipole field generated by an oscillating small body: (a) oscillating small body; (b) oscillating sphere along x -axis.

represented by

$$p_{\omega}(\mathbf{r}) = \iiint \mathbf{F}_{\omega}(\mathbf{r}_0) \cdot \nabla_0 g_{\omega}(\mathbf{r}, \mathbf{r}_0) dx_0 dy_0 dz_0 \quad (41.18)$$

where $\iiint \text{div}_0(g_{\omega} \mathbf{F}_{\omega}) dx_0 dy_0 dz_0 = \iint_S g_{\omega} \mathbf{F}_{\omega} dS_n(x_0, y_0, z_0) = 0$ is applied. Assume that a small sphere of radius a_0 is oscillating along the x -axis with angular frequency ω . Instead of an oscillating sphere with velocity $U_t = U_{\omega} e^{-i\omega t}$, the sound field is generated by the concentrated body force, $F(t) = -m(d/dt)U(t) = i\omega m U_{\omega} e^{-i\omega t}$, (m is the mass of the sphere), at the origin, $\mathbf{r}_0 = 0$. Then $\mathbf{F}_{\omega}(\mathbf{r}_0)$ is expressed by $F_{\omega}(\mathbf{r}_0) = (F_{x\omega} \mathbf{i}) \delta(x_0) \delta(y_0) \delta(z_0)$; $F_{x\omega} = i\omega m U_{\omega}$. This approximate reduction is appropriate when $ka_0 \ll 1$ is valid. Substituting the approximation, Equation 41.18 is rewritten as

$$p_{\omega}(\mathbf{r}) \cong F_{x\omega} \frac{\partial}{\partial x_0} g_{\omega}(\mathbf{r}, \mathbf{r}_0, \theta) = -k^2 D_{\omega} \frac{\rho c}{4\pi r} \cos \theta \left(1 + \frac{i}{kr}\right) e^{ikr} \quad (41.19a)$$

$$D_{\omega} = \frac{i}{k\rho c} F_{\omega x} \quad (41.19b)$$

As the sound field is axisymmetric about x -axis, the sound pressure, $p_{\omega}(\mathbf{r}, \theta)$, depends only on \mathbf{r} and θ , where \mathbf{r} and θ are defined in Figure 41.4(b). The expression is applicable to the sound field generated by an oscillating small body in a free space.

41.2.3 Radiation from a Plane Surface

41.2.3.1 Radiation from a Small Body in Infinite Plane Surface

The introduction of an infinite rigid plane surface to the sound field, as shown in Figure 41.3, simplifies the formulation of the sound field generated by an oscillating body adjacent to a large plane.

The configuration discussed in this section relates to a source in the presence of an infinite plane barrier, so that the medium is confined to one side of the plane.

By taking the effect of the image caused by the rigid plane surface, the Green's function, $g_\omega(\mathbf{r}, \mathbf{r}_0)$, in this case simplifies as given below, to what is called Rayleigh's formula [2]:

$$g_\omega(\mathbf{r}, \mathbf{r}_0) = \frac{1}{2\pi R} e^{ikr}, \quad R = |\mathbf{r} - \mathbf{r}_0| \quad (41.20)$$

where \mathbf{r}_0 denotes the projection position of the source on the surface. Therefore, Equation 41.16 is rewritten as follows:

$$p_\omega(\mathbf{r}) = \iint \int \frac{e^{ikR}}{2\pi R} [m_\omega(\mathbf{r}_0) - \text{div } \mathbf{F}_\omega(\mathbf{r}_0)] dx_0 dy_0 dz_0 \quad (41.21)$$

41.2.3.2 Radiation from a Circular Piston

Let us consider the sound field generated by a rigid circular piston of radius a mounted flush with the surface of an infinite baffle and vibrating with simple harmonic motion of angular frequency, ω . The solution of this example is applicable to a number of related problems, including the radiation from the open end of a flanged organ pipe.

The coordinate system is shown in Figure 41.5, where the infinite baffle and the piston are placed in the Oxy -plane. Note that the observation point, P , is denoted by $\mathbf{r} = \overrightarrow{OP}$, while the source point, Q , is denoted by $\mathbf{r}_0 = \overrightarrow{OQ}$.

Since sound is observed only in the semi-infinite plane where $z > 0$ is valid, only $m_\omega(\mathbf{r}_0)$ remains nonzero in Equation 41.21. As the velocity of the piston is denoted by $U_\omega e^{-i\omega t}$ along the z -axis, $m_\omega(\mathbf{r}_0) = -i\omega\rho U_\omega \delta(z_0)$, is distributed only on the circular piston. Finally, Equation 41.21 is rewritten as

$$p_\omega(\mathbf{r}) = \frac{-i\omega\rho U_\omega}{2\pi} \iint_S \frac{e^{ikR}}{R} dx_0 dy_0 \quad (41.22)$$

FIGURE 41.5 The rigid circular piston and the coordinate system.

Assuming $a \ll r$, the following approximation can be made:

$$R \cong r - (x_0 \cos \varphi + y_0 \sin \varphi) \sin \theta, \quad (41.23)$$

$$\frac{1}{R} \cong \frac{1}{r}$$

where φ and θ denote the angles defining the observation point, P , as shown in Figure 41.5. By changing from Cartesian coordinates, x_0, y_0 , to polar coordinates, ρ, φ_0 , such that $x_0 = \rho \cos \varphi_0$, $y_0 = \rho \sin \varphi_0$ in the integral above, we rewrite Equation 41.22 as

$$p_\omega(\mathbf{r}) = -\frac{i\omega\rho U_\omega}{2\pi R} e^{ikr} \int_0^{2\pi} d\varphi_0 \times \int_0^a \exp[-k\rho \cos(\varphi_0 - \varphi) \sin \theta] \rho d\rho \quad (41.24)$$

The integration is performed by introducing the Bessel function of the first order, $J_1(z)$ as follows:

$$p_\omega(\mathbf{r}) = -\frac{i\omega\rho e^{ikr}}{2\pi r} f_\omega(\theta), \quad (41.25)$$

$$f_\omega(\theta) = \pi a^2 U_\omega \left[\frac{2J_1(ka \sin \theta)}{ka \sin \theta} \right]$$

Note that dependency on φ has disappeared in the integration process, which follows from the axisymmetry of the sound field. The corresponding intensity at \mathbf{r} is given by

$$I_r(\theta) \cong \frac{|p_\omega|^2}{\rho c} = \frac{\rho c U_\omega^2 a^2}{4r^2} (ka)^2 \left[\frac{2J_1(ka \sin \theta)}{ka \sin \theta} \right]^2 \quad (41.26)$$

Figure 41.6 illustrates the dependency of I_r on θ for two cases of ka . Note that, for the smaller $ka = 2\pi a/\lambda$, I_r is almost independent on θ , which is similar to the dependence of the monopole.

41.2.3.3 Radiation from a Rectangular Plate

An normal velocity distribution, $u_\omega(x_0, y_0)$, is prescribed over a baffled planar radiator located in the plane $z_0 = 0$ in the region $-L_x \leq x_0 \leq L_x, -L_y \leq y_0 \leq L_y$, as shown in Figure 41.7.

In this case, the sound pressure field is represented by the following equation, similar to the previous section:

$$p_\omega(\mathbf{r}) = \frac{-i\omega\rho}{2\pi} \int_{-L_y}^{L_y} dy_0 \int_{-L_x}^{L_x} \frac{U_\omega(x_0, y_0) e^{ikR}}{R} dx_0 \quad (41.27)$$

Assuming $2L_x, 2L_y \ll r$, the same approximation in as Equation 41.23 is acceptable. Therefore, $p_\omega(\mathbf{r}) = p_\omega(r, \theta, \phi)$ takes the form [2]:

$$p_\omega(r, \theta, \phi) = \frac{-i\omega\rho e^{ikr}}{2\pi r} \int_{-L_y}^{L_y} dy_0 \int_{-L_x}^{L_x} U_\omega(x_0, y_0) \exp[-ik \sin \theta (x_0 \cos \phi + y_0 \sin \phi)] dx_0 \quad (41.28)$$

The result of the above integration, assuming $U_\omega(x_0, y_0) = U_\omega = \text{const}$, which means the rigid rectangular piston oscillates with amplitude U_ω along the z -axis, is

$$p_\omega(r, \theta, \phi) = \frac{i\omega\rho U_\omega}{2\pi r} (4L_x L_y) e^{ikr} S(kL_x \sin \theta \cos \phi) S(kL_y \sin \theta \sin \phi) \quad (41.29a)$$

FIGURE 41.6 Directivity of sound intensity generated by an oscillating piston.

FIGURE 41.7 A flexural rectangular plate and the coordinate system.

where the function $S(z)$ is defined by

$$S(z) = \frac{\sin z}{z} \quad (41.29b)$$

Now, let us discuss the case of flexural plate, which has the same lengths, $2L_x$ and $2L_y$, but $U_\omega(x_0, y_0)$ represents the flexural vibration mode. Flexural mode patterns of rectangular panels take the general form of contiguous regions of roughly equal area and shape, which vary alternately in vibration phase, and are separated by nodal lines of zero vibration.

For simply supported edges, the normal vibration velocity distribution is (see Chapter 4)

$$U_\omega(x_0, y_0) = U_{mn} \sin\left(\frac{m\pi x}{2L_x}\right) \sin\left(\frac{n\pi y}{2L_y}\right), \quad (0 \leq x \leq 2L_x, 0 \leq y \leq 2L_y) \quad (41.30)$$

Note that the coordinate system $O-x_0y_0z_0$ shifts its origin from the center point of the panel to the edge at the leftmost and frontmost point in Figure 41.7.

The approximation represented by Equation 41.23 is valid as well in this case. The result of integration is rather simple as given below [3]:

$$p_\omega(r, \theta, \phi) = \frac{-i\omega\rho U_{mn} e^{kr}}{2\pi r} \frac{4L_x L_y}{mn\pi^2} \left[\frac{(-1)^m e^{i\alpha} - 1}{(\alpha/m\pi)^2 - 1} \right] \left[\frac{(-1)^n e^{i\beta} - 1}{(\beta/n\pi)^2 - 1} \right] \quad (41.31)$$

where α and β are defined by

$$\alpha = 2kL_x \sin \theta \cos \phi, \quad \beta = 2kL_y \sin \theta \sin \phi \quad (41.32)$$

The corresponding intensity, $I_r(\theta, \phi)$, at \mathbf{r} is expressed by

$$I_r(r, \theta, \phi) = \frac{|p_\omega|^2}{\rho c} = 4\rho c |U_{mn}|^2 \left(\frac{4kL_x L_y}{\pi^3 r mn} \right)^2 \left\{ \frac{\cos\left(\frac{\alpha}{2}\right) \cos\left(\frac{\beta}{2}\right)}{[(\alpha/m\pi)^2 - 1][(\beta/n\pi)^2 - 1]} \right\} \quad (41.33)$$

where $\cos(\alpha/2)$ is used when m is an odd integer, and $\sin(\beta/2)$ is used when m is an even integer; $\cos(\beta/2)$ is used for even n and $\sin(\beta/2)$ for odd n .

41.2.4 Estimation of Noise-Source Sound Power

41.2.4.1 Power Conversion Factor of Machinery

It is often necessary to estimate the expected sound power that a particular machine might introduce into an environment [4]. One way where such an estimate may be approached for a particular class of machine is by means of the sound power conversion factor, η_n . This factor is defined as

$$\eta_n = \frac{P}{P_m}$$
 (41.34)

where P = sound power of the machine (W), and P_m = power of the machine (W). This relationship is valid for both mechanical and electrical machinery. The conversion factors for some common noise sources are given in Table 41.1.

Example 41.1

Estimate the sound power level of a typical 1-kW electric motor that operates at 1200 rpm.

Solution

From Table 41.1, we find that for typical electric motors, $\eta_n = 1 \times 10^{-7}$. Thus, using Equation 41.34, we obtain

$$P = \eta_n P_m = (1 \times 10^{-7}) \times 1000 = 10^{-4} \text{ (W)}$$

as the total sound power of motor. Then using Equation 37.7, L_W is given by

$$L_W = 10 \log \left(\frac{10^{-4}}{10^{-12}} \right) = 80 \text{ (dB)}$$

41.2.4.2 Fan Noise

We are familiar with noise nuisance caused by a domestic ventilating fan. The mechanical power of the fan is expressed by

$$P_m = p_T Q$$
 (41.35)

where p_T denotes the total pressure rise through the fan and Q denotes the volumetric flow rate. According to the law of sixth power of flow velocity deduced by the aeroacoustics theory, sound power of the fan is proportional to $p_T^{2.5} Q$. Therefore, the specific ratio k_T defined below is more useful than η_n for the fan:

$$k_T = \frac{P_m}{p_T^{2.5} Q}$$
 (41.36)

TABLE 41.1 Estimated Sound Power Conversion Factors for Common Noise Sources^a

Noise Source	Conversion Factor		
	Low	Midrange	High
Compressor, air (1–100 hp)	3×10^{-7}	5.3×10^{-7}	1×10^{-6}
Gear trains	1.5×10^{-8}	5×10^{-7}	1.5×10^{-6}
Loud speakers	3×10^{-2}	5×10^{-2}	1×10^{-1}
Motors, diesel	2×10^{-7}	5×10^{-7}	2.5×10^{-6}
Motors, electric (1200 rpm)	1×10^{-8}	1×10^{-7}	3×10^{-7}
Pumps, over 1600 rpm	3.5×10^{-6}	1.4×10^{-5}	5×10^{-5}
Pumps, under 1600 rpm	1.1×10^{-6}	4.4×10^{-6}	1.6×10^{-5}
Turbines, gas	2×10^{-6}	5×10^{-6}	5×10^{-5}

^a Total sound power for the four octave bands from 500 to 4000 Hz.
Source: Irwin, J. D. and Graf, E. R. 1979. *Industrial Noise and Vibration Control*, Prentice Hall, Englewood Cliffs, NJ.

TABLE 41.2 Specific Fan Noise Level for Low-Pressure Fans

Type	K_T (dB)
Axial	− 87.5 to − 70.7
Centrifugal/cirroco	− 87.5 to − 85.7
Centrifugal/radial	− 98.7 to − 84.7
Centrifugal/turbo	− 104.7 to − 89.7
Cross-flow	− 76.7 to − 68.7

Furthermore, usually the specific fan noise level, K_T , as given below is more useful than k_T .

$$K_T = L_W - 10 \log(p_{T^{2.5}} Q) \text{dB} \quad (41.37)$$

where p_T denotes the total pressure rise in mmAg, Q denotes the flow rate in m^3/min , L_W denotes the total sound power level in dB, and K_T represents the radiation efficiency of the fan noise. This efficiency varies with the type of the fan and with the flow rate when the model is assigned. In particular, K_T will be the lowest at the flow rate at which the aerodynamic power efficiency is the highest. Therefore, we will have the best advantage on the sound environment when the fan is operated at the highest efficiency. For convenience of design, the L_W is often evaluated by A-weighted total sound level (dB-A) not by linear total level (dB). Table 41.2 gives the specific fan noise level evaluated with dB-A for five types of the low-pressure fans.

Example 41.2

Consider a ventilating axial-flow fan, the specifications of which are: $p_T = 10$ mmAg, $Q = 30$ m^3/min , $D = 30$ cm (diameter of the duct containing fan rotor). Estimate the directional distribution of intensity $I_r(\theta)$, assuming $r = 3$ m and $f = 150$ Hz for the main component of the fan noise, and $K_T = -79.0$ dB-A from Table 41.2. The fan noise is assumed to be radiated as a plane sound wave at the mouth of the duct.

Solution

First, we modify the K_T in dB-A to that of linear scale. From the frequency response for A-weighting network shown in Figure 2.5, for $f = 150$ Hz, the modification is found as $\Delta K_T = 15$ dB. Then, the modified specific fan noise level is $K_T = -79.0 + 15.0 = -64.0$ dB. By using Equation 41.37, $L_W = K_T + 25 \log p_T + 10 \log Q = -64 + 25 + 15 = -24$ dB is obtained. This means the emitted total sound power is $W = 10^{-24/10} = 3.98 \times 10^{-3}$ W. Since we assume a plane sound wave at the mouth of the duct for the fan noise, we can use the sound radiation model of a circular piston with $a = 15$ cm for the radiated sound wave. In our case $k_a = 2\pi a/(c/f) = 0.415$, or $\lambda/a = 15.1$. A monopole model will be valid for the directional distribution of intensity from Figure 41.6. Therefore, $I_r = W/2\pi r^2 = 0.704 \times 10^{-4}$ W/m² or $|p|^2 = I_r \rho c = 2.92 \times 10^{-2}$ (Pa²). This is the same as the sound pressure level $L_p = 10 \log |p|^2 / p_{\text{ref}}^2 = 78.6$ dB or $L_p(A) = L_p - 15 = 63.6$ dB-A.

Summary

This chapter presents the basics of designing devices for sound absorption. The absorption coefficient and acoustic impedance are introduced. Characteristic properties and parameters of sound absorption material and basic elements are presented. Acoustic modeling, analysis, and design considerations of components, such as ducts, and noise attenuation devices, such as mufflers, are presented. A practical design example is presented for illustration of the concepts presented in the chapter.

42.1 Introduction

Sound-absorption equipment is used for multiple purposes in architectural acoustics, mechanical noise countermeasures, and so on. In this context, the necessity for designing sound-absorption equipment from the viewpoint of noise control is explained. Architectural acoustics is an important area of study, which involves architecture, sound-absorption design, and sound-measurement facility.

In the area of noise reduction, the characteristics of sound are important, and proper sound-absorbing material should be selected based on how much attenuation is necessary for each frequency of sound. In particular, acoustic characteristics of sound-absorbing material such as the type of material and the

sound-absorption mechanism are important. In this chapter, the basics of sound absorption are given, and the prediction and calculation methods for attenuation of lined or dissipative mufflers are outlined.

42.2 Fundamentals of Sound Absorption

42.2.1 Attenuation of Sound

When an acoustic wave propagates in a medium, the sound energy attenuates due to such reasons as viscosity, heat conduction, and the effects of molecular absorption. In a medium of small volume surrounded by a boundary surface, the attenuation is particularly considerable, for example, when the medium is a thin tube. This is because there is the dissipation of the energy controlled by the viscosity of the medium and heat conduction between the material and the medium of tube wall. A sound-absorbing material may be utilized to adjust such dissipation of acoustic energy.

42.2.1.1 Absorption Coefficient and Normal Acoustic Impedance

Some amount of energy is lost when an acoustic wave hits the surface of a sound-absorbing material. Figure 42.1 illustrates an infinite medium of absorbing material separated by air and the reflected wave (sound pressure p_r) from the boundary surface with the air where a plane wave of sound pressure p_i is emitted in the direction indicated by an arrow, at an angle θ . When $\theta = 0$, sound pressure p in air is given by

$$p = p_i + p_r = (Ae^{-jkx} + Be^{jkx})e^{j\omega t} \quad (42.1)$$

where

A, B = the amplitude of sound pressure of incident and reflected waves (in Pa),

$j = \sqrt{-1}$,

$k = 2\pi f/c$; wave number (1/m),

ω = angular frequency (rad/sec).

The sound pressure, p_m , in the absorbing material may be expressed using a complex propagation constant, by the equation:

$$p_m = p_{x=0} e^{-\gamma x} e^{j\omega t} \quad (42.2)$$

where

γ = the propagation constant in the absorbing material (m^{-1}). *Note:* $\gamma = \delta + j\beta$. γ is a property of the material itself and is not dependent on the mounting conditions when large areas of material are considered.

δ = attenuation constant. *Note:* δ tells us how much of the sound wave will be reduced as it travels through the material.

β = phase constant. *Note:* β is a measure of the velocity of propagation of the sound wave through the material.

The relation for determining the velocity of sound in the material is given by

$$c_m = \omega/\beta \quad (42.3)$$

FIGURE 42.1 Plane wave incidence on an infinite absorbing material.

Boundary conditions must be satisfied on the boundary surface. The acoustic impedance of a unit area of air and of absorbing material are, respectively, denoted by z and z_a . The pressure and the particle velocity on both sides of the boundary are equal. We have

$$\left. \begin{aligned} p_i + p_r &= p_{x=0} \\ \frac{p_i - p_r}{z_a} &= \frac{p_{x=0}}{z} \end{aligned} \right\} \quad (42.4)$$

The amplitude of reflectance of sound pressure, r , is obtained from Equation 42.4, and is given by

$$r = \frac{p_r}{p_i} = \frac{z_a - z}{z_a + z} \quad (42.5)$$

The reflectivity is the energy reflection rate. The absorption coefficient, α , of an absorbing material is defined as

$$\alpha = 1 - |r|^2 \quad (42.6)$$

The impedance, z_n , through a surface is the quantity that represents the dissipation of energy of sound as well as the absorption coefficient. It is given as a ratio between sound pressure and particle velocity on boundary surface in the reflecting acoustic wave:

$$z_n = \left(\frac{p}{u} \right)_{x=0} = \left(\frac{\rho c}{\cos \theta} \right) \frac{p_i + p_r}{p_i - p_r} \quad (42.7)$$

Note that z_n is a complex quantity and involves both amplitude and phase, both of which depend on the sound pressure at the boundary surface in the reflecting acoustic wave.

In the case of oblique incidence, the surface impedance can be expressed by following equation:

$$z_n = Z \gamma z / q \quad (42.8)$$

where z = the acoustic impedance (Pa sec/m³). Here,

$$Z = \frac{z_1 \cosh(ql) + (\gamma z/q) \sinh(ql)}{z_1 \sinh(ql) + (\gamma z/q) \cosh(ql)}$$

$$q = \sqrt{\gamma^2 + k^2 \sin^2 \theta}$$

The absorption coefficient, $\alpha(\theta)$, for an oblique incidence with angle θ may be expressed by

$$\alpha(\theta) = 1 - \left| \frac{z_n \cos \theta - \rho c}{z_n \cos \theta + \rho c} \right|^2 \quad (42.9)$$

42.3 Sound-Absorbing Materials

42.3.1 Porous Material

Porous acoustical materials are a special category of a more general class of gas–solid mixtures. They range from porous solids, for example, porous rocks, fibrous granular solids, expanded plastics, and form materials, to porous or turbid gases, for example, suspensions and emulsions. Sound is attenuated in a gas-saturated porous solid due to the restriction on the gas movement within it. A convenient microstructure model for such materials is one of a rigid solid matrix through which run cylindrical, capillary pores (tubing) with constant radius, normal to its surface. This model enables the use of Kirchoff's theory of sound propagation in narrow tubes with rigid walls. Accordingly, this mechanism of dissipation may be identified as (1) a viscous loss in the boundary layer at the wall of each capillary tube

associated with the relative motion between the viscous gas and the solid wall, or (2) heat conduction between compressions and rarefactions of the gas and the conducting solid walls.

42.3.2 Tubular Material

Consider the absorption of low-frequency sound using the tubular absorbing material. By itself, sound absorption is not satisfactory with the tubular absorbing material. The material produces bending vibration due to an acoustic wave through it, and sound absorption occurs by the internal friction of the material. For hard plywood and gypsum boards, there is a natural frequency in the range 100 to 200 Hz, and the absorption coefficient ranges from 0.3 to 0.5. It is possible to increase the absorption coefficient by coating the board surface with fibrous absorbing material.

42.3.3 Membrane Material

For membrane material, the sound-absorption mechanism makes use of resonant vibration. Hence, resonant frequency is a governing parameter. The imaginary part (the reactance term) of the acoustic impedance of a membrane gives rise to a resonance. The associated natural frequency is given by

$$f_r = \frac{1}{2} \left\{ \frac{1}{m} \left(\frac{1.4 \times 10^5}{L} \right) + K_m \right\} \quad (42.10)$$

where

f_r = natural frequency (Hz)

m = surface density (kg/m^2)

L = thickness of air space (m)

K_m = board rigidity ($\text{kg/m}^2 \text{sec}^2$)

The K_m values of some boards are shown in Figure 42.2. The absorption coefficient is approximately 0.3 to 0.4 in the frequency range of 300 to 1000 Hz, when the thickness of the air space between the membrane and the rigid wall behind it is 50 to 100 mm.

42.3.4 Perforated Plate

A perforated board of sound absorbing material (i.e., a board with holes) is placed over a rigid wall at a fixed clearance, as shown in Figure 42.3. The sound-absorption characteristics depend on the board thickness, t , the hole diameter of the perforations, d , the clearance, L , between the perforated board and the rigid wall, and so on. The absorption coefficient becomes a maximum at resonant frequency. In the present case, the resonant frequency is given by

$$f_r = \frac{c}{2\pi} \sqrt{\frac{\varepsilon}{(t + 0.8d)L}} \quad (42.11)$$

where sound speed is c , the airspace thickness is L (typically, 300 mm or less), and the ratio of the total area of holes to the total area of the board is ε . The absorption coefficient is approximately 0.3 to 0.4.

42.3.5 Acoustic Resonator

Yet another method of achieving sound absorption is using an acoustic resonator of Helmholtz type, which consists of a vessel of any shape containing a volume air, as shown in Figure 42.4. The air volume is in direct communication with the ambient air in the room through an interconnecting tube, which may be long or short and of any cross-sectional shape. An example of a resonator of Helmholtz type may be a 1 gal jar. When a sound wave impinges on the aperture of neck of the jar, the air in the neck will be set in oscillation, periodically expanding and compressing the air in the vessel.

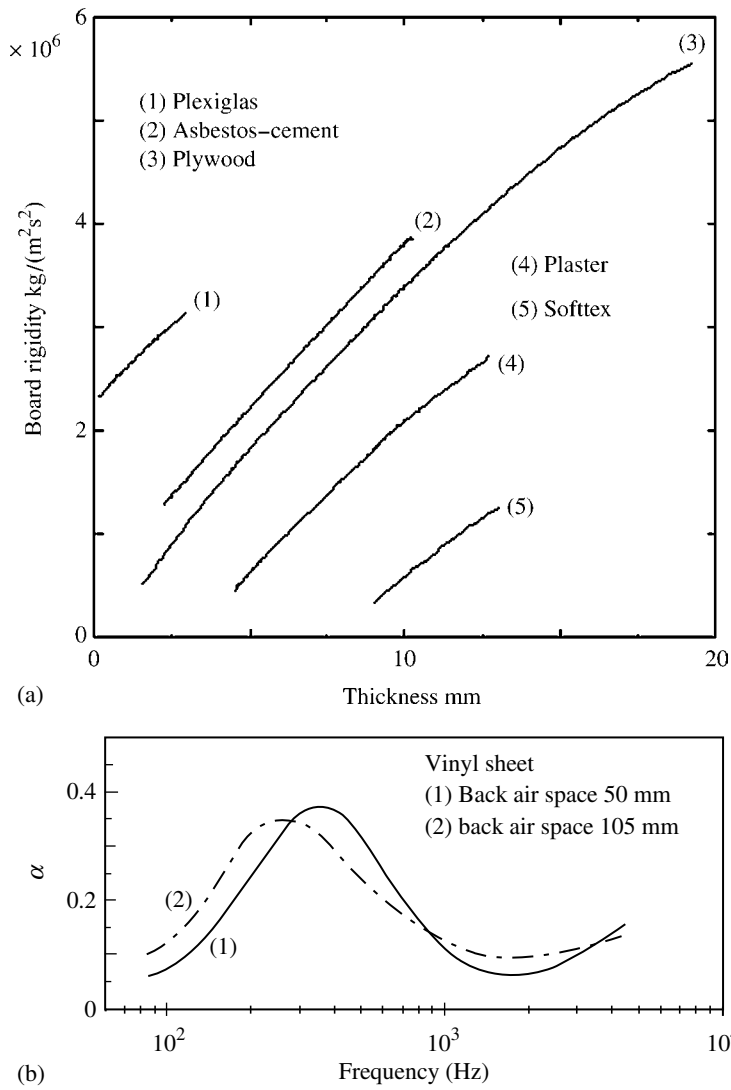

FIGURE 42.2 Some K_m values for membrane absorbing materials.

The resulting amplified motion of the air particles in the neck of the jar, due to phase cancellation between the air plug in the neck and the air volume in the vessel, causes energy dissipation due to friction in and around the neck. This type of absorber can be designed to produce maximum absorption over a very narrow frequency band or even a wide frequency band. The resonant frequency of a Helmholtz resonator may be expressed as

$$f_r = \frac{c}{2m} \sqrt{\frac{\varepsilon}{(t + 0.8d)L}} \tag{42.12}$$

where

- c = speed of sound (m/sec)
- S_n = cross-sectional area of neck of jar (m²)
- d_n = diameter of neck of jar (m)
- V = volume of vessel (m³)

FIGURE 42.3 Sound-absorption characteristics of a perforated plate structure: (a) cross sectional view; (b) plan view.

42.4 Acoustic Characteristic Computation of Compound Wall

42.4.1 Absorption Coefficient of Combined Plate with Porous Blanket

A common form of problem in noise control is the need to reduce the sound radiated from a duct or some other object. A way to achieve this is by lining the duct with several centimeters of porous acoustic material, and covering it with a solid plate of some type, as indicated in Figure 42.5.

Consider the case of normal incidence with the sound-absorbing structure of Figure 42.5. Assume that the boundary conditions for the sound pressure and the volume flow-rate are identical. For plane wave incidence on the hard wall, the magnitude of reflection coefficient is -1 [1]. The following equation is obtained:

$$\begin{bmatrix} 1 & -1 & -1 & 0 \\ -1 & -m_1 & m_1 & 0 \\ 0 & e^{-\gamma l_1} & e^{\gamma l_1} & -(1 + e^{-2jkl_2}) \\ 0 & m_2 e^{-\gamma l_1} & m_2 e^{\gamma l_1} & -(1 - e^{-2jkl_2}) \end{bmatrix} \begin{bmatrix} B_1 \\ A_1 \\ B_1 \\ B_2 \end{bmatrix} = \begin{bmatrix} -1 \\ -1 \\ 0 \\ 0 \end{bmatrix} \quad (42.13)$$

FIGURE 42.4 Geometry of a Helmholtz resonator. Volume, V , is connected to an infinitely open area by a neck tube of diameter d and length l_n .

where

$$j = \sqrt{-1}$$

$$m_1 = z_0/z_1, m_2 = z_1/z_2$$

z_0, z_1, z_2 : acoustic impedance of each medium
(Pa sec/m³)

γ = complex propagation constant (1/m)

The absorption coefficient for normal incidence is given by the following equation:

$$\alpha_0 = 1 - \left| \frac{B_0}{A_0} \right|^2 = 1 - |B_0|^2 \quad (42.14)$$

The absorption coefficient for random incidence may be approximated by

$$\alpha = \frac{1}{n} \sum_{i=1}^n \alpha(\theta)_i \quad (42.15)$$

where θ = the incident angle of sound, $0 < \theta < \pi/2$.

It is known that the propagation speed of the sound in fibrous materials changes with air, and the following equation holds on the boundary surface:

$$\sin \theta / \sin \theta' = c/c_m \quad (42.16)$$

Here, c_m is the sound speed in fibrous materials, which is calculated from the imaginary part of Equation 42.18, given later. The angle of reflection, θ' , in the boundary surface of the back air space is obtained in a similar way. Hence, the following equation is substituted in Equation 42.13 instead of the thickness of the absorber, l_1 , and the thickness of the air space, l_2 , to obtain the absorption coefficient in oblique incidence:

$$l'_1 = l_1 / \cos \theta', \quad l'_2 = l_2 / \cos \theta'' \quad (42.17)$$

The complex propagation constant, γ , is an important physical quantity in absorbing material of propagated sound, which is given per unit length of acoustic attenuations, and phase changes. Between the aeroelasticity rate, K_a , of absorbing material and the bulk modulus, Q , of absorbing material, γ is given by the following equation, for $K_a > 20 Q$ [2,3]:

$$\gamma = j\omega\sqrt{Y/K}\sqrt{\langle\rho_1\rangle - j\langle R_1\rangle/\omega} \quad (42.18)$$

$$\langle R_1 \rangle = \frac{R_1[1 - \rho_0(1 - Y)/\rho_m]}{\left[1 + \frac{\rho_0(\kappa - 1)}{\rho_m}\right]^2 \left[1 + \frac{R_1^2}{\rho_m^2 \omega^2 [1 + \rho_0(\kappa - 1)/\rho_m]^2}\right]}$$

$$\langle\rho_1\rangle = \rho_0\kappa - \frac{\frac{R_1^2(Y/\kappa + \rho_m/\rho_0\kappa)}{\rho_m^2 \omega^2 [1 + \rho_0(\kappa - 1)/\rho_m]^2} + \frac{1 + \rho_0 Y(\kappa - 1)/\rho_m \kappa}{1 + \rho_0(\kappa - 1)/\rho_m}}{1 + \frac{R_1^2}{\rho_m^2 \omega^2 [1 + \rho_0(\kappa - 1)/\rho_m]^2}}$$

where

ρ_m = density of acoustical material (kg/m³)

ρ_0 = density of air (kg/m³)

c_0 = speed of sound in air (m/sec)

FIGURE 42.5 Structure for sound absorption using a blanket and an air space showing angles θ_1 in the air and θ_2 in the blanket.

K = volume coefficient of elasticity of air (N/m²)
 R_1 = alternating flow resistance for unit thickness of material due to the difference between the velocity of the skeleton and the velocity of air in the interstices (Pa sec/m²). R_1 values are given in Table 42.1
 Y = porosity = the ratio of the volume of the voids in the material to the total volume; porosity equals the total volume minus the fiber volume, all divided by total volume
 $\kappa = 5.5 - 4.5Y$, the structure factor of the interstices in the skeleton
 $\omega = 2\pi f$, the angular frequency (radians/sec)

The acoustic impedance, z_1 , of absorbing material is given by

$$z_1 = R + jX = -\frac{jK\gamma}{\omega Y} \tag{42.19}$$

in which

$$R = \rho_0 c_0 \left\{ 1 + 0.0571(\rho_0 f / R_f)^{-0.754} \right\}$$
$$X = -\rho_0 c_0 \left\{ 0.0870(\rho_0 f / R_f)^{-0.732} \right\}$$

42.4.2 Transmission Loss through a Single Porous Board

Assume that a sound wave impinges on the left side of a porous board at normal incidence and emerges with a reduced amplitude from the right side. The associated transmission loss of the porous board is obtained from

$$\left. \begin{aligned} & TL_0 = 10 \log_{10}(X + Y) \\ & X = \left\{ 1 + \frac{\omega^2 m^2 P R_f}{2 \rho_0 c_0 (\omega^2 m^2 P^2 + R_f^2)} \right\}^2 \\ & Y = \left\{ \frac{\omega m R_f^2}{2 \rho_0 c_0 (\omega^2 m^2 P^2 + R_f^2)} \right\}^2 \end{aligned} \right\} \tag{42.20}$$

where

m = surface density of the blanket (kg/m²)
 P = porosity of the blanket (porosity = the total volume minus the fiber volume, all divided by the total volume)
 R_f = specific flow resistance of material (Pa sec/m)

TABLE 42.1 Flow Resistance Values of Glass-Wool Board (Quality Regulation Range by JIS)

Board Type	K value	Gross Specific Gravity (kg/m ³)	Specific Flow Resistance ($\times 10^{-3}$ N sec/m ⁴)	Standard of JIS for Glass Wool
#1 Glass-wool board	8	8 \pm 2	1.5 ~ 7.0	JIS A 9505-A
	12	12 \pm 2	2.5 ~ 12.0	
	16	16 \pm 2	4.7 ~ 17.0	
	20	20 \pm 3	5.0 ~ 22.0

ρ_0 = density of air (kg/m³)
 c_0 = sound speed in air (m/sec)

42.4.3 Transmission Loss through a Sandwich Board

Consider a wide wall formed by two panels (sheets) of infinite area separated with a homogeneous filling of fibrous acoustical material, as shown in Figure 42.6. Suppose that a plane wave impinges at an angle θ . As the pressure of both sides of the wall is equal with regard to the amplitude of the progressing wave and the reflected wave in each boundary surface, the following result may be established [4]:

$$\left. \begin{aligned} A_0 + B_0 &= A_1 + B_1 \\ (A_0 - B_0)/z_0 &= (A_1 - B_1)/z_1 \\ A_1 e^{-jkl'_1} + B_1 e^{jkl'_1} &= A_2 + B_2 \\ (A_1 e^{-jkl'_1} - B_1 e^{jkl'_1})/z_1 &= (A_2 - B_2)/z_2 \\ A_2 e^{-\gamma l'_2} + B_2 e^{\gamma l'_2} &= A_3 + B_3 \\ (A_2 e^{-\gamma l'_2} - B_2 e^{\gamma l'_2})/z_2 &= (A_3 - B_3)/z_3 \\ A_3 e^{-\gamma l'_3} + B_3 e^{\gamma l'_3} &= A_4 + B_4 \\ (A_3 e^{-\gamma l'_3} - B_3 e^{\gamma l'_3})/z_3 &= (A_4 - B_4)/z_0 \end{aligned} \right\} \quad (42.21)$$

where A and B are the amplitude of sound pressures.

From Equation 42.17, $l'_1 = l_1/\cos \theta_1$, $l'_2 = l_2/\cos \theta'_2$, and l'_1 and l'_2 may be calculated.

The speed of sound in the walls is given by the following equation in terms of the modulus of longitudinal elasticity, E_i :

$$c_i = \sqrt{E_i/\rho_i} \quad (42.22)$$

The real part of acoustic impedance, z_i ($i = 1, 3$), is given by $R_i = r_i/\cos \theta$, and of the imaginary part is given at $X_i = m_i\omega$. The internal resistances, r_i , are functions of such factors as the material, frequency, temperature, and density. Some typical values are given in Table 42.2.

If the space of the transmission side is infinite, B_4 in Equation 42.21 becomes equal to zero. Then, the transmission loss is given is given by

$$TL(\theta) = 10 \log_{10} \left| \frac{A_4}{A_0} \right|^2 \quad (42.23)$$

FIGURE 42.6 Cross-sectional view of a sandwich panel.

TABLE 42.2 Internal Resistance Values of Several Useful Materials

Material	Thickness (mm)	Internal Resistance (Pa sec/m ³)
Aluminum	0.4	3.0
Plywood	3.0	7.5
Plaster board	7.0	15.0

42.5 Attenuation of Lined Ducts

42.5.1 Computation of Attenuation in a Lined Duct

A lined duct is an air passage with one or more of the interior surfaces covered with an acoustical material such as a glass or mineral fiber blanket. The parallel baffles are merely a series of side-by-side ducts that generally have a rectangular or round cross section. If the walls are covered with absorptive material, attenuation will occur because of the viscous motion of the air in and out of the porous of blanket.

Figure 42.7 shows an isometric illustration of a lined duct. The attenuation of sound for a lined duct is dependent primarily on the duct length, l_e , the thickness of the lining, b , the density of the lining, ρ , the width of the air passage, l , and the wavelength of sound, λ . At low frequencies ($l/\lambda < 0.1$), the attenuation of sound in a lined duct may be calculated from the following empirical formula:

$$ATT = K_1 P/S \tag{42.24}$$

where

K_1 = the coefficient, which is determined from the random incidence absorption coefficient of lined material, given in the chart of Figure 42.8

P = acoustically lined perimeter of duct (m)

S = cross-sectional open area of duct (m²)

If the absorbing material is lined in the rectangular cross section as shown in Figure 42.9 to Figure 42.11, the attenuation can be estimated using the formulas given in Table 42.3 [5].

42.5.2 Attenuation in a Lined Bend

A lined bend duct is shown in Figure 42.12. The insertion loss, IL, of a lined bend results from two mechanisms: the reflection of sound back toward the source side, and the scattering of sound energy into the high-frequency region is rapidly attenuated by the lining beyond the bend. Higher-frequency modes will be attenuated by even an unlined duct for frequencies below the ratio of the air passage between the linings to the wavelength of sound equal to 0.5. At frequencies well above this ratio, the insertion loss of a lined bend is expected to be comparable to the reverberant-field

FIGURE 42.7 Illustration of a lined duct.

FIGURE 42.8 K_1 value for sound-absorption coefficient by reverberation room method.

FIGURE 42.9 Duct-liner configurations corresponding to Table 42.3.

end correction derived for the duct. The insertion loss of a lined bend may be obtained as following equation [6]:

$$IL = \frac{K_1 P}{S} + (l_1 + l_2) + \Phi \tag{42.25}$$

where Φ is obtained from Figure 42.13.

FIGURE 42.10 Relationship between absorption coefficient and stationary wave factor, n .

The total insertion loss for a lined bend is given in Figure 42.13 along with the attenuation of the lining beyond the bend.

42.5.3 Attenuation in Splitter Lined Duct

The use of parallel or zigzag baffle-type separators (splitters) to increase the perimeter–area ratio results in more compact attenuators. In rock-wool blankets, the attenuation of a parallel type splitter duct may be obtained directly from Figure 42.14. The peak value of the attenuation is related to wavelength of sound and the splitter interval. With the zigzag arrangement of acoustic blankets, the attenuation of high frequencies is improved over that of the parallel splitter [7].

FIGURE 42.11 Damping function KSL^2 as a function of dimensionless frequency, $\omega l / nc$.

42.6 Attenuation of Dissipative Mufflers

42.6.1 Transmission Loss of Lined Expansion Chamber

The geometry and nomenclature for a dissipative muffler are given in Figure 42.15. For $f < 1.2c/D$, the assumption of plane wave is acceptable where D = the diameter of the muffler.

The transmission loss for the light lining in the chamber may be obtained using [8,9]:

$$TL = 10 \log_{10} \left[\left\{ \cosh(\delta_e l_e / 2) + \frac{m+1}{2m} \sinh(\delta_e l_e / 2) \right\}^2 \cos^2 kl_e + \left\{ \sinh(\delta_e l_e / 2) + \frac{m+1}{2m} \cosh(\delta_e l_e / 2) \right\}^2 \sin^2 kl_e \right] \quad (42.26)$$

TABLE 42.3 Formulas for Attenuation of Several Lined Ducts

See Figure 42.7	Low-Frequencies Range: $\frac{\omega l}{nc} < 1$	Middle-Frequencies Range ($K_y S_y l_y$; see Figure 42.7)	High-Frequencies Range: $\frac{\omega l}{nc} > 5$
(A)	$\beta = \frac{4.34}{nl_y}$	$\beta = \frac{8.7c}{l_y^2 \omega} (K_y S_y l_y^2)$	$\beta = 21.4 \frac{c^2 n}{\omega^2 l_y^3}$

in which δ_e = the attenuation per unit length for the lined duct, which is given by the following equation:

$$20 \log_{10}(\delta_e l_e) = \frac{K_1 P l_e}{S} \tag{42.27}$$

The K_1 values are obtained from the absorption coefficient, as shown earlier (see Figure 42.8). In particular, δ_e is given by

$$\delta_e = \frac{1}{l_e} 10^{0.05 K_1 P l_e / S} \tag{42.28}$$

where m = the ratio of the area of expanded or lined sections to the area of inlet or outlet sections of muffler; $k = 2\pi f/c$, and l_e = the length of the muffler.

The transmission loss for the case of a thick lining of glass wool in the chamber is obtained using the empirical formula [10]

$$TL = 10 \log_{10} \left[1 + \left\{ \frac{1}{2} \alpha_g m k l_e \right\}^2 \right] \tag{42.29}$$

where

α_g = the coefficient, which is obtained from Table 42.4, using the filling volume and the density of glass wool

m = the ratio of the area of expanded or lined sections to the area of inlet or outlet sections of muffler

$k = 2\pi f/c$

l_e = the length of muffler

42.6.2 Transmission Loss of a Plenum Chamber

The geometry and nomenclature for a plenum chamber are given in Figure 42.16. A plenum chamber is similar in many ways to a lined expansion chamber. The main difference is that the inlet and outlet of a plenum chamber are not located in line. Generally, there is an offset to direct transmission of sound. Sound is reflected at the square-cornered bend as the cross section dimension of the duct is

sufficiently large. Particularly at high frequencies, almost all of the sound energy may reflect many times off the lined sides when propagating from the inlet to the outlet. The transmission loss of a single plenum chamber can be obtained approximately from [11]:

$$TL = 10 \log_{10} \left\{ S_w \left(\frac{\cos \theta}{2\pi d^2} + \frac{1}{R} \right) \right\} \quad (42.30)$$

where

- $S_w = IW =$ area of the inlet and outlet
- $d = \{(L - l)^2 + H^2\}^{1/2} =$ the slant distance from inlet to outlet
- $\cos \theta = H/d$
- $R = a/(1 - \alpha_m)$
- $a =$ the total lined area in chamber times absorption coefficient
- $\alpha_m =$ the statistical absorption coefficient of the lining

FIGURE 42.16 A single-plenum chamber showing the nomenclature used in Equation 42.26.

42.7 General Considerations

In order to carry out the design of noise-control measures for a particular problem, we must consider not only the fundamental acoustical properties of the material as discussed before, but also such practical aspects of the problem as (1) gas flow velocities, (2) temperature of gas, (3) moisture exposure, and (4) head losses for gas-flow. The client depends heavily on the expertise of the designer to realize adequate protection of the noise-control equipment under operating conditions.

42.7.1 Surface Treatment with Lining of Acoustic Material

Fibrous material in the market has some form of resin binder. Comparatively long fiber flocculent and comparatively short fiber are available. The packaging density of flocculent is about 60 to 100 kg/m³. It is necessary to cover with perforated thin metal or wire netting so that an arbitrary shape may be maintained in the absorbing material. The perforated metal does not take into account the numerical aperture, hole shape, hole diameter, and metal thickness. From the acoustic viewpoint, a suitable numerical aperture is given in Table 42.5.

42.7.2 Gas Flow Velocity

Noise control problems often involve the use of an acoustical material in high-velocity gas-flow such as those found in the exhaust of engines or ventilating systems. Deterioration of the acoustical

TABLE 42.5 Perforated Metal for Treatment of Absorbing Material (Gas Flow Velocity is 25 m/sec or Less)

Perforation rate: 30 to 50%
Hole diameter: 5 to 10 mm
Hole shape: round, plus, slit and interminglement
Metal: iron, stainless steel (used in case of the corrosive gas)

material due to high-velocity gas flowing past it can be a serious problem. In addition, turbulence in the gas flow subjects the materials to vibration and can cause further deterioration. One solution to this problem is to install the acoustical material behind some form of protective facing, which will vary in complexity depending on the gas velocity.

A limited amount of information on this subject is available through field experience, as shown in Figure 42.17 [12]. However, the parameters of the treatment structure are not well established, for example, those concerning perforated metal, wire net, absorbing material, and gas flow. Multiple layers are used under conditions of flow velocity exceeding 25 m/sec, and the associated performance analysis can become rather complex.

Surface Treatments with Gas Flow		
$u < 8 \text{ m/s}$	Flow → 	
$8 < u < 10$	Flow → 	
$10 < u < 25$	Flow → 	Perforated metal Glass fiber cloth
$25 < u < 40$	Flow → 	Wire screen
$40 < u < 60$	Flow → 	Two corrugated steel sheets
$60 < u < 100$	Flow → 	Blanket

42.7.3 Gas Temperature

In many noise-control problems, temperature is a very important factor. Sometimes high-temperature ducts that are radiating noise, for example, in diesel engines, and induced draft fans, must be wrapped. With a proper choice, it is possible to combine thermal and acoustical insulations using one single material. Under extremely high temperatures, the tensile strength of materials tends to decrease, and the material may be subjected to thermal shock.

Examples of absorbing materials that are currently available for use where temperature is an important consideration are given in Table 42.6.

FIGURE 42.17 Protective surface for absorbing material subjected to high-velocity gas flow.

42.7.4 Dust and Water Exposure

The holes of perforated metal can be blocked if a dust treatment is not carried out, and the sound absorption performance will deteriorate with adhesion to the surface of the absorbing material. Methods of dust accumulation and removal may be designed into cavity type mufflers used on the sound absorption equipment.

A fan of a cooling tower, for example, experiences a considerable amount of moisture. Precautions must be taken so that water droplets are not deposited on the sound absorbing material. The underside of the equipment should be treated with rust prevention material. Figure 42.18 shows the degradation

TABLE 42.6 Fibrous Materials of Use in Hot Gas Flows

Materials	Maximum Allowable Temperature (°C)
Glass fibers with binder	320 ~ 360
Glass wool	960 ~ 1060

Mineral wool	1660
Asbestos fibers	760
Alumina-silica	1900

of the acoustic characteristic of absorbing material due to moisture, using the normal incidence absorption coefficient [13].

42.8 Practical Example of Dissipative Muffler

An example is given on the design of a dissipative muffler for noise reduction in an axial-flow fan for a ventilation system.

1. Specification of the axial-flow fan

- Volume flow rate: $Q = 125 \text{ m}^3/\text{min}$
- Wind pressure: $p = 80 \text{ mm Aq}$
- Rotor blade number: $Z = 10$
- Stationary blade number: $Z_s = 5$
- Rotational speed: $N = 2580 \text{ rpm}$
- Shaft horsepower: $P = 3.75 \text{ kW}$

2. The desired values of attenuation and head loss with the muffler installation follow. The noise of the fan propagates both intake and discharge sides. A performance level (noise reduction) of about 37.5 dB is required, when specific sound level K_s is obtained on the basis of the axial-flow fan specification given by

$$K_s = L_A - 10 \log_{10}(p^2 Q) \quad (42.31)$$

3. Figure 42.19 gives the noise spectrum for the axial-flow fan. The blade passing frequency, BPF, is a fundamental component of the velocity fluctuation as the flow passes the blades. It is seen in the noise spectrum in Figure 42.19 at 430 Hz ($Q \times Z = (2580/60) \times 10$). By adding the background noise spectrum to this spectrum, it is seen that a muffler that provides an attenuation over 20 dB near 430 Hz, and about 15 dB in the frequency range of 800 to 1000 Hz is necessary. The head loss value of the muffler is to be maintained within 4 mm Aq.

FIGURE 42.18 Degradation of the absorption coefficient by water content.

FIGURE 42.19 Noise spectrum of the axial flow fan of a factory ventilation system.

FIGURE 42.20 Half cross-sectional view of dissipative muffler for the axial flow fan.

4. The structure of the dissipative muffler is shown in Figure 42.20. The maximum value of outer diameter of the muffler is 750 mm, and the length chosen to optimize the performance.
5. The packing density of glass wool is chosen as 65 kg/m^3 . The surface treatment of glass wool uses perforated metal with 1 mm thickness, 36% open area with 6 mm hole diameter. A sound absorption body of 200 mm diameter is supported in the center part, and it is welded to the outside cylinder by three props in the flow direction, and two in the circumferential direction.
6. The attenuation characteristics of the dissipative muffler may be calculated using Equation 42.27

$$TL = 10 \log_{10} \left[1 + \left\{ \frac{1}{2} \alpha_g m k l_e \right\}^2 \right]$$

The proportion of the volume of glass wool filled into the muffler is approximately $(0.75^2 - 0.55^2 + 0.2^2)/0.75^2 = 0.53$. For a packing density of 100 kg/m^3 , we have $0.53 \times 65/100 = 0.347$. The value of $\alpha_g \approx 0.6$ is obtained from Table 42.2.

The required expansion ratio, m , length, l_e , and wave number, k , are given by

$$m = (750/500)^2 = 2.25, \quad l_e = 1.2 \text{ m}, \quad k = 2\pi f/c$$

The speed of sound c depends on the environmental temperature. For a temperature of 25°C , we get 346.5 m/sec ($= 331.5 + 0.6 \times 25$). The TL values at 100 to 1000 Hz are calculated. We have

$$f = 100 \text{ Hz}; \quad TL = 5.0 \text{ dB}$$

$$f = 430 \text{ Hz}; \quad TL = 16.1 \text{ dB}$$

$$f = 1000 \text{ Hz}; \quad TL = 23.4 \text{ dB}$$

The flow velocity satisfies desired value of head loss p_{loss} (in mm Aq), and is calculated by following empirical equation [12]:

$$p_{\text{loss}} = \left\{ 0.142 m_f^{-0.1} \left(\frac{l_e}{d_1} \right)^{3/4} \left(\frac{d_m}{d_1} \right)^{-1/3} \right\} \frac{u^2}{g} \quad (42.32)$$

Use the numerical values as follows:

- $m_f = (550/500)^2 = 1.21$, ratio of cross-sectional area between air passage and muffler.
- $d_1 = 500 \text{ mm}$, diameter of inlet.
- $l_e = 1.2 \text{ m}$, length of muffler.
- $d_m = 200 \text{ mm}$, diameter of absorption body.
- $u = 10 \text{ m/sec}$ or less, flow velocity at inlet.
- $g = 9.8 \text{ m/sec}^2$, acceleration of gravity force.

FIGURE 42.21 Noise-reduction characteristics of the designed dissipative muffler.

The corresponding head loss is 3.25 mm Aq, which corresponds to JIS B 833, and nearly agrees with the predicted value. Specifically, the condition of 4 mm Aq or less of the designed value is satisfied. The connection of axial-flow fan and the muffler uses vibration isolation, using the thick synthetic rubber.

7. The result of the attenuation realized from the spectrum after the muffler installation is shown in Figure 42.21. It is proven that the attenuation characteristics almost parallel the designed value. The frequency range where the approximation is valid is given by

$$f < c/d = 346.5/0.175 = 1980 \text{ Hz}$$

For frequencies below 250 Hz, the estimated result of the attenuation becomes slightly overestimated.

Summary

This chapter concerns the design of noise suppression devices such as mufflers. In particular, reactive mufflers that are inserted into long ducts are considered in detail. Analytical and empirical equations and information that are useful in the modeling and analysis of mufflers are presented, with an indication of their application ranges and limitations. A design procedure, complete with the necessary computations, is given. Methodologies and parameters of the performance analysis of acoustic systems with mufflers are indicated. An illustrative example of a muffler for a double-acting reciprocating compressor is presented.

43.1 Introduction

In noise-reduction applications, the need for a reactive muffler usually arises when transporting gas through a duct. For sound transmission through the duct to be minimized, an acoustic suppression device must be incorporated into the duct system. For example, in internal-combustion engines, it is required to reduce the intake and exhaust noise to acceptable levels. This may be accomplished by inserting a muffler in the intake and exhaust ducting to attenuate the pressure pulsations before they reach the environment.

A successful muffler design must satisfy at least the following three criteria: (1) muffler performance as a function of frequency (the maximum permissible noise generated by the gas flow through the muffler may have to be specified as well); (2) the maximum permissible average pressure drop through the muffler at a given temperature and mass flow; (3) the maximum allowable volume and restrictions on space utilization.

The customer may ask for a muffler with unrealistically high noise attenuation, virtually no backpressure, and very small size. In addition, it is important to the customer that the muffler is inexpensive and durable, and presents no maintenance problems. Needless to say, in practice, these

criteria for muffler design are unrealistic, and have to be modified to practical levels. In this chapter, we will present some of the analytical and empirical tools that are helpful in muffler design.

43.2 Fundamental Equations

43.2.1 Analytical Model

The physical behavior of a reactive muffler may be adequately modeled by linear differential equations. The law of conservation of mass must hold, while three simultaneous equations, Newton's, Boyle–Charles, and that of conservation, must be satisfied. When these equations are combined, we obtain the wave equation for the plane, one-dimensional sound-pressure wave:

$$\frac{\partial^2 \xi}{\partial t^2} = c^2 \frac{\partial^2 \xi}{\partial x^2} \quad (43.1)$$

$$p = \rho c^2 \frac{\partial \xi}{\partial x} \quad (43.2)$$

where

ξ = displacement of particle motion (m)

c = velocity of sound (m/sec)

p = sound pressure (Pa)

ρ = density of air (kg/m³)

t = time (sec)

x = coordinate system along which wave travels (m)

The stationary solutions for angular frequency ω of Equation 43.1 and Equation 43.2 are given by

$$\xi = (A e^{-jkx} - B e^{jkx}) e^{j\omega t} \quad (43.3)$$

$$p = -\rho c^2 k (A e^{-jkx} + B e^{jkx}) e^{j\omega t} \quad (43.4)$$

where A, B = amplitudes of sound pressure or particle motion for traveling and reflecting waves, $k = 2\pi f/c$, wave number, and $j = \sqrt{-1}$.

43.2.2 Boundary Conditions

The boundary conditions are given below.

(1) *Sound source.* The sound source is assumed to be independent of the existence of the muffler, and the volume rate of the particles is assumed constant, as given by

$$S \dot{\xi} = \text{const} \quad (43.5)$$

in which $\dot{\cdot}$ denotes the time derivative.

(2) *Open end of duct.* The reflection coefficient, R , at the open end of an unflanged circular pipe is available, and is given by

$$R = \frac{B e^{jkx}}{A e^{-jkx}} \quad (43.6)$$

The magnitude of the reflection coefficient, $|R|$, is shown in Figure 43.1a as a function of ka , where a is the pipe radius. The phase shift can be determined from Figure 43.1b, which is a plot of α/a as a function of ka . Also, the reflection coefficient is [1]:

$$R = -|R| e^{-2jk\alpha} \quad (43.7)$$

For the small values of ka that are most often encountered in reactive muffler design, $|R| \approx 1$ and $\alpha/a = 0.613$.

(3) *Closed end.* The displacement of particle motion is zero at a rigid wall. Hence, we have

$$\xi = 0 \quad (43.8)$$

FIGURE 43.1 (a) Magnitude of the reflection coefficient at open end of an unflanged circular pipe; (b) End correction for an unflanged circular pipe. (Source: Levine, H. and Schwinger, J., On the radiation of sound from an unflanged circular pipe, *J. Phys. Rev.*, 73, 383, 1948. With permission.)

(4) *Junction conditions.* The following equations correspond to the continuity of volume flow rate of the particles and the continuity of pressure, even if the cross section changes suddenly:

$$S_i \dot{\xi}_i = S_{i+1} \dot{\xi}_{i+1} \quad (43.9)$$

$$p_i = p_{i+1} \quad (43.10)$$

43.3 Effects of Reactive Mufflers

The acoustic behavior of a reactive muffler may be expressed in term of the insertion loss, the difference in the noise levels measured at some external point with and without the muffler in the system. The transmission loss is defined as the insertion loss for a nonreflecting source and the end of exhaust duct.

43.3.1 Insertion Loss

A single expansion-type muffler installation is shown schematically in Figure 43.2. At the open end of a pipe, as in Figure 43.2, the traveled and reflected waves of the source become $A_0 e^{-jkl}$, $B_0 e^{jkl}$, over a length l , where the amplitudes are denoted by A_0 , B_0 . The reflective coefficient for length l_0 is given by

$$R_0 = \frac{B_0 e^{jkl_0}}{A_0 e^{-jkl_0}} \quad (43.11)$$

This is obtained from Equation 43.6 with $x = l_0$.

The energy, W_0 , of the acoustic wave escaping from the open end of the pipe is given by

$$W_0 \propto \frac{S_0 A_0^2 (1 - R_0^2)}{\rho_0 c_0} \quad (43.12)$$

in which ρ_0 = density of air, and c_0 = speed of sound in air. The equation of the sound-pressure level measured at an open point at some distance is given by

$$p_0 = 10 \log_{10} \left(\frac{Q_d}{4\pi r_0^2} + \frac{4}{R_r} \right) + PWL_{r_0} \quad (43.13)$$

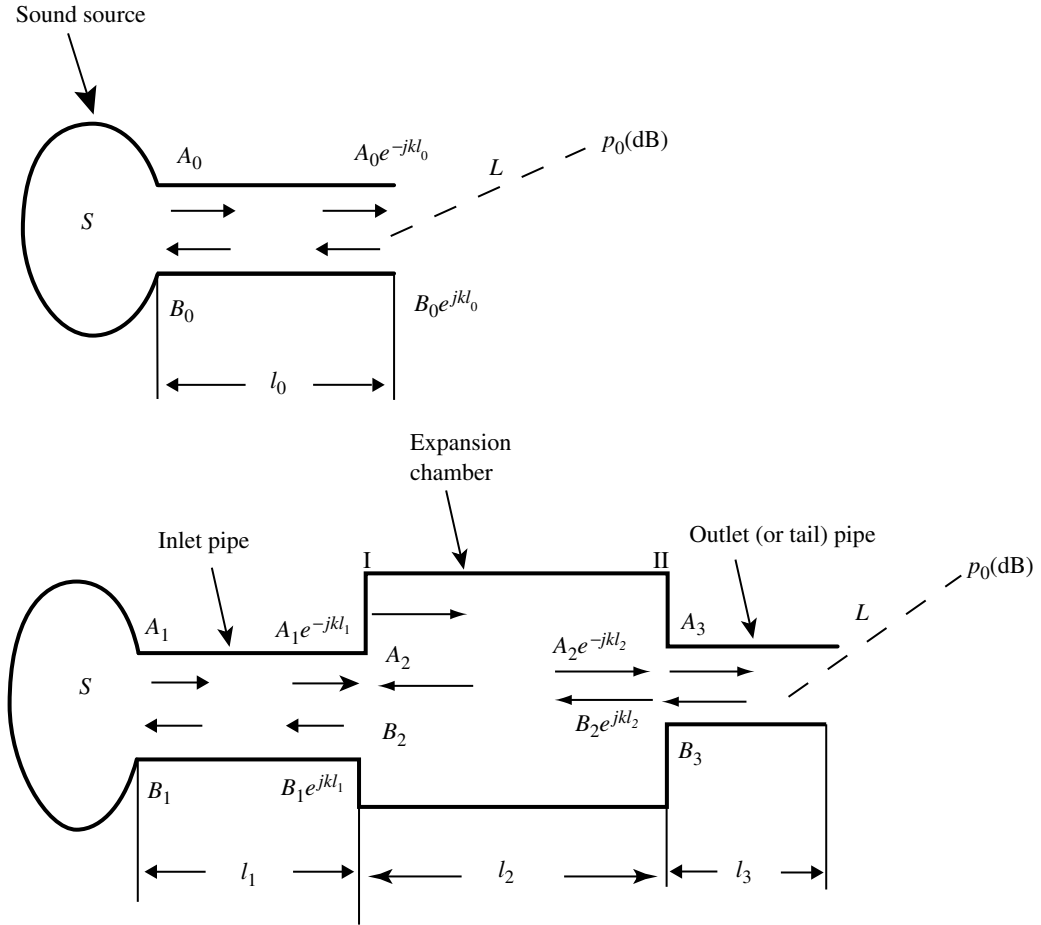

FIGURE 43.2 Measurement of insertion loss.

where

r_0 = distance

$R_r = A/(1 - \alpha)$, room constant

A = the indoor sound absorbing power (indoor surface area times indoor average absorption coefficient)

α = the indoor average absorption coefficient

Q_d = the directivity factor from the open end

Therefore, the measured value of insertion loss can be obtained from Equation 43.14, when Q_d values are equal. Power level is defined as

$$\text{PWL} = 10 \log_{10} \left(\frac{W}{10^{-12}} \right)$$

Now,

$$\text{IL} = \text{PWL}_{r_0} - \text{PWL}_r \quad (43.14)$$

Using Equation 43.14, it can be shown that IL can be expressed by

$$\text{IL} = 10 \log_{10} \left| \frac{S_0}{S_3} \left| \frac{A_0}{A_3} \right|^2 \right| \left| \frac{1 - R_0^2}{1 - R_3^2} \right| \quad (43.15)$$

FIGURE 43.3 Definition of transmission loss for a muffler.

3.2 Transmission Loss

It is desirable to eliminate the source and radiation characteristics from the system in Figure 43.3, and to look only at some property of the muffler itself. This may be accomplished by defining a quantity called “transmission loss” (TL) as follows:

$$TL = 10 \log_{10} \left| \frac{A_1}{A_2} \right|^2 \frac{S_1}{S_2} \quad (43.16)$$

In the measurement of TL, it is difficult to separate the reflected wave. The theoretical calculation is easy and useful.

43.4 Calculation Procedure

For the reactive muffler shown in Figure 43.2, the following equations are obtained from Equation 43.5 to Equation 43.7 and Equation 43.9. The inlet pipe, cavity, and tail pipe are denoted by suffix in the figure [2].

- (1) The sound source:

$$S_0(A_0 - B_0) = S_1(A_1 - B_1) \quad (43.17)$$

- (2) The open end of pipes:

$$\left. \begin{aligned} B_0 e^{jkl_0} &= A_0 e^{-jkl_0} R_0 \\ B_3 e^{jkl_3} &= A_3 e^{-jkl_3} R_3 \end{aligned} \right\} \quad (43.18)$$

- (3) The sudden expansion (junction I):

$$\left. \begin{aligned} A_1 e^{-jkl_1} + B_1 e^{jkl_1} &= A_2 + B_2 \\ S_1(A_1 e^{-jkl_1} - B_1 e^{jkl_1}) &= S_2(A_2 - B_2) \end{aligned} \right\} \quad (43.19)$$

- (4) The sudden contraction (junction II):

$$\left. \begin{aligned} A_2 e^{-jkl_2} + B_2 e^{jkl_2} &= A_3 + B_3 \\ S_2(A_2 e^{-jkl_2} - B_2 e^{jkl_2}) &= S_3(A_3 - B_3) \end{aligned} \right\} \quad (43.20)$$

From these linear equations, the following equation can be obtained:

$$\frac{A_0}{B_0} = \frac{m_{10}}{1 - R_0 e^{-2jkl_0}} \left\{ j \left(1 + R_3 e^{-2jkl_3} \right) (\sin kl_1 \cos kl_2 + m_{21} kl_1 \sin kl_2) \right. \\ \left. + m_{32} \left(1 - R_3 e^{-2jkl_3} \right) (m_{21} \cos kl_1 \cos kl_2 - \sin kl_1 \sin kl_2) \right\} \quad (43.21)$$

When the reflection coefficients are absent, $R_0 = R_3 = 0$, we have

$$IL = 10 \log_{10} m_{03} \left\{ m_{10}^2 (\sin kl_1 \cos kl_2 + m_{21} \cos kl_1 \sin kl_2)^2 + m_{10}^2 m_{32}^2 \right. \\ \left. \times (m_{21} \cos kl_1 \cos kl_2 - \sin kl_1 \sin kl_2)^2 \right\} \quad (43.22)$$

where $m_{10} = S_0/S_1$, $m_{21} = S_2/S_1$, $m_{32} = S_3/S_2$, $m_{03} = S_0/S_3$, which are ratios of cross-sectional areas of the pipes.

For the reflection factors, $R_0 = R_3 = -1$, $S_0 = S_1 = S_3$, and $m_{21} = m$, the equation of insertion loss becomes

$$IL = 20 \log_{10} \left\| \frac{\cos kl_1}{\cos kl_0} \left\{ \cos kl_{21} \cos kl_3 - m \sin kl_2 \sin kl_3 - \tan kl_1 \left(\cos kl_2 \sin kl_3 + \frac{1}{m} \sin kl_2 \cos kl_3 \right) \right\} \right\| \quad (43.23)$$

The ratio $|A_1/A_3|$ may also be obtained from Equation 43.17 to Equation 43.20. When the magnitude of reflection coefficients $R_0 = R_3 = 0$, $S_0 = S_1 = S_3$, and expansion ratio of the cross-sectional open area of the pipes $m_{21} = m$, the transmission loss is given by

$$TL = 10 \log_{10} \left\{ 1 + \frac{1}{4} \left(m - \frac{1}{m} \right)^2 \sin^2 kl_2 \right\} \quad (43.24)$$

When $R_0 = R_3 = -1$, $S_0 = S_1 = S_3$, and $m_{21} = m$, TL is obtained from the following equation:

$$TL = 10 \log_{10} \left| 1 + \frac{1}{m^2} (m^2 - 1) \{ (m^2 + 1) \sin^2 kl_3 - 1 \} \sin^2 kl_2 + \frac{1}{2} \left(-m + \frac{1}{m} \right) \sin 2kl_2 \sin 2kl_3 \right| \quad (43.25)$$

Computation formulas of insertion loss and transmission loss for the case of an expansion chamber with insertion pipe and resonator are shown in [Table 43.1](#).

The principal structures of several reactive mufflers are shown in [Figure 43.4](#).

43.5 Application Range of Model

43.5.1 Condition for Approximation of Plane Wave

The frequency range where the approximation of a plane wave is valid is given by

$$f_c < 1.22 \frac{c}{D} \quad (43.26)$$

where

f_c = critical frequency of plane wave (Hz)

c = speed of sound (m/sec)

D = diameter of muffler (m)

It is seen that the expansion ratio of an open area of a pipe increases with IL or TL. However, the application range of the analytical model decreases with increasing diameter of chamber.

43.5.2 Effect of Temperature

Under conditions of high-temperature and high-speed gas flow, as in an engine exhaust system, the primary effect of a change in pipe temperature is the corresponding change in the speed of sound, which is proportional to the square root of the absolute temperature. In the design of a reactive muffler, it is necessary to use the actual speed of sound in the gas inside the pipe. The most accurate values available for density (ρ_0) and the speed of sound (c_0) at each element should be used in calculating the impedance

A is the radius of tube in orifice hole or diameter of side branch, c is the sound speed, C_0 is the conductivity, D is the diameter of chamber, f is the frequency, f_r is the resonant frequency of the resonator, $k = 2\pi f/c$ is the wave number, L is the length, $m = S_i/S_{i+1}$ is the ratio of the cross section, IL is the insertion loss, N is the number of holes, R is the reflection coefficient, S is the cross section, TL is the transmission loss, V is the volume of chamber, Z is the acoustic impedance, ρ is the density, λ is the wavelength, $\omega = 2\pi f$, angular frequency.

FIGURE 43.4 Sketches of the 12 principal structures of reactive mufflers.

of the elements. The impedance, z , is given by

$$z = -j \frac{\rho_0 c_0}{S} \frac{1}{kl} \quad (43.27)$$

where

S = the cross-sectional open area of pipe

$k = 2\pi f/c_0$, wave number

l = the length of the pipe element

Note that the impedance of the resonator chamber is proportional to $\rho_0 c_0^2$. However, c_0^2 is proportional to the absolute temperature of gas (T) and ρ_0 is proportional to $1/T$. Hence, the chamber impedance is independent of temperature. The connector impedance is a function of T , but in most cases the connector will be at the pipe temperature. For a resonator-type muffler, a temperature difference between the pipe and chamber is expected to have little effect on the performance of the muffler.

43.5.3 Effect of Gas Flow in Pipe

Under conditions of high-temperature and high-speed gas flow in a pipe, the pressure amplitude in the pipe is large, and is larger than what is predicted by theory. Analysis by the characteristic curve method is desirable under such conditions.

In a reactive muffler where the pipe flow passes through a sudden pipe expansion or an orifice, the computed transmission loss or insertion loss tends to be an overestimate because of new noise that is generated due to the resulting irregular air-flow within the muffler.

43.5.4 Effect of Friction Loss in Pipe

When an acoustic wave propagates in a pipe, it will attenuate due to viscous friction. The effect is large for long pipes of small diameter. Friction damping in a pipe may be incorporated into the propagation constant, γ , such that

$$\gamma = \delta + jk \quad (43.28)$$

where δ is the attenuation constant per unit length of pipe. By substituting Equation 43.28 into Equation 43.3 and Equation 43.4, we obtain

$$\xi = (A e^{-\gamma l} - B e^{\gamma l}) e^{j\omega t} \quad (43.29)$$

$$p = -\rho c^2 k (A e^{-\gamma l} + B e^{\gamma l}) e^{j\omega t} \quad (43.30)$$

Empirical formulas are given below for two cases of the attenuation coefficient δ [3].

(1) The formula for seamless steel or chloride-ethylene pipes (regression formula when the inside roughness is 4 to 8 μm and length under 3 m) is

$$\delta = 26,100 \lambda^{-0.5} \frac{\mu}{\rho c d} \quad (43.31)$$

where

λ = wavelength of sound (m)

μ = viscosity of gas in the pipe (Pa sec)

ρ = density of gas (kg/m^3)

d = diameter of the pipe (m)

(2) The equations for lining with glass wool are

$$\left. \begin{aligned} \delta_2 &= 2491 \lambda^{-0.476} \left(\frac{\rho c d}{\mu} \right)^{-1.068} \\ \delta_6 &= 5175 \lambda^{-0.476} \left(\frac{\rho c d}{\mu} \right)^{-1.303} \\ \delta_6 &= 11596 \lambda^{-0.476} \left(\frac{\rho c d}{\mu} \right)^{-1.270} \end{aligned} \right\} \quad (43.32)$$

The suffix of δ gives the thickness of absorbing material in mm.

43.6 Practical Example

43.6.1 Expansion-Type Muffler for Reciprocating Compressor

Consider a double-acting (i.e., fluid on both sides of the piston in the cylinder) reciprocating compressor for supplying high-pressure air to a machine shop of a factory, for example.

The specifications of the reciprocating compressor follow:

- Delivery pressure: 6.9×10^5 Pa
- Rotational speed of driving shaft: 600 rpm
- Power of driving shaft: 450 kW
- Diameter of inlet pipe: 380 mm

Pressure pulsations of 10 and 20 Hz are produced by the compressor due to the rotational speed, as seen in Figure 43.5. The pressure wave from the inlet propagates the free space and can the damage nearby private houses. Wooden doors with glass paneling, wooden sliding-doors, and leaves of plants and foliage, and have been found to vibrate due to low-frequency audible sound. An attenuation of 15 to 20 dB was

FIGURE 43.5 Noise spectrum at inlet of reciprocating compressor and insertion loss of designed muffler.

necessary at the frequencies 10 and 20 Hz. A muffler using an expansion and tail pipe type was suggested to handle the problem. The reflection coefficient of the tail pipe is approximately $R = -1$ and $ka = 2\pi fa/c = 2\pi \times 20 \times 0.19/345 = 0.0692$.

$$IL = 20 \log_{10} |\cos kl_2 \cos kl_3 - m \sin kl_2 \sin kl_3|$$

where

$k = 2\pi f/c$; wave number (1/m)

l_2 = the length of the chamber (m)

l_3 = the length of the tail pipe (m)

m = the expansion ratio of the cross section between the chamber and inlet

With $kl_2 = kl_3 = \pi/2$, we have

$$IL = 20 \log_{10} |m|$$

We need $m > 10$ in order to satisfy the desired value of IL. For 20 Hz, we use $kl_2 = kl_3 = \pi$. When $kl_2 = kl_3 = \pi/2$ at $f = 10$ Hz, we have $IL = 0$. Then, using $kl_2 = kl_3 = \pi/2$ at frequency 15 Hz, we can satisfy the IL condition of 20 dB at both frequencies. Hence, $l_2 = l_3 = 345/(4 \times 15) = 5.75$ (m) is chosen at a speed of sound $c = 345$ m/s.

The noise spectrum at the inlet of the reciprocating compressor under study and insertion loss of the muffler design in this example are shown in Figure 43.5.

The diameters or the lengths of the chamber and the tail pipe are properly selected, as shown and in Figure 43.6. At 10 Hz, IL is determined as

FIGURE 43.6 The muffler designed for the noise control of a reciprocating compressor.

indicated below:

$$\begin{aligned} \text{IL} &= 20 \log_{10} |\cos(2\pi \times 10 \times 4.5/345) \cos(2\pi \times 10 \times 6/345) - (1.6/0.38)^2 \sin(2\pi \times 10 \times 4.5/345) \\ &\quad \times \sin(2\pi \times 10 \times 6/345)| \\ &= 20 \log_{10} |0.6825 \times 0.4600 - 17.728 \times 0.7308 \times 0.8879| = 21.0 \text{ (dB)} \end{aligned}$$

Similarly, at 20 Hz, we have

$$\begin{aligned} \text{IL} &= 20 \log_{10} |\cos(2\pi \times 20 \times 4.5/345) \cos(2\pi \times 20 \times 6/345) - (1.6/0.38)^2 \sin(2\pi \times 20 \times 4.5/345) \\ &\quad \times \sin(2\pi \times 20 \times 6/345)| \\ &= 20 \log_{10} |(-0.0682) \times (-0.5767) - 17.728 \times 0.9977 \times 0.8170| = 23.2 \text{ (dB)} \end{aligned}$$

Clearly, the attenuation at both frequencies satisfies the desired lower limit of 20 dB. Calculated values of IL at low frequencies are shown by a curved continuous line in [Figure 43.5](#).

Summary

This chapter presents useful theory and design procedures for sound insulation. Related concepts and representations of transmission loss, the transmission coefficient, and impedance are given. Analysis and design procedures for sound insulation structures such as single and multiple panels and walls with sound absorption material are presented. Practical applications for the design of sound insulation components and systems are described.

44.1 Theory of Sound Insulation

44.1.1 Expressions of Sound Insulation [1]

44.1.1.1 Transmission Coefficient

Let us denote by I_i the acoustic energy incident on a wall per unit area and unit time. Some energy is dissipated in the wall, and, apart from the energy that is reflected by the wall, the rest is transmitted through the wall. Using I_t to denote the transmitted acoustic energy, the transmission coefficient of the wall is defined as

$$\tau = \frac{I_t}{I_i} \quad (44.1)$$

44.1.1.2 Transmission Loss

As an expression for sound insulation performance, we may use transmission loss (TL), which is defined as (also see Chapter 42 and Chapter 43)

$$TL = 10 \log\left(\frac{1}{\tau}\right) = 10 \log\left(\frac{I_i}{I_t}\right) \quad (44.2)$$

44.1.2 Transmission Loss of a Single Wall

Consider a plane sound wave incident on a impermeable infinite plate at angle θ , which is placed in a uniform air space as shown in Figure 44.1. The sound pressure of the incident, reflected, and transmitted

waves, denoted by p_i , p_r , and p_t , respectively, are given by

$$\begin{aligned} p_i &= P_i e^{j\omega t - jk(x \cos \theta + y \sin \theta)} \\ p_r &= P_r e^{j\omega t - jk(-x \cos \theta + y \sin \theta)} \\ p_t &= P_t e^{j\omega t - jk(x \cos \theta + y \sin \theta)} \end{aligned} \quad (44.3)$$

where P_i , P_r , and P_t are the sound pressure amplitudes of incident, reflected, and transmitted waves, respectively; ω is angular frequency; k is the wave number of the sound wave; c is the speed of sound, respectively in the air. Assuming that the plate is sufficiently thin compared with the wavelength of the incident sound wave, the vibration velocities on the incident and transmitted surfaces of the plate are equal. Then vibration velocity, u , of the plate in the x direction is equal to the particle velocity of the incident and transmitted sound waves, and we obtain relations

$$u = -\frac{1}{j\omega\rho} \frac{\partial(p_i + p_r)}{\partial x} = -\frac{1}{j\omega\rho} \frac{\partial p_t}{\partial x} \quad (44.4)$$

$$\frac{p_i + p_r - p_t}{u} = Z_m \quad (44.5)$$

where ρ is the air density and Z_m is the *mechanical impedance* of the plate per unit area. From these equations, the transmission coefficient, τ_θ , and then the transmission loss, TL_θ , at the incident angle, θ , are obtained according to

$$TL_\theta = 10 \log \frac{1}{\tau_\theta} = 10 \log \left| \frac{p_i}{p_t} \right|^2 = 10 \log \left| 1 + \frac{Z_m \cos \theta}{2\rho c} \right|^2 \quad (44.6)$$

44.1.2.1 Coincidence Effect

Consider the vibration of the plate in the x - y plane shown in Figure 44.1. Denoting by m the surface density, and by B the bending stiffness per unit length of the plate, the equation of motion of the plate is given by

$$m \frac{\partial^2 \xi}{\partial t^2} + B(1 + j\eta) \frac{\partial^4 \xi}{\partial y^4} = p_i + p_r - p_t, \quad B = \frac{Eh^3}{12(1 - \nu^2)} \cong \frac{Eh^3}{12} \quad (44.7)$$

where

ξ = displacement in the x direction
 E = Young's modulus of the plate
 h = thickness of the plate
 η = loss factor of the plate
 ν = Poisson's ratio of the plate

The plane sound wave of angular frequency, ω , and of incidence angle, θ , causes a bending wave in the plate where displacement is assumed to be $\xi = \xi_0 e^{j(\omega t - k_1 y)}$, as a solution of Equation 44.7. Hence, the mechanical impedance per unit area is obtained:

$$Z_m = \frac{p_i + p_r - p_t}{\partial \xi / \partial t} = \eta \frac{Bk_1^4}{\omega} + j \left(\omega m - \frac{Bk_1^4}{\omega} \right) \quad (44.8)$$

where $k_1 = k \sin \theta$ ($k = \omega/c$) is the wave number of the bending wave in y direction caused by the incident sound wave. Propagation speed of the forced bending wave, c_1 , and a free bending wave of

FIGURE 44.1 Plane sound wave incidence on an infinite plate.

the plate, c_B , are given by

$$c_1 = \omega/k_1, \quad c_B = \left(\frac{\omega^2 B}{m} \right)^{1/4} \quad (44.9)$$

Equation 44.9 reduces Equation 44.8 to

$$Z_m = \eta \omega m \left(\frac{c_B}{c_1} \right)^4 + j \omega m \left[1 - \left(\frac{c_B}{c_1} \right)^4 \right] \quad (44.10)$$

When the speed of forced bending wave, c_1 , and the speed of free bending wave, c_B , are equal in Equation 44.10, the imaginary part of Z_m becomes 0, and a form of “resonance” occurs. Then the transmission loss decreases rapidly. This phenomenon is called the *coincidence effect*, and the resonant frequency dependent on the incident angle is given by

$$f = \frac{c^2}{2\pi \sin^2 \theta} \sqrt{\frac{m}{B}} \quad (44.11)$$

The minimum of the resonant frequency is called coincidence critical frequency, or critical frequency for short, and it reduces to

$$f_c = \frac{c^2}{2\pi} \sqrt{\frac{m}{B}} \cong \frac{c^2}{1.8 c_L h} \quad (44.12)$$

where $c_L = \sqrt{E/\rho_P}$ is the speed of longitudinal wave in the plate, and ρ_P denotes the density of the plate.

Let us show the relations of the critical frequency and the plate thickness of typical material of sound insulation shown in Figure 44.2. Using the relation $c_B/c_1 = \sqrt{f/f_c} \sin \theta$, Equation 44.10

FIGURE 44.2 Critical frequency vs. plate thickness of typical sound insulation materials: (1) aluminum, steel, or glass; (2) hardboard or copper; (3) dense concrete, plywood, or brick; (4) gypsum board; (5) lead or light weight concrete. (Source: Beranek, L.L. 1988. *Noise and Vibration Control*, INCE/USA. With permission.)

becomes

$$Z_m = \eta \omega m \left(\frac{f}{f_c} \right)^2 \sin^4 \theta + j \omega m \left[1 - \left(\frac{f}{f_c} \right)^2 \sin^4 \theta \right] \quad (44.13)$$

44.1.2.2 Mass Law of Transmission Loss

When $f \ll f_c$, Equation 44.13 becomes $Z_m \cong j \omega m$. Then, the transmission loss depends on the incident angle, the frequency and the surface density of the plate. This is called the mass law of transmission loss.

Mass law of normal incidence represents the transmission loss at the incident angle $\theta = 0$, as given by

$$TL_0 = 10 \log \left[1 + \left(\frac{\omega m}{2 \rho c} \right)^2 \right] \quad (44.14)$$

For $\omega m \gg 2 \rho c$, it becomes

$$TL_0 \cong 10 \log \left(\frac{\omega m}{2 \rho c} \right)^2 = 20 \log mf - 42.5; \text{ for air} \quad (44.15)$$

Mass law of random incidence represents the transmission loss at the angle averaged over a range of θ from 0 to 90° , which is realized for perfectly diffused sound field. We have

$$TL_r = 10 \log(1/\tau_r) \cong TL_0 - 10 \log(0.23 TL_0) \quad (44.16)$$

where the random incident transmission coefficient, τ_r , is defined as

$$\tau_r = \int_0^{\pi/2} \tau_\theta \cos \theta \sin \theta d\theta / \int_0^{\pi/2} \cos \theta \sin \theta d\theta \quad (44.17)$$

An approximation for Equation 44.16, as given below, is generally used for a practical use and this is often useful.

$$TL_r = 18 \log mf - 44 \quad (44.18)$$

Mass law of field incidence represents the transmission loss at the angle averaged over a range of θ from 0 to about 78° , which is said to agree with actual sound field. We have

$$TL_f = TL_0 - 5 \quad (44.19)$$

The three types of transmission loss presented above are compared in [Figure 44.3](#).

44.1.2.3 Stiffness Law of Transmission Loss [2]

The plate described above is assumed to be infinite. However, an actual plate is always supported by some structures at its boundaries and the plate size is finite. Transmission loss of a finite plate is considered to be related to the nature of excitation of vibration in the plate, for example, sound wave incidence, modes of vibration and characteristics of sound radiation. Therefore, the governing relationships become very complex. However, in the following frequency range, it is known that the transmission loss conforms to the mass law

$$\frac{c}{2a} < f < f_c \quad (44.20)$$

where a is length of shorter edge for rectangular plate.

When $f < c/2a$, the whole plate is excited in phase, and stiffness effects from the supports of its edges will appear. If we denote the equivalent stiffness of the plate as K and assume a loss factor of 0,

FIGURE 44.3 Theoretical transmission loss based on mass law.

the mechanical impedance of the plate is obtained by using Equation 44.8; thus

$$Z_m = j\left(\omega m - \frac{K}{\omega}\right) \quad (44.21)$$

The frequency at $Z_m = 0$ corresponds to the first mode natural frequency, f_{11} , of the plate (see Chapter 4), and consequently, the equivalent stiffness of rectangular plate with simple edge-support is given by

$$f_{11} = \frac{1}{2\pi} \sqrt{\frac{K}{m}} \equiv \frac{\pi}{2} \sqrt{\frac{B}{m}} \left[\left(\frac{1}{a}\right)^2 + \left(\frac{1}{b}\right)^2 \right] \quad (44.22)$$

Then,

$$K = B\pi^4 \left(\frac{1}{a^2} + \frac{1}{b^2} \right)^2$$

where a and b are the length of the short and long edges for the rectangular plate, respectively. When $f \ll f_{11}$ is assumed in Equation 44.21, the mass term can be neglected, and from Equation 44.6 the normal incidence transmission loss, TL_{s0} , is given by

$$\begin{aligned} TL_{s0} &= 10 \log \left| 1 - j \frac{K}{2\omega\rho c} \right|^2 \\ &= 10 \log \left[1 + \left(\frac{K}{2\omega\rho c} \right)^2 \right] \\ &\cong 20 \log(K/f) - 74.5 \end{aligned} \quad (44.23)$$

This is called the stiffness law of the transmission loss, and it shows a 6 dB decay per octave.

The characteristics mentioned above for single wall transmission loss are shown in Figure 44.4 and summarized below.

FIGURE 44.4 Transmission loss characteristics of a single wall.

1. Region I ($f \ll f_{11}$). Transmission loss is controlled by the stiffness of the panel:

$$TL = TL_0 - 40 \log\left(\frac{f}{f_{11}}\right) \quad (44.24)$$

2. Region II ($f \approx f_{11}$). Transmission loss is controlled by the lower-mode natural frequencies of the panel, and the estimation becomes very complex.
3. Region III ($f_{11} \ll f \leq f_c/2$). Transmission loss is controlled by the mass (surface density) of the panel:

$$TL = 18 \log mf - 44 \quad (44.25)$$

4. Region IV ($f > f_c/2$). Transmission loss is controlled by the mass and the damping of the panel, and it is reduced by coincidence effects.

For $f_c/2 < f \leq f_c$:

TL is represented by a straight line connecting the value at $f = f_c/2$ of Equation 44.25 and the value at $f = f_c$ of Equation 44.26.

For $f > f_c$:

$$TL = TL_0 + 10 \log\left(\frac{2\eta}{\pi} \frac{f}{f_c}\right) \quad (44.26)$$

44.1.3 Transmission Loss of Multiple Panels

To realize sound insulation of high performance, we often use a double wall or a multiple panel composed of insulation materials like steel plates and absorbing materials like fiber-glass. In this subsection, transmission loss of a multiple panel is described [3].

44.1.3.1 Calculation Method

Consider a multiple panel of infinite lateral extent as shown in Figure 44.5, which is composed of n acoustic elements, each element consisting of three basic materials, an impermeable plate, air space, and an absorption layer. Furthermore, consider a plane wave incident on the left-hand side surface of the n th element at angle θ . Let the sound pressure of the incident wave be p_i , and of the reflected wave be p_r , and the wave be propagating through the structure, and then radiating from the right-hand side of the first element as a plane wave of pressure p_t into a free field at transmission angle θ .

In the analysis, we append the subscript $k(= 1, 2, \dots, n)$ to the physical parameters of the k th element, and “2” and “1” to the left- and right-hand side values of these parameters, respectively, as shown in Figure 44.5. The ratio of the sound pressure at the incident surface, p_{n2} , to the incident wave, p_i , is given by

$$\frac{p_{n2}}{p_i} = \frac{p_i + p_r}{p_i} = \frac{2Z_{n2}}{Z_{n2} + \rho c / \cos \theta} \quad (44.27)$$

where Z_{n2} is the acoustic impedance of the left-hand side normal to the surface of the n th element and $\rho c / \cos \theta$ is the acoustic impedance normal to the surface, which is equal to the radiation impedance of the

FIGURE 44.5 Calculation model of n -element multiple panel.

first element, Z_{11} , shown in Figure 44.5. Using the usual condition of pressure matching at each interface, we can write the expression for the oblique incidence transmission coefficient as

$$\tau(\theta) = \left| \frac{p_t}{p_i} \right|^2 = \left| \frac{p_{11}}{p_i} \right|^2 = \left| \frac{p_{n2}}{p_i} \right|^2 \left| \frac{p_{n1}}{p_{n2}} \dots \frac{p_{k1}}{p_{k2}} \dots \frac{p_{11}}{p_{12}} \right|^2 \quad (44.28)$$

Hence, we obtain the following expression for the random incidence transmission loss:

$$TL = 10 \log \left(\frac{\int_0^{\theta_1} \cos \theta \sin \theta d\theta}{\int_0^{\theta_1} \tau(\theta) \cos \theta \sin \theta d\theta} \right) \quad (44.29)$$

where θ_1 is the limiting angle above which no sound is assumed to be received, and it varies between 78° and 85° .

If we know Z_{n2} in Equation 44.27 and the pressure ratio across each of the single elements in Equation 44.28, we can calculate the TL using Equation 44.29. We can obtain Z_{n2} by using the conditions of impedance matching at each interface from the rightmost to the leftmost element in order, if we know the impedance relations across each of the single elements.

Now, we present the pressure ratios and the acoustic impedance relations across three basic elements.

44.1.3.2 Impermeable Plate

Consider the vibration of an infinite impermeable plate of thickness, h , induced by the sound pressure difference on each side of the plate, as illustrated in Figure 44.6. In this case, the particle velocity on both sides of the plate must be the same as the plate vibration velocity. Then, from Equation 44.8, the following expressions are obtained:

$$Z_2 = Z_1 + Z_m \quad (44.30)$$

$$\frac{p_2}{p_1} = \frac{Z_2}{Z_1} \quad (44.31)$$

where p_2, p_1 are the sound pressure at the incident surface $x = 0$ and at the transmitted surface $x = h$,

respectively, Z_m is the mechanical impedance of the plate, and Z_2, Z_1 are the acoustic impedance normal to the incident surface at $x = 0$ and the transmitted one at $x = h$, respectively.

FIGURE 44.6 Excitation of infinite plate by a plane sound wave.

44.1.3.3 Sound Absorbing Material

For a sound absorbing material layer of thickness d and infinite lateral extent, consider a plane wave incident at an angle θ to the normal, as shown in Figure 44.7. Deriving the wave equation in the sound absorbing material and applying the continuity conditions of the sound pressure across the surface at $x = 0$ and $x = d$, with some mathematical manipulation we get the following results:

$$Z_2 = \frac{\gamma Z_0}{q} \coth(qd + \varphi) \quad (44.32)$$

$$\frac{p_2}{p_1} = \frac{\cosh(qd + \varphi)}{\cosh \varphi} \quad (44.33)$$

$$q = \gamma \sqrt{1 + \left(\frac{k}{\gamma}\right)^2 \sin^2 \theta}, \quad \varphi = \coth^{-1} \left(\frac{q Z_1}{\gamma Z_0} \right) \quad (44.34)$$

where γ is a propagation constant and Z_0 is a characteristic impedance of a homogeneous, isotropic absorbing material.

If porous material is used as the absorbing material, the following relations are applicable for γ and Z_0 [4]:

$$Z_0 = R + jX$$

$$R/\rho c = 1 + 0.0571(\rho f/R_1)^{-0.754} \quad (44.35)$$

$$X/\rho c = -0.0870(\rho f/R_1)^{-0.732}$$

$$\gamma = \alpha + j\beta$$

$$\alpha/k = 0.189(\rho f/R_1)^{-0.595} \quad (44.36)$$

$$\beta/k = 1 + 0.0978(\rho f/R_1)^{-0.700}$$

$$(0.01 \leq \rho f/R_1 \leq 1)$$

where ρ is the air density, f is the frequency, and R_1 is the flow resistivity, respectively. Specifically, note that R_1 is defined as the flow resistance of the porous absorbing material per unit thickness. With data measured with a measuring tube of flow resistance, we can write

$$R_1 = \frac{\Delta p}{l \cdot u} \quad (44.37)$$

where Δp is pressure difference between the inlet and the outlet of the absorbing material in the tube, u is the mean flow velocity in the tube, and l is the thickness of the absorbing material. It is known that the flow resistivity of porous absorbing material such as fiber-glass or rock wool is related to the bulk density, as shown in Figure 44.8.

44.1.3.4 Air Space

For an air space, $Z_0 = \rho c$ and $\gamma = jk$. Hence, Equation 44.32 to Equation 44.34 reduce to

$$Z_2 = \frac{\rho c}{\cos \theta} \coth(jkd \cos \theta + \delta) \quad (44.38)$$

$$\frac{p_2}{p_1} = \frac{\cosh(jkd \cos \theta + \delta)}{\cosh \delta} \quad (44.39)$$

$$\delta = \coth^{-1} \left(\frac{Z_1 \cos \theta}{\rho c} \right) \quad (44.40)$$

44.1.3.5 Double Wall [2]

Applying the theory formulated above, we can easily obtain the transmission loss of a double wall composed of the three elements: impermeable plate, air space, and impermeable plate, as shown in Figure 44.9. Assume that the two impermeable plates have the same surface density, m , and the mechanical impedance of the plates is $j\omega m$. Then, we can obtain following equations for element

FIGURE 44.7 Schematic relation of sound wave directions.

FIGURE 44.8 Flow resistivity vs. bulk density for porous, sound absorbing materials.

one and element three:

$$Z_{12} = Z_{11} + Z_m = \frac{\rho c}{\cos \theta} + j\omega m, \quad (44.41)$$

$$\frac{p_{12}}{p_{11}} = \frac{Z_{12}}{Z_{11}} = 1 + j \frac{\omega m \cos \theta}{\rho c}$$

$$Z_{32} = Z_{31} + Z_m = Z_{22} + j\omega m, \quad (44.42)$$

$$\frac{p_{32}}{p_{31}} = \frac{Z_{32}}{Z_{22}} = 1 + j \frac{\omega m}{Z_{22}}$$

For element two:

$$Z_{22} = \frac{\rho c}{\cos \theta} \coth (jkd \cos \theta + \delta'), \quad (44.43)$$

$$\frac{p_{22}}{p_{21}} = \frac{\cosh (jkd \cos \theta + \delta')}{\cosh \delta'}$$

where, by applying impedance matching

conditions at the interface of element one and element two, the following definition is introduced:

$$\delta' = \coth^{-1} \left(\frac{Z_{21} \cos \theta}{\rho c} \right) = \coth^{-1} \left(\frac{Z_{12} \cos \theta}{\rho c} \right) = \coth^{-1} \left(1 + j \frac{\omega m \cos \theta}{\rho c} \right) \quad (44.44)$$

In this case, Equation 44.27 reduces to

$$\frac{p_i}{p_{32}} = \frac{Z_{32} + \rho c / \cos \theta}{2Z_{32}} = \frac{Z_{22} + j\omega m + \rho c / \cos \theta}{2(Z_{22} + j\omega m)} \quad (44.45)$$

Substituting Equation 44.41 to Equation 44.45 into Equation 44.28, we obtain the transmission loss of the double wall:

$$TL_\theta = 10 \log[1/\tau(\theta)] = 10 \log[1 + 4a^2 \cos^2 \theta (\cos \beta - a \cos \theta \sin \beta)^2] \quad (44.46)$$

$$a = \omega m / 2\rho c, \quad \beta = kd \cos \theta$$

In Equation 44.46, the transmission loss is zero, and full passage (i.e., “all-pass” in the filter terminology) of sound occurs when the following equation holds:

$$\cos \beta - a \cos \theta \sin \beta = 0 \quad (44.47)$$

When $\beta \ll 1 (kd \ll 1)$, the frequency of full passage for normal incidence is given by

$$f_r = \frac{1}{2\pi} \sqrt{\frac{2\rho c^2}{md}} \quad (44.48)$$

This is the natural frequency of a vibrating system consisting of two masses, m , connected by a spring of spring constant, $\rho c^2/d$.

When $\beta \gg 1 (kd \gg 1)$, the solution of Equation 44.47 for β is $\beta \cong n\pi$, and the frequency of all passage for normal incidence is given by

$$f_n = \frac{nc}{2d} \quad (n = 1, 2, 3, \dots) \quad (44.49)$$

These are the acoustic resonant frequencies of the air space d .

Characteristics of the transmission loss given by Equation 44.46, in case of normal incidence ($\theta = 0$), are as follows:

$$1. f < f_r (\beta < \sqrt{2\rho d/m})$$

$$TL \cong 10 \log(4a^2) = TL_0 + 6 \quad (44.50)$$

This is equal to the transmission loss of a single wall of surface density $2m$.

FIGURE 44.9 Calculation model of a double wall with air space.

$$2. f_r \leq f < f_1/\pi \left(\sqrt{2\rho d/m} \leq \beta < 1 \right)$$

$$TL \cong 10 \log(4a^4\beta^2) = 2TL_0 + 20 \log(2kd) \quad (44.51)$$

This transmission loss indicates an 18 dB increase per octave.

$$3. f = (2n - 1)c/4d (\beta = n\pi - \pi/2)$$

$$TL \cong 10 \log(4a^4) = 2TL_0 + 6 \quad (44.52)$$

A straight line connecting the transmission losses at these frequencies in Figure 44.10 indicates a 12 dB increase per octave. When the two impermeable plates have different surface densities, m_1 and m_2 , Equation 44.41 to Equation 44.52 reduce to

$$1. f < f_r (\beta < \sqrt{2\rho d/m})$$

$$TL = 20 \log[\omega(m_1 + m_2)/2\rho c] \quad (44.53)$$

$$2. f_r \leq f < f_1/\pi (\sqrt{2\rho d/m} \leq \beta < 1)$$

$$TL = TL_1 + TL_2 + 20 \log(2kd) \quad (44.54)$$

$$3. f = (2n - 1)c/4d (\beta = n\pi - \pi/2)$$

$$TL = TL_1 + TL_2 + 6 \quad (44.55)$$

In these equations, TL_1 and TL_2 are the transmission losses of each plate, which are given by Equation 44.15.

The transmission loss of a double wall, as mentioned above, is shown schematically in Figure 44.10. An actual double wall, however, is finite in size and the air space forms a closed acoustic field, which

FIGURE 44.10 Transmission loss of a double wall with air space.

FIGURE 44.11 Design chart for estimating the transmission loss of a double wall with sandwiched porous material or air space.

makes the transmission loss deviate from the theoretical value. Figure 44.11 gives a design chart of an actual double wall, which is based on theory and experiments.

44.1.4 Transmission Loss of Double Wall with Sound Bridge [5]

In the previously presented theory, each plate of the multiple panel is considered to be structurally independent. In actual multiple panels, such as partitions of a building or sound insulation laggings of a duct, however, each plate is connected with steel sections, stud bolts, and the like, which are called sound bridges. This is illustrated in Figure 44.12.

The sound pressure of the transmitted wave through a double wall with sound bridges is given by the summation of radiated sound pressure from the vibration of the transmitted side plate excited by the sound in the air space and that mechanically excited by the sound bridges.

FIGURE 44.12 Examples of actual double wall with sound bridges.

The acoustic power radiated from the area, S , of an infinite plate excited by sound pressure is given by

$$W_p = \rho c S v_2^2 \quad (44.56)$$

where v_2^2 is the space averaged mean square vibration velocity over the plate. The acoustic power radiated from the plate mechanically excited by a point force or a line force is

$$W_B = \rho c \chi v^2 (f < f_c) \quad (44.57)$$

$$\chi = \begin{cases} \frac{8}{\pi^3} \lambda_c^2 & \text{(point force excitation)} \\ \frac{2}{\pi} l \lambda_c & \text{(line force excitation)} \end{cases} \quad (44.58)$$

where v^2 is the mean square vibration velocity of the plate at the excitation point, $\lambda_c = c/f_c$ is the wavelength of the bending wave at the critical frequency, and l is the length of the line force. By comparing Equation 44.56 and Equation 44.57, it is noted that χ is the effective area of the acoustic power radiated from the infinite plate excited by the point or line force. Acoustic power, W_B , is the power radiated from a small area near the excitation point, because a free bending wave propagating in an infinite plate can radiate little sound when $f < f_c$.

From the equations given above, the total acoustic power radiated from the transmitted side plate is obtained as

$$W_T = W_p + W_B = \rho c S v_2^2 \left[1 + \frac{n\chi}{S} \left(\frac{v}{v_2} \right)^2 \right] \quad (44.59)$$

where n is the number of excitation forces applied to the area, S . Then, transmission loss TL_T of the double wall with sound bridges is given by

$$TL_T = 10 \log \left(\frac{W_I}{W_T} \right) = 10 \log \left(\frac{W_I}{W_p} \cdot \frac{W_p}{W_T} \right) = TL - TL_B \quad (44.60)$$

where W_I is the acoustic power incident on the double wall, TL is the transmission loss of the double wall without a sound bridge, and TL_B denotes the transmission loss reduction by the sound bridges, and is given by

$$TL_B = 10 \log \left(\frac{W_T}{W_p} \right) = 10 \log \left[1 + \frac{n\chi}{S} \left(\frac{v}{v_2} \right)^2 \right] \quad (44.61)$$

We assume the following:

1. The vibration velocity of the incident side plate is not affected by the sound bridges.
2. The vibration velocity of the transmitted side plate at the excitation points (connecting points) is equal to the velocity v_1 of the incident side plate, and consequently, the next equation holds

$$\frac{v}{v_2} \cong \frac{v_1}{v_2}$$

With these assumptions, we apply the method presented in section 44.1.3, to determine v/v_2 as

$$\frac{v}{v_2} \cong \frac{v_1}{v_2} = \frac{\omega^2 m_2 d}{\rho c^2} \quad (f_r < f < f_1/\pi) = \frac{\omega m_2}{\rho c} \quad (f > f_1/\pi) \quad (44.62)$$

Using Equation 44.60 and Equation 44.53, we can obtain the increase in transmission loss, ΔTL , from the transmission loss of mass law based on the total mass of the double wall, as presented below.

FIGURE 44.13 Design chart for estimating the transmission loss of a double wall with sound bridges.

1. Point connection

$$\begin{aligned}\Delta TL &= TL - TL_B - 20 \log \left[\frac{\omega(m_1 + m_2)}{2\rho c} \right] \\ &= 20 \log(e f_c) + 20 \log \left(\frac{m_1}{m_1 + m_2} \right) + 10 \log \left(\frac{\pi^3}{8c^2} \right)\end{aligned}\quad (44.63)$$

2. Line connection

$$\begin{aligned}\Delta TL &= TL - TL_B - 20 \log \left[\frac{\omega(m_1 + m_2)}{2\rho c} \right] \\ &= 10 \log(b f_c) + 20 \log \left(\frac{m_1}{m_1 + m_2} \right) + 10 \log \left(\frac{\pi}{2c} \right)\end{aligned}\quad (44.64)$$

where $e = \sqrt{S/n}$ is the distance between point forces and $b = S/nl$ is the distance between line forces.

Figure 44.13 presents a practical and useful design chart of the transmission loss for a double wall with sound bridges, which is based on Figure 44.11 and Equation 44.63 and 44.64.

44.2 Application of Sound Insulation

44.2.1 Acoustic Enclosure

Performance of an enclosure may be represented by the insertion loss (IL), which is the difference of acoustic power level before and after installation of the enclosure. When we assume a noise source and also an enclosure with one-dimensional model as shown in Figure 44.14a, the insertion loss through frequency is shown in Figure 44.14b. It is divided into the following four regions:

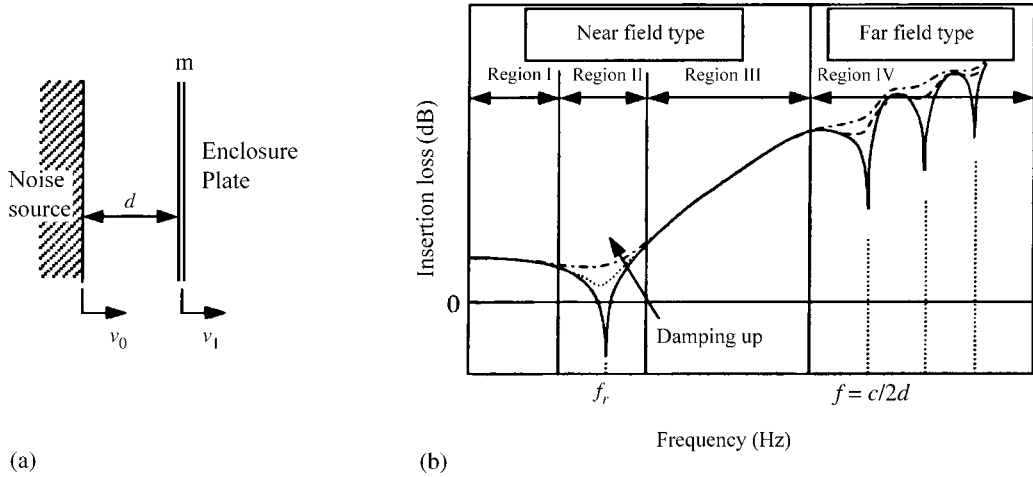

FIGURE 44.14 One-dimensional model for calculating the insertion loss characteristics of an acoustic enclosure: (a) One-dimensional model; (b) insertion loss of an enclosure.

1. Region I ($f < f_r$) is controlled by the stiffness of the enclosure plate and air space.
2. Region II ($f \cong f_r$) is the resonance region for a vibrating system consisting of the mass, the stiffness of the enclosure plate, and the capacitance of air space.
3. Region III ($f_r < f < c/2d$) is controlled by the mass of the enclosure plate.
4. Region IV ($f > c/2d$) is controlled by the diffused sound field. This region cannot be represented by a one-dimensional model.

44.2.1.1 Near Field Type [4]

When the distance between the noise source and the enclosure is less than half of a wavelength of the emitted sound from the source, insertion loss corresponds to the characteristics of the regions I to III, and we can represent them with a one-dimensional acoustic model, as shown in Figure 44.14a.

Consider an infinite flat enclosure plate with distance d from a noise source of plane sound wave, as shown in Figure 44.14a. The insertion loss of the plate is given by

$$IL = 10 \log \left(\frac{v_0}{v_1} \right)^2 = 10 \log \left[1 - \frac{2 \sin \theta (X \cos \theta - R \sin \theta)}{\rho c} + \frac{\sin^2 \theta (X^2 + R^2)}{\rho^2 c^2} \right] \quad (44.65)$$

$$\theta = kd = \omega d/c, \quad R = \eta \omega m, \quad X = (\omega m - K/\omega) = \omega m [1 - (\omega_{11}/\omega)^2], \quad \omega_{11} = \sqrt{K/m}$$

where m and K are the density and equivalent stiffness of the plate per unit area, respectively, and η is the loss factor of the plate. If the enclosure is a rectangular plate of size $a \times b$ and is simply supported at its edges, the equivalent stiffness is given by Equation 44.22, and ω_{11} is the natural (angular) frequency of the first mode.

In Equation 44.65, the conditions in which the brackets of the right-hand side are equal to zero or $IL = -\infty$ are satisfied by following frequencies:

- (1) $\theta \ll \pi$

$$f_r = \frac{1}{2\pi} \sqrt{\frac{K + \rho c^2/d}{m}} = \frac{1}{2\pi} \sqrt{\omega_{11}^2 + \frac{\rho c^2}{md}} \quad (44.66)$$

This is the natural frequency of vibration of the one-degree-of-freedom (one-DoF) system determined by the stiffness of the plate, the spring constant of the air space, and the surface density of the plate, as shown in Figure 44.15.

$$(2) \theta = n\pi \quad (n = 1, 2, \dots)$$

$$f_n = \frac{nc}{2d} \quad (n = 1, 2, \dots) \quad (44.67)$$

These are the resonant frequencies of the air space.

The frequency characteristics of the IL given by Equation 44.65 are shown in Figure 44.16, where the normal incidence transmission losses are shown by broken lines, as a reference. Equation 44.65 is approximated by

$$1. f < f_r$$

$$IL \cong 10 \log \left(1 + \frac{2Kd}{\rho c^2} \right) \quad (44.68)$$

$$2. f_r \leq f < f_1$$

$$IL \cong 20 \log(mdf^2) + 20 \log \left(\frac{4\pi^2}{\rho c^2} \right) \quad (44.69)$$

$$= 20 \log(mdf^2) - 71$$

44.2.1.2 Far Field-Type (Absorption Type) Enclosure [1]

When the distance between the noise source and the enclosure is larger than half of a wavelength of the emitted sound, insertion loss may be represented by the characteristics of Region IV, and it can be analyzed using the theory of room or hall acoustics.

Consider the enclosure shown in Figure 44.17, with a noise source of power level L_{W0} .

From the theory of room acoustics, the average sound pressure level, L_{p0} , on the inner surface of the enclosure plate is obtained as the sum of the direct and reverberant sound pressures:

$$L_{p0} = L_{W0} + 10 \log \left(\frac{1}{S} + \frac{4}{R} \right)$$

$$= L_{W0} - 10 \log S + 10 \log \left(1 + \frac{4S}{R} \right) \quad (44.70)$$

$$R = \frac{\bar{\alpha}S}{(1 - \bar{\alpha})} \quad (44.71)$$

where S is the inner surface area of the enclosure and $\bar{\alpha}$ is the average absorption coefficient on the inner surface of the enclosure. In Equation 44.70, the first and the second terms of the right-hand side represent the influence of the direct sound field, and the third term represents the buildup caused by the covering.

When we use S_p for the area of the enclosure plate and $S_O (= S - S_p)$ for the area of the enclosure opening, and assume diffusing condition for the sound field in the enclosure, acoustic power levels

$$\text{Curve A: } f_{11} = 0 \text{ Hz, } \eta \cong 0.033 \text{ (at 33 Hz)}$$

$$\text{Curve B: } f_{11} = 100 \text{ Hz, } \eta \cong 0.033 \text{ (at 105 Hz)}$$

$$\text{Curve C: } f_{11} = 475 \text{ Hz, } \eta \cong 0.033 \text{ (at 475 Hz)}$$

FIGURE 44.16 Example of theoretical insertion loss of a near field-type enclosure.

FIGURE 44.17 Calculation model of a far field type enclosure.

radiated from the plate and the opening are given, respectively, by

$$L_{WP} = L_{P0} - (TL + 6) + 10 \log S_P, \quad (44.72)$$

$$L_{W0} = L_{P0} - 6 + 10 \log S_O$$

where TL is the random incident transmission loss of the enclosure plate. Then, the insertion loss of the enclosure is

$$IL = L_{W0} - 10 \log(10^{L_{WP}/10} + 10^{L_{W0}/10}) \quad (44.73)$$

In the design of an acoustic enclosure, special attention should be paid to the following points:

1. *Buildup* increases the sound pressure in the enclosure and also the power level radiated from the enclosure. We must treat the inner surface of the enclosure with sound absorbing materials to reduce the absorption coefficient and to decrease the buildup.
2. *Opening* radiates more acoustic power than the enclosure plate by TL, as is clear from Equation 44.72. It is desirable to make the opening as small as possible within the range given by

$$\frac{S_O}{S_P} \leq 10^{-TL/10} = \tau \quad (44.74)$$

This equation means that the acoustic power from the opening is less than that from the enclosure plate. If the relation in Equation 44.74 cannot be satisfied because of ventilation requirements, and so on, some type of silencers should be provided at the opening, as shown in Figure 44.18.

3. *Structure-borne noise*, which is caused by the vibration propagating from the base of the machine (noise source) to the enclosure plate, significantly decreases the insertion loss of the enclosure. In this case, some means of noise/vibration suppression should be provided, for example, the following:
 - Place supporting structures of the enclosure at the points of lowest vibration level, and the vibrations of the machine should be prevented from propagating to the enclosure plate, using vibration isolation materials.
 - Add damping materials to the enclosure plate so as to reduce the vibration level of the plate.

FIGURE 44.18 Example of a silencer at the opening.

44.2.2 Sound Insulation Lagging

In electric power plants and chemical plants, for example, piping for high-pressure water or steam, and ducts for air or gas flow form major noise sources. For controlling these noise sources, we usually use sound insulation laggings, which cover the noise sources with heavy and impermeable plates or sheets with sound absorbing materials, as shown in Figure 44.19.

44.2.2.1 Pipe Lagging [2]

Approximate the cylindrical piping and pipe lagging with a one-dimensional model as shown in Figure 44.20. The insertion loss of one-layered lagging approximated by a one-DoF system is given by Equation 44.69 in the frequency region $f_r \leq f < f_1$, as mentioned before. It is not practical, however, to directly apply Equation 44.69 to actual laggings, and we approximate the insertion loss of actual laggings by

$$IL = a \log(mdf^2) + b$$

where a and b are constants.

FIGURE 44.19 Examples of typical sound insulation laggings: (a) pipe lagging, (b) duct lagging.

By taking mdf^2 as the horizontal axis and plotting the insertion loss data from laboratory tests and field tests (the vertical coordinates), we obtain Figure 44.21. Apply regression analysis to the data in Figure 44.21 to obtain the insertion loss of one layered lagging as

$$IL = 11.7 \log(mdf^2) - 43.3 \quad (5 \times 10^3 \leq mdf^2 \leq 10^8) \quad (44.75)$$

Applying the same method to double layered lagging, approximated by a two-DoF vibrating system, we get Figure 44.22, and the insertion loss

$$IL = 6.9 \log(m_1 m_2 d_1 d_2 f^4) - 40.3 \quad (10^6 \leq m_1 m_2 d_1 d_2 f^4 \leq 10^{15}) \quad (44.76)$$

where the subscripts “1” and “2” denote the first layer and the second layer, respectively.

FIGURE 44.20 Examples of pipe laggings and calculation model: (a) one-layered lagging; (b) double-layered lagging.

FIGURE 44.21 Measured insertion loss data obtained from laboratory and field tests for one-layered laggings and regression analysis.

FIGURE 44.22 Measured data of insertion loss obtained from laboratory and field tests for double-layered laggings and regression analysis.

44.2.2.2 Duct Lagging [4]

Various types of the duct laggings are used according to the need, for example, as shown in Figure 44.19. A simpler and more practical approach is to place a thin plate on the duct casing through absorbing materials, as shown in Figure 44.23. In this case, assuming that vibration of the duct casing is not affected by the placed plate, the insertion loss of the duct lagging is obtained by following equations, which can be deduced from the method used in the transmission loss of double wall with sound bridges.

FIGURE 44.23 Examples of duct laggings and connection types of thin plate to the duct casing: (a) point connection; (b) line connection.

1. Point connection

$$IL = -10 \log \left[\beta^2 \frac{8}{\pi^3} n_p \frac{c^2}{f_c^2} + \left(\frac{f_r}{f} \right)^4 \right] + 10 \log \sigma \quad (44.77)$$

2. Line connection

$$IL = -10 \log \left[0.64 n_L \frac{c}{f_c} + \left(\frac{f_r}{f} \right)^4 \right] + 10 \log \sigma \quad (44.78)$$

where

β = vibration isolation factor of the flexible support ($\beta = 1$ for rigid support)

n_p = number of attachment points per unit area

n_L = number of studs per unit length

FIGURE 44.24 Plateau height for point connection as a function of the number of bridges per unit area [4]. (Source: Beranek, L. L. 1988. *Noise and Vibration Control*, INCE/USA. With permission.)

FIGURE 44.25 Plateau height for line connection as a function of the number of studs per unit length [4]. (Source: Beranek, L. L. 1988. *Noise and Vibration Control*, INCE/USA. With permission.)

f_c = critical frequency of the thin plate given by Equation 44.12

f_r = resonant frequency given by Equation 44.66

σ = sound radiation efficiency of the thin plate

Knowing the critical frequency, f_c , and the resonant frequency, f_r , we can obtain the insertion loss from the charts given in Figure 44.24 and Figure 44.25 instead of using Equation 44.77 and Equation 44.78. In Figure 44.24 and Figure 44.25, it is assumed that $\sigma = 1$. Note from Equation 44.77 and Equation 44.78 that we must consider the following measures to obtain a higher insertion loss.

1. Make the distance between attachment points or studs as large as possible (decrease n_p and n_L).
2. Make the air space as large as possible (decrease f_r).

Summary

This chapter presents the basics of statistical energy analysis (SEA) as applied to acoustic problems in structural systems. Power flow equations for structures consisting of two or more subsystems are described. The modeling and analysis procedures for the structural subsystems and acoustic subsystems are given. An estimation procedure of the necessary SEA parameters is given. The practical application of the SEA procedure in structures is illustrated using a two-story building as an example.

45.1 Introduction

This chapter describes the basic concepts of the method of statistical energy analysis (SEA) and presents its application to structures. The analysis and computation techniques for vibration response and radiating sound in instruments and structures vary according to the characteristics of the physical object and the frequency range of interest. Here, we analyze vibration and noise in relation to a rather large-scale structure over a wide frequency band. Extensive computations are usually required, when, for example, the finite element method (see Chapter 9) is used for the computations, with respect to a given oscillation mode. In particular, when the computations must be performed in the high-frequency range and when many modes are included in the frequency band, the level of computation becomes considerable, generally resulting in reduced computational accuracy. To supplement the weak point of the traditional approach, it is necessary to redistribute statistically the energy equally from all modes in the analytical frequency band. This allows computed results to be compared with experimental results for a structure across a wide frequency band. This is the SEA method [1]. Early in its development, the objective of this analytical method was to predict the vibration response of artificial satellites and rockets that receive sound excitation when the jet discharges, and to predict the response of vibration stress in the boundary layer noise of an aircraft's airframe. It also became a model that allows an

exciting force to be statistically (randomly) diffused (distributed) over a wide frequency band. This technique considers energy of excitation of a diffused (distributed) sound field and its variables that represent the sound pressure, acceleration, and force. Thus, it can be applied to problems of solid-borne sound in which vibration propagates through each element [2] and problems of air-borne sound in which multiple barriers exist [3], even when more excitation points than one are present.

45.2 Power Flow Equations

With the SEA method, we do not deal with specific characteristic modes (see Chapter 3 and Chapter 4) of the analyzed structure. Instead, we consider the structural components as a set of equivalent vibrating elements, and evaluate the vibration condition of the components as a macroscopic quantity averaged statistically over the frequency band and space (by describing the energy). We assume that the vibration modes within a given frequency band are distributed uniformly and are excited to the same degree.

Using the SEA method, we can formalize the relationships of power flows between subsystems, and by solving these relationships, we can compute the energy stored in each subsystem. Next, the equations of such basic power flow [4] are explained.

45.2.1 Power Flow Equations of a Two-Subsystem Structure

The power flow relationships of a structure consisting of a two-subsystem structure are shown in Figure 45.1. The equations for the power flows between subsystem 1 and subsystem 2 under typical conditions are expressed as

$$\text{Subsystem 1: } P_{i1} = P_{l1} + P_{12} \quad (45.1)$$

$$\text{Subsystem 2: } P_{i2} = P_{l2} + P_{21} \quad (45.2)$$

where P_{i1} is the input power to subsystem 1 from outside, P_{l1} is the internal power loss of subsystem 1, and P_{12} is the transmitted power from subsystem 1 to subsystem 2.

The internal power loss, P_{l1} , is written as

$$P_{l1} = \omega \eta_1 E_1 \quad (45.3)$$

where ω is the central angular frequency in the band, E_1 is the energy in the bandwidth $\Delta\omega$ of subsystem 1, and η_1 is the internal loss factor (ILF).

The average modal energy E_{m1} in subsystem 1, and E_{m2} in subsystem 2, are given by

$$E_{m1} = \frac{E_1}{N_1}, \quad E_{m2} = \frac{E_2}{N_2} \quad (45.4)$$

where N_1 is number of modes in the bandwidth $\Delta\omega$ of subsystem 1, and N_2 is number of modes in the bandwidth $\Delta\omega$ of subsystem 2.

The transferred power, P_{12} , between subsystems 1 and 2 is expressed as

$$P_{12} = -P_{21} = P'_{12} - P'_{21} \quad (45.5)$$

$$P'_{12} = \omega \eta_{12} E_1 = \omega \eta_{12} N_1 E_{m1} \quad (45.6)$$

$$P'_{21} = \omega \eta_{21} E_2 = \omega \eta_{21} N_2 E_{m2} \quad (45.7)$$

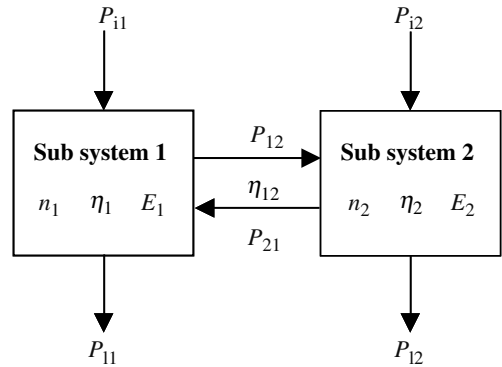

FIGURE 45.1 Power flow relationships between two subsystems.

where η_{12} and η_{21} are the coupling loss factors (CLFs) from subsystem 1 to subsystem 2, and from subsystem 2 to subsystem 1. They satisfy the reciprocity relationship $\eta_{12}n_1 = \eta_{21}n_2$. Therefore, transferred power, P_{12} , becomes

$$P_{12} = \omega\eta_{12}N_1(E_{m1} - E_{m2}) = \omega\eta_{12}N_1\left(\frac{E_1}{N_1} - \frac{E_2}{N_2}\right) \quad (45.8)$$

Consequently, the power flow equations (Equation 45.1 and Equation 45.2) can be expressed as follows:

$$P_{11} = \omega\eta_1E_1 + \omega\eta_{12}N_1\left(\frac{E_1}{N_1} - \frac{E_2}{N_2}\right) \quad (45.9)$$

$$P_{12} = \omega\eta_2E_2 + \omega\eta_{21}N_2\left(\frac{E_2}{N_2} - \frac{E_1}{N_1}\right) \quad (45.10)$$

If the SEA parameters (i.e., the modal density, intrinsic loss factor, CLF, and input power) are given, then each subsystem's energy condition can be easily computed.

45.2.2 Power Flow Equations of a Multiple Subsystem Structure

By expanding the formulation in the previous section, it is possible to formalize the power flow relationships of a structure composed of multiple subsystems in the same way. The power flow equation for a structure composed of N subsystems is expressed by the following equation in the matrix form:

$$\omega \begin{bmatrix} \left(\eta_1 + \sum_{i \neq 1}^N \eta_{1i}\right)n_1 & -\eta_{12}n_1 & \cdots & -\eta_{1N}n_1 \\ -\eta_{21}n_2 & \left(\eta_2 + \sum_{i \neq 2}^N \eta_{2i}\right)n_2 & \cdots & -\eta_{2N}n_2 \\ \vdots & \vdots & \ddots & \vdots \\ -\eta_{N1}n_n & \cdots & \cdots & \left(\eta_N + \sum_{i \neq N}^{N-1} \eta_{Ni}\right)n_N \end{bmatrix} \times \begin{bmatrix} E_1/n_1 \\ E_2/n_2 \\ \vdots \\ E_N/n_N \end{bmatrix} = \begin{bmatrix} P_{11} \\ P_{12} \\ \vdots \\ P_{1N} \end{bmatrix} \quad (45.11)$$

From Equation 45.11, if the SEA parameters are given in the same way as for the structure of two subsystems, then the energy equation of each subsystem can be obtained.

The average energy of a subsystem is expressed by the following equations by using the vibration velocity and sound pressure:

$$E = M\langle v^2 \rangle \quad (45.12)$$

$$E = \frac{M\langle p^2 \rangle}{Z_0^2} \quad (45.13)$$

where M is the mass of the subsystem, $\langle v^2 \rangle$ is the average spatial square of the vibration velocity, $\langle p^2 \rangle$ is the average spatial square of the sound pressure, and Z_0 is the specific acoustic impedance of air.

Accordingly, if each condition of component's energy is determined from Equation 45.11, it is possible to compute the vibration variable and the sound pressure with Equation 45.12 and Equation 45.13.

45.3 Estimation of SEA Parameters

To solve the power flow equations, it is necessary to determine the SEA parameters (i.e., the modal density, ILF, CLF, and input power). In this subsection, a method is given for computing the SEA parameters.

45.3.1 Modal Density

45.3.1.1 Structural Subsystem

Modal density is a key parameter for determining the dynamic characteristic of a structure. The number of modes, N , included in the frequency band (for estimation), is a factor denoting how easily energy, in transferring between subsystems, can be obtained. To determine N in the prescribed frequency band, it is first necessary to determine the modal density $n(f)$, that is, the gradient of N in the frequency band.

The modal density of a structural subsystem is computed by using the following equation [4,5]:

$$n(f) = \frac{dN}{df} = \frac{1}{f_0} = \frac{A}{2t} \sqrt{\frac{12\rho(1-\nu^2)}{E}} \quad (45.14)$$

where A is the area of cross section, t is the thickness of the structural subsystem, ρ is the mass density, ν is the Poisson's ratio, E is the Young's modulus, and f_0 is the fundamental natural frequency of the structural subsystem.

45.3.1.2 Acoustic Subsystem

The modal density of an acoustic subsystem is determined by the following analytical equation [6]:

$$n(f) = \frac{dN}{df} = \frac{4\pi V}{c^3} f^2 \quad (45.15)$$

where c is the speed of sound propagation within the acoustic subsystem, and V denotes the volume of the acoustic subsystem.

Modal density of the cavity in the low frequency band is deduced in a similar manner to that in the two-dimensional space. Define the depth of the cavity by d , and the frequency of the standing wave in the cavity by $f_d = c/2d$. If $f < f_d$, then the modal density is assumed to be uniformly distributed, and is estimated by

$$n(f) = \frac{2\pi S}{c^2} f \quad (45.16)$$

where S is the area of the cavity.

If $f > f_d$, modal density can be estimated using Equation 45.15, because the cavity is designated as acoustically three dimensional.

45.3.2 Internal Loss Factor

45.3.2.1 Structural Subsystem

The ILF, η_1 , of a subsystem gives the loss ratio when the input power to the subsystem from the outside is converted to kinetic energy of the subsystem. An excitation test to measure the damping ratio is employed to estimate the ILF of the structural subsystem. There are several methods for estimating the internal loss factor. The ILF applied in the SEA method is estimated by measuring input energy and output energy simultaneously, or by measuring the attenuation ratio within a given period of time. Both methods require the same setup to conduct an excitation test, and one is able to improve the measurement precision by conducting both methods.

With the energy measuring methods mentioned above, the ILF can be estimated by

$$\eta = \frac{\int_{f_1}^{f_2} \text{Re}(Y) F^2 df}{\omega_0 M \left\langle \int_{f_1}^{f_2} v^2 df \right\rangle} \quad (45.17)$$

where Y is the complex mobility at the driving point in the range of f_1 to f_2 , F^2 is the power spectrum of the input vibration force, and v^2 is the power spectrum of the response speed. In addition, $\langle \rangle$ denotes the space average operator.

45.3.2.2 Acoustic Subsystem

The ILF of an acoustic subsystem is determined by [7]

$$\eta = \frac{cS\bar{\alpha}}{4V\omega} \quad (45.18)$$

where $\bar{\alpha}$ is the average acoustic absorption coefficient, V is the volume of the acoustic subsystem, and S denotes the surface area. The acoustic absorption coefficient can be estimated by measuring the reverberation time.

Both the ILF of the cavity in the low-frequency band and the modal density are deduced similar to that in two-dimensional spaces. For $f < f_d$, the ILF is estimated using

$$\eta = \frac{cS_p\alpha_p}{\pi\omega V_c} \quad (45.19)$$

where α_p is the acoustic absorption coefficient in the cavity, S_p is the peripheral area of the cavity, and V_c is the volume of the cavity.

For $f > f_d$, the modal density can be estimated using Equation 45.18 because the cavity is taken as an acoustic subsystem.

45.3.3 Coupling Loss Factor

45.3.3.1 Between Structural Subsystems

The CLF η_{ij} gives the loss ratio when power transmits between two subsystems [4]. For example, the CLF between two flat plates can be estimated using

$$\eta_{ij} = \frac{c_{gi}L_c\tau}{\pi\omega S_i} \quad (45.20)$$

where c_{gi} is the group velocity of the bending waves, L_c is the coupled length, S_i is the surface area, and τ_{ij} is the energy transmission factor from subsystem i to subsystem j . The transmission factor varies with the type of coupling, for example, I-type, L-type, or T-type shown in Figure 45.2. In this section, we use energy transmission efficiency of vertical incidence, reported by Cremer [7].

FIGURE 45.2 Coupled type.

45.3.3.2 Between a Structural Subsystem and an Acoustic Subsystem

Coupling power between a structural subsystem and an acoustic subsystem is the power flow based on resonance at transmission. The CLF between a structural subsystem and an acoustic subsystem is given by

$$\eta_{ij} = \frac{Z_0 S_c \sigma}{\omega M_i} \quad (45.21)$$

where Z_0 is the specific acoustic impedance of air, S_c is the surface area of coupling, σ is the acoustical radiation efficiency, and M_i is the mass of the structural subsystem.

45.3.3.3 Between an Acoustic Subsystem and a Cavity

Coupling power between an acoustic subsystem and a cavity is power flow based on resonance in transmission. The CLF between an acoustic subsystem and a cavity is given by [8]

$$\eta_{sc} = \frac{c_s S_{cs} \tau_m}{4\omega V_s} \quad (45.22)$$

where c_s is the sound velocity in the acoustic space, V_s is the volume in the acoustic space, τ_m is the transmission factor at random incidence depending on mass flow through the partition, and S_{cs} is the coupling area.

45.3.4 Input Power

45.3.4.1 Vibration Input Power

The vibration input power P_{iN} is given by

$$P_{iN} = \omega M_i \langle v_i^2 \rangle \quad (45.23)$$

where M_i is the equivalent mass, $\langle v_i^2 \rangle$ is the spatial average of square of the vibration velocity, and ω is the central angular frequency.

45.3.4.2 Acoustical Input Power

The acoustical input power P_s is given by

$$P_s = \frac{\langle p^2 \rangle S^2 n(f)}{4M} \sigma_{\text{rad}} \frac{c^2}{2\pi S f^2} \quad (45.24)$$

where $\langle p^2 \rangle$ is the square average of the input sound pressure, S is the surface area of the component, M is the mass of the component, $n(f)$ is the modal density, and σ_{rad} is the sound radiation factor [2].

FIGURE 45.3 Modeling of the tractor cabin.

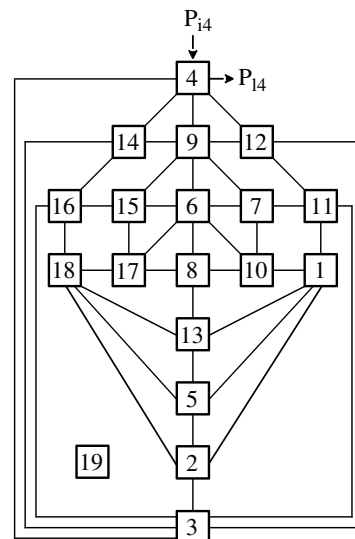

FIGURE 45.4 Power flows in the tractor cabin.

45.4 Application in Structures

In this section, we present an example of modeling with significant analytical accuracy, and discuss the application of the SEA method for structures.

45.4.1 Application for Prediction of Noise in a Tractor Cabin

Figure 45.3 shows a model of the tractor cabin. This figure shows that the cabin consists of a floor, a door, a ceiling, and other components. Figure 45.4 presents the power flow relationships within the cabin [9,10].

FIGURE 45.5 Results of estimating the sound pressure level in a cabin.

FIGURE 45.6 The configuration of the building.

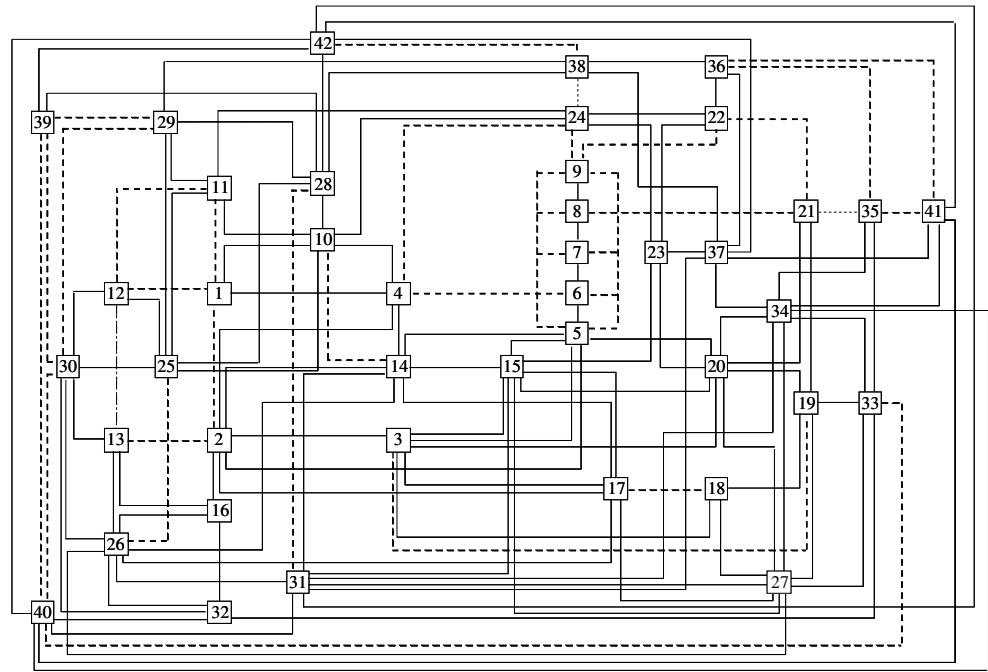

FIGURE 45.7 The power flow relationships between structural subsystems in the entire building.

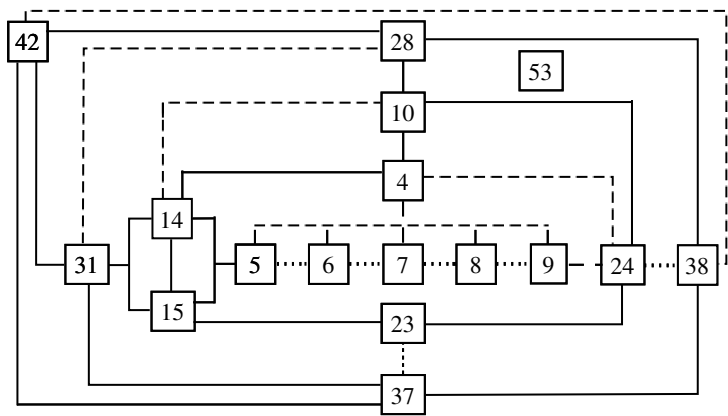

FIGURE 45.8 The power flow relationships in the acoustical laboratory room.

The results obtained for the cabin are shown in Figure 45.5. According to this figure, the disagreement between the computation and the measurement was found about 2 dB in the medium- to high-frequency band.

45.4.2 Application for Prediction of Noise and Vibration in a Building

Consider a two-story laboratory reinforced with concrete [11]. The building configuration is shown in Figure 45.6. This building comprises a driving room, an acoustical laboratory room, a computer room, a measurement room, an equipment room, and others.

We modeled the structural subsystem using I-, L-, or T-type connected points, and the acoustic subsystem as an element shown in Figure 45.6.

The SEA model constructed in this manner is composed of 61 elements, and has 244 connecting points. Subsystems 1 to 17 and subsystems 19 to 42 are concrete components. Subsystem 18 and subsystems 43 to 48 are plasterboard components; subsystems 49 to 55 are room components; and subsystems 56 to 61 are cavity components. For example, Figure 45.7 shows the power flow relationships between structural subsystems in the entire building, while Figure 45.8 shows them in the acoustical laboratory room. Here, the thin-dotted, dotted, and solid lines indicate the I-, L-, and T-type combinations, respectively. Subsystem 53 is the room component, and it is connected with all structural components shown in Figure 45.8. The plasterboards located between the computer room and the measurement room are considered as a partition; therefore, connections between subsystem 49 and subsystems 56 to 59 (cavity components), and subsystem 50 and subsystems 60 and 61 (cavity components) are derived from nonresonant modes.

The results obtained for some other rooms are shown in Figure 45.9. Computing accuracy in this building is worse than in the cabin because the structure of this building is complicated, although the differences between the computed values and the measured values were approximately 4 dB in the medium- to high-frequency band.

The computations take approximately 10 sec, so the workload on the personal computer is quite light.

FIGURE 45.9 Estimated sound pressure level results for other rooms.

Glossary

A + B vibration

Vertical vibration of an aircraft represented by the sum of the vibrations measured at the two sides of the cockpit.

A – B vibration

Roll vibration of an aircraft represented by the difference in the vibrations measured at the two sides of the cockpit.

A-weighted sound level

Sound pressure level that has been weighted according to A-weighting networks, commonly used in measurements that relate to human response to noise (dBA). [See Sound level.](#)

Abnormality scaling

The process of scaling the level of abnormality in each vibration feature between 0 and 1 to signify the degree of deviation from its normal value.

Absolute acceleration shock response spectrum

This is an SRS for acceleration. [See Response spectrum \(RS\)](#) and [Shock response spectrum \(SRS\)](#).

Absolute error

The absolute value of the difference between the exact solution and the computed solution, or between the true value and the measured value.

Absolute limit

Conditions that could result in catastrophic failure.

Absorber

[See Vibration absorber.](#)

Absorption coefficient

Fraction of the incident energy absorbed by a sound surface.

AC

Alternating current.

AC bridge

A bridge circuit that uses an AC excitation. It is more stable than a DC bridge.

AC motor

A motor that uses an AC excitation. Single-phase and multiphase, induction, and synchronous varieties are available.

Acceleration

Rate of change of velocity with respect to time along a specified axis (m/sec^2 or g) or about an axis (rad/sec^2). Second derivative of displacement. Gives both magnitude and direction (vector).

Accelerogram

A recording of the acceleration of the ground during an earthquake.

Accelerograph

An instrument (accelerometer) that records the acceleration of the ground during an earthquake.

Accelerometer

Sensor or transducer measuring acceleration; output (typically voltage) is proportional to acceleration. A piezoelectric accelerometer contains one or more piezo-electric crystal elements, which produce electric charges or voltages when stressed in tension, compression, or shear. Can be two or three axial. The output can be in digital in some cases, with proper transducers.

Acceptability index

The percentage of times an adjustment set will result in the vibration satisfying the specification.

Accuracy

How well a measurement (reading) or a computed result represents the true (correct) value. Accuracy of a value and accuracy of an instrument are related because the latter can determine the former.

Acoustic absorption coefficient

A ratio (fraction) expressing the ability of a material to absorb acoustic power.

Acoustic emission (AE)

Sound or ultrasound pulses generated during crack initiation or propagation in materials and coatings from being subjected to stress.

Acoustic enclosure

A rigid box surrounding noise sources to provide noise isolation for machinery or equipment.

Acoustic holography

A method using phase and amplitude information over a closed surface to reconstruct a sound field in the region outside the surface.

Acoustic impedance

Acoustic pressure acting on a surface divided by the volume (or particle) velocity at the surface. Assumes a plane wave is falling perpendicular to the surface. May assume acoustic material of infinite depth on which the wave is applied.

Acoustic power

The rate of acoustic energy flow emitted or radiated by a specified sound or noise source (W).

Acoustic resonance

Condition of peak (maximum) response of a fluid-borne system to a periodic driving pressure oscillation. Typically, the frequency at which the system tends to oscillate naturally.

Across wind response

Response perpendicular to the direction of wind.

Action plan

When measured values of noise or vibration violate the local or national regulatory limits, “action plans” shall be developed for correcting of the situation.

Active bridge

A bridge circuit (with four bridges; e.g., Wheatstone bridge) that uses an operational amplifier (an active device, which uses an external power source).

Active control

[See Active vibration control.](#)

Active damping

Controlled damping where the damping force is generated by an actuator (with an external power source) in response to sensing (e.g., active suspensions and magnetorheology).

Active device

A device (hardware) that needs an external power source to operate.

Active filter

Uses an operational amplifier (an active device), as opposed to a passive filter, which uses only passive devices.

Active gauge

The strain gauge mounted on the deforming member and forms a part of the bridge circuit. [See Dummy gauge.](#) The bridge output is proportional to the change in the active gauge (automatically compensated for ambient changes by the dummy gauges).

Active mount

An engine mount that uses actuators (with external power) for providing proper suspension and isolation (force and motion).

Active resonator absorber

[See Vibration absorber](#) and [Resonator absorber](#). A resonator absorber that utilizes an active device to generate resonance ([see Resonance](#)) within the absorber subsection.

Active suspension

A suspension system (of a vehicle) that uses actuators (with external power) with feedback control for providing proper suspension.

Active vibration control

A vibration control method in which an external force (utilizing external power) is applied to control vibrations.

ADC

An analog-to-digital converter, which samples an analog signal at some frequency (sampling rate) and converts the sampled data into a digital form.

Adiabatic process

A process that takes place with no heat transfer with the environment.

Adjustable suspension element

Typically includes variable rate damper and stiffness.

Aeroelastic model

The model that simulates the dynamic properties of buildings to capture the motion-dependent loads.

Air-borne sound

A sound that is transmitted from one structure to another.

Aliasing distortion

The error that results due to sampling (discretization) of an analog signal.

Along-wind response

Response in the direction of wind.

Amplitude

Peak magnitude of variation (displacement, velocity, acceleration, etc.) of each oscillation of vibration. The maximum value of a sinusoidal quantity. A measure of floor vibration.

Amplitude-dependent damping

Nonlinear form of damping where its value depends on the amplitude but not frequency of motion, e.g., fluid friction or aerodynamic damping or whose magnitude is proportional to the square of the velocity; nonhysteretic internal damping.

Amplitude ratio

The ratio of forced vibration amplitude to the static amplitude.

Analog device

A device with analog circuitry (hardware) but no digital components. It deals with analog or time-continuous signals but not digital signals.

Analog-to-digital conversion

See [ADC](#).

Anelasticity

Property of real solids responsible for internal friction (prefix “an” means “other than”). Anisotropic damping where there are differences depending on directions relative to crystalline axes.

Angular frequency

Frequency of a periodic quantity, measured in radians per unit time. Cyclic frequency multiplied by 2π . The usual symbol is ω .

Angular velocity

The rate of change of angular position (i.e., orientation) of an object (radians per second [rad/sec], revolutions per minute [rpm], etc.).

Annular clearance

The uniform gap between the rotor and stator of a turbine or compressor motor or some rotating machine.

Antialiasing filter

A low-pass filter with its cut-off set near half the sampling rate of the filtered signal in order to minimize the aliasing error.

Appendages

Additional secondary devices. Additional nonstructural elements to the main structure to increase the building's function to the occupants.

Asymptotic stability

Stability representation where the response naturally decays to zero.

Asymptotic stability borderline

Maximum depth-of-cut below which chatter will not occur for all spindle speeds.

Attenuate

Decrease. To make small.

Attenuation of muffler

Decrease in sound power between two points in a muffler system (noise suppressor).

Autocorrelation

Correlation of a signal with itself, with a phase shift (reference time shift) expressed as a function of the shift. Inverse Fourier transform of the power spectrum.

Autonomous system

Self-contained system with internal control (no external control). A system whose parameters are time-invariant (i.e., do not vary with time).

Autotuning

Automatic tuning ([see tuning](#)) of controller parameters to achieve desired performance (e.g., in vibration control).

Average tuning iteration number (ATIN)

The average number of iterations taken for tuning an aircraft.

Average value

A representative value of a data set. The centroid of the data. The approximate point at which the sum of moments of all the data values is zero. A first-order statistic of random data. Mean value. Expected value. Mathematical expectation.

Axi-symmetric wave

A sound wave generated by a point dipole. When propagation of sound wave is described by polar coordinates, its magnitude is independent of the angle about the given axis.

Axial

Along the shaft centerline. Along the axis.

Back e.m.f.

An electromotive force (e.m.f.) is a voltage generated in a conductor located in a magnetic field when there is a relative motion (in an orthogonal direction). The back e.m.f. is the voltage generated in a moving coil that is connected to a voltage source (like motor rotor windings) and located in a magnetic field, where the generated e.m.f. opposes the applied voltage.

Backlash

Mechanical looseness in between meshed gear wheels due to unavoidable clearances between meshing teeth.

Baffled space

The idealized boundary condition to model the sound field generated by a compact source embedded in a plane large in size compared to wavelength, e.g., a radiation field generated by a circular vibrating piston mounted flush with the surface.

Balance

A condition where the rotating centerline between bearings coincides with that which defines the center of mass distribution. See [Static balancing](#) and [Dynamic balancing](#).

Balance weight adjustments

Weights added to or removed from the rotor hub to tune vibrations through changes in blade mass. Balance weights are measured in grams or ounces, with positive adjustments representing the addition of weight.

Balancing

A procedure for adjusting the mass distribution of a rotor by adding or removing weight, with the goal of achieving less vibration amplitude at rotational speed. See [Static balancing](#) and [Dynamic balancing](#).

Band-pass filter

A filter that allows through the signal components within a given range of frequencies, stopping (filtering) those above and below that band.

Bandstop filter

A filter that suppresses a given range of frequencies, transmitting only those above and below that band. Also called band-elimination filter. Also called a notch filter when the band is very small.

Bandwidth

Operating frequency range of a device. The difference between the upper- and lower-cut-off frequencies at which the signal is attenuated by 3 dB. The difference between the limiting frequencies within which performance of a device falls within specified limits with respect to some characteristic. A measure of speed of response of a device.

Barkhausen effect

Jerkiness in the magnetization curve of a ferrous specimen.

Base isolation

See [Isolation](#). An engineering technology that uncouples the motion of a structural system from the ground motion by inserting an isolation layer under the structure.

Basis

Countable set of linearly independent functions or vectors that can represent a general function or a vector space.

Bathtub curve

Curve (based on anecdotal and statistical data) describing the frequency of failures. Applicable to an individual machine or population of machines of the same type.

Beam

A structural (vibrating) component that is long and slender and has some flexibility (bending or flexure). Commonly modeled by Euler–Bernoulli equation or Timoshenko equation.

Bearing

A support for the ends of a shaft, a rotating member, etc. May be dry or lubricated. Will introduce some damping, but it should be minimized for proper operation. Linear bearing is one that provides a guideway for rectilinear motion (rather than rotary motion).

Beats

The alternating and significant rise and fall of vibration amplitude caused by two sources vibrating at nearly equal frequencies (or engines or rotating machines rotating at nearly equal speeds).

Bernoulli–Euler beam

A common analytical model (partial differential equation with respect to time and length coordinate) used to analyze slender beams. Rotatory inertia and deformation due to shear are neglected in this model (holds for slender beams), unlike the Timoshenko beam model.

Bicoherence

Second-order correlation measure between signals.

Biorthogonal wavelets

Symmetric wavelets with compact support created by two sets of wavelets; one set for decomposition and one set for reconstruction.

Bisection method

A nonlinear root-finding method which repeatedly bisects the interval to find a root. For this method to be successful, the initial interval has to be such that the function is positive at one endpoint and negative at the other.

Blast mitigation

Physical defensive measures taken to reduce the damaging effects of explosions from devices introduced by hostile parties. Includes both exterior hardening (wall, etc.) and internal measures taken to improve the survival of the protected resources (e.g., using more stable chemicals in a protected process).

Bode plot

The pair of plots of amplitude versus frequency and phase versus frequency. Usually, the amplitude is given in dB (or in log scale) as a nondimensional magnification factor of a transfer-function magnitude. The frequency is given in log scale.

Boom

A long, overhanging pole or beam like structure. As in a crane or a robot, a boom can be used to position and manipulate objects at a remote location.

Boundary conditions (BCs)

The conditions (force, moment, motion, deformation, etc.) at the boundary locations of an object (e.g., beam, plate, structure) used for solving the governing equations of the object. These are conditions expressed with respect to spatial coordinates (space) rather than time. Also require initial conditions (ICs) which are conditions at the initial time, for a complete solution of the system equations.

Boundary layer

A thin stationary layer of liquid with a hypothetical boundary next to a solid surface where much of the velocity changes (gradients) occur.

Bracing

Temporary supports of a structure using struts in vertical and lateral directions during seismic rehabilitation of the structure.

Bridge circuit

An electric circuit with four arms having resistances or impedances, and input (source) and an output. Where pure resistances are used, we have a Wheatstone bridge. Hydraulic circuits also may be represented as bridge circuits, and analyzed using similar techniques.

Bridge balance

The condition (the relation between bridge resistances or impedances) such that the output of the bridge circuit is zero (even when the source provides an excitation).

Bridge constant

The constant parameter relating a variation in a bridge arm (resistance or impedance) to the corresponding bridge output, starting with a balanced bridge.

Broadband (wideband) process

A random process where most of the energy is in a wideband of frequency.

Broadband excitation

An excitation with a significant range of frequency (almost a white noise spectrum).

Buffer

A device provided at an isolation bearing which will be hit by the moving plate of an isolation bearing to limit the bearing displacement during extreme earthquakes.

Bulk modulus

Change in volume divided by initial volume gives the bulk strain. The bulk stress (or pressure) divided by the bulk strain is the bulk modulus.

Bump

Simple shock that is generally repeated many times when testing, e.g., half-sine, 10g, 16 msec, 3000 bumps (shock) per axis, 3 bumps per second.

Bump test

See Bump. An impact test. A test carried out on an object (equipment, structure, etc.) using a bump impact.

Butterworth filter

A low-pass filter with many poles (i.e., high order) to provide good roll-off (i.e., sharp cut-off).

Calibration

Adjusting some parameters or conditions (using knobs, keys, computer interface, etc.) of a device so that its performance (output or reading) is accurate with known engineering units.

Cantilever

A flexible beam fixed at one end (zero displacement and zero slope) and free at the other (zero bending moment and zero shear force).

Carrier

A sufficiently high-frequency signal that can carry another (transient) signal of lower frequency for maintaining the accuracy of the carried signal during signal transmission and analysis.

Carrier frequency

Frequency of the carrier signal.

Carrier signal

[See Carrier.](#)

Cartesian coordinates

Orthogonal (perpendicular) coordinates in a rectangular coordinate frame with a common origin.

Cascade connection

Connection in series of two or more devices.

Cascade plots

Successive spectra plotted with respect to time and displayed in a three-dimensional manner. Also known as Waterfall plots.

Catastrophic failure

Sudden and complete failure of a machine. Cannot be analyzed by conventional methods of nonlinear system analysis.

Causality

Cause–effect behavior of a dynamic system. The numerator order (or the input order) cannot be greater than the denominator order (or the output order) of the system transfer function. This determines the physical realizability of the system.

Center of gravity

The point representing the average position of weight in a body. The point of intersection of orthogonal axes, relative to which the first moment of weight is zero. Typically the same as the center of mass. Denoted by COG or CG.

Center of mass

The point representing the average position of matter (mass) in a body. The point of intersection of orthogonal axes, relative to which the first moment of mass is zero. Typically the same as the center of gravity, denoted by COG or CG.

Center of stiffness

The point of intersection of orthogonal axes relative to which the first moment of stiffness is zero.

Centered difference

Finite difference approximation that uses the Taylor series expansions on either side of the point in question.

Centrifugal acceleration

Acceleration of a rotating mass (e.g., attached to a string or arm) directed towards the center rotation. Equal to $\omega^2 r$ where ω is the angular speed of rotation and r is the radius of rotation.

Centrifugal compressor

A compressor (a machine in which air or gas is compressed) by the mechanical action of rotating vanes or impellers. The flow is in a radial direction through the impeller, which imparts velocity (kinetic energy) to the fluid. Passing through a diffuser section at exit, the kinetic energy is converted into pressure (potential energy).

Centrifugal pump

See [Centrifugal compressor](#). As the impeller of the pump (enclosed in a casing or volute with an inlet and a discharge connection), kinetic energy is imparted to the fluid by the rotating impeller and is converted into pressure at the outlet.

Centripetal acceleration

See [Centrifugal acceleration](#) (synonymous).

Centroid

Same as the center of mass or center of gravity for practical purposes.

Cepstra

Plural of cepstrum. Equivalent to spectra, but in the “quefrency domain” rather than the frequency domain.

Cepstrum

The inverse Fourier spectrum of the logarithm of the Fourier spectrum of a signal.

Change limit

Warning levels that provide early warning well in advance of the absolute limit.

Channel

A signal line in a piece of equipment or hardware. Both input channels and output channels are important. The capability and complexity increase as the number of channels increases.

Chaos

Deterministic form involving the “butterfly effect” (work of E. Lorenz).

Characteristic equation

See Characteristic polynomial.

Characteristic polynomial

The polynomial, when set to zero (characteristic equation) and solved, gives the eigenvalues (or poles or characteristic roots) of a dynamic system. The denominator polynomial of the transfer function of a dynamic system. The roots are complex in general. The imaginary parts give the natural frequencies. The real parts give the reciprocal of time constants or damping level.

Charge amplifier

An electronic amplifier used to convert the high-output impedance of a device (e.g., piezoelectric accelerometer) into low-output impedance so that it is compatible with common signal acquisition and readout devices (processors, controllers, displays, recorders, etc.).

Chatter

An instability in a machine tool, which occurs at high frequencies, causing poor machining quality, increasing tool wear, generating noise, and causing other problems to the machine.

Chatter frequency

Dominant frequency of vibration during the occurrence of chatter (unstable vibration in a machine tool).

Chatter marks

Distinctive undulating patterns left on a part after machining that are indicative of chatter.

Cholesky decomposition

A symmetric positive definite matrix may be written as the product of a lower triangular matrix and its transpose (an upper triangular matrix): $A = U^t U$.

Circle fit

Fitting vibration test data to a transfer function that approximates to a circle on the complex plane (horizontal real axis and vertical imaginary axis). True for a single degree-of-freedom (single-DoF) in relation to some specific transfer functions (e.g., mobility) with some types of damping. Parameters of the system (damping, natural frequency) can be extracted from the fitted circle. Used in experimental modal analysis or modal testing.

Cofferdam

A temporary watertight enclosure that is pumped dry to expose the bottom of a body of water so that construction (e.g., of piers) may be undertaken.

COG

Centre of gravity (or center of mass). See their definitions.

Coherence

First-order correlation measure (normalized) between different signals, expressed in the frequency domain (as a function of frequency). It has a magnitude and a phase.

Coincidence effect

A form of acoustic resonance phenomena where the transmission loss decreases rapidly when the acoustically forced bending wave speed is equal to the free bending wave speed (flexural natural frequency) in a structure (plate).

Cold welding

Bonding between two parts of seismic isolation bearings (which are supposed to move relatively to each other during earthquake attacks) because of long durations of contact.

Color centers

Defects introduced into a crystal such as lithium fluoride by ionizing radiation.

Combined adjustments

The net adjustments to opposite blade-pairs in a four-bladed aircraft.

Common-mode rejection

Improvements in signal-to-noise ratio (SNR) by the reduction of noise signals that are common to both inputs of a differential amplifier.

Commutator

A device that provides power to a set of coil segments (circuits) in a rotating electric machine (motor). Analogous methods may be used in linear actuators (which perform rectilinear motion rather than rotary motion). A commutator with a slip-ring with split segments connected to the circuit segments, and brushes (carbon blocks) in contact to provide the power, is called a "slip-ring brush commutator." Alternatively, electronic commutation may be used where the power is switched into to different circuit segments by electronic means.

Compact source condition

When the scale of the source region is small (compared with the wavelength of generated sound wave), the compact source condition is mathematically valid for modeling the sound field. [See Monopole and Dipole.](#)

Compensating element

A resistor or a coil in a circuit (e.g., eddy-current sensor, bridge circuit, potentiometer circuit), which is used to compensate for environmental changes (e.g., change in temperature).

Complex modes

In some vibrating systems with some complex types of damping, the mode shapes (eigenvectors) obtained analytically ([see mode shapes](#)) can be complex (as opposed to real). Strictly then, these mode shapes are not realizable in practice. In fact, some distinct shapes will appear (similar to real modes) but with some changes (e.g., movements of nodes, small changes in phase of the moving elements) at the corresponding natural frequencies.

Complex propagation constant

This constant γ has two parts; the real part, δ , called the attenuation constant in decibels per meter (dB/m), and the imaginary part, β , called the phase constant in radians per meter (rad/m).

Compound pendulum

[See Pendulum.](#) A pendulum having more than one degree of freedom (e.g., two swinging degrees and one twisting degree).

Compressor circuit

In controlling a vibration shaker, this circuit ensures that the drive signal to the shaker satisfies the required spectrum of the test signal that needs to be applied to the test object. It compresses the frequency components that exceed the specification.

Condition-based maintenance

A strategy where maintenance is performed after assessing the actual condition of the machinery (rather than scheduling it at fixed intervals) in order to optimally schedule maintenance, thereby achieving maximum production and still avoiding unexpected catastrophic failures.

Condition monitoring

Monitoring the operation of a machine or other dynamic system, for the purpose of checking proper operation and possible faults or malfunction. Vibration signal analysis is one approach to condition monitoring.

Confined concrete

Concrete confined by transverse reinforcement, commonly using closely spaced steel spirals or hoops to increase the ductility.

Consistent mass

Representation of the mass of a system based on the virtual work principle and that results in a nondiagonal mass matrix.

Constant percentage bandwidth

Frequency bandwidths over the entire frequency range that remain a constant percentage of the frequency being monitored.

Consumer product noise

Noise perceived by a user or bystander of a noise generating product over which the individual has some control. Excludes occupational noise and environmental noise.

Contrast enhancement

Adaptation of the weights associated with features classified as normal or abnormal to enhance the contrast.

Continuous monitoring

Constant or very frequent data collection and analysis, usually with a permanently installed monitoring system.

Continuous wavelet transform

Wavelet transform on continuous ranges of scale-shift parameters.

Controllability

The ability of a controller to drive the response of the dynamic system, which it controls, to any desired value in a finite time, using a finite input (excitation).

Convolution integral

Integral of the product of two functions (usually of time), where one function is the shifted complement of the other (i.e., one is a function of τ and the other is a function of $t - \tau$, and the integration is done over τ). If one function is the system input and the other is the response of the system to a unit impulse, then the convolution integral gives the system response to the given input. The Fourier transform of a convolution integral is the product of the Fourier spectra of the individual time functions. In general, a product in the frequency (or Laplace) domain is a convolution integral in the time domain, and vice versa.

Correlation function

The correlation function is the mathematical expectation of a random function with another random function in the time domain. It is a measure of how two random functions correlate with each other over various time differences.

Coulomb damping

Friction force that is constant in magnitude, and acts on a body in the opposite direction to the velocity of the body relative to the surface in contact.

Coupling loss factor

The fraction of the original vibrating energy between two subsystems that is lost when interconnected.

Coverage index

The reach of each sensor (accelerometer) location in reflecting faulty components. It is defined in terms of the structural influences that represent the proximity of each sensor (accelerometer) to various system (gearbox) components.

Creep

Slow dimensional changes of a specimen due to structural defects. They progress through three distinctive phases called primary, secondary, and tertiary.

Crest factor

The ratio ($\frac{\text{Peak Level}}{\text{RMS Level}}$) of a waveform. It can indicate early stages of rolling element (bearing) failure.

Critical damping

The minimum value of damping that produces a nonoscillatory decaying motion of a system under free vibration. Value of damping that provides most rapid response to a step function without overshoot. When this occurs, damping ratio = 1.

Critical damping coefficient

Damping coefficient corresponding to critical damping. [See Damping coefficient](#) and Critical damping. This occurs when $(c/2m)^2 = k/m$, where k = spring constant, m = mass, and c = damping coefficient or damping constant. At this value, damping ratio = 1.

Critical frequency

The minimum frequency at which the coincidence effect occurs when the propagation speed of a bending wave in a plate equals the speed of sound in air.

Critical speed

The rotational speed that is equal to a natural frequency of bending of a rotor–shaft–bearing system (rotor dynamic resonant frequency). It can cause large amplitude vibration or whirling with only slight excitation.

Cross sensitivity

The sensitivity of a device (e.g., sensor) in a direction orthogonal (perpendicular) to the direction of direct sensitivity. Normally, the cross sensitivity of a sensor has to be minimized and the direct sensitivity maximized.

Crust

The outermost major layer of the Earth, ranging from about 10 to 65 km in thickness worldwide. The uppermost 15 to 35 km of crust is brittle enough to produce earthquakes.

Cumulative modification set

The total number of tuning iterations performed in the field on an aircraft.

Curve-fitting

Fitting a set of data to an analytical curve, as accurately as possible. [See Circle fit](#), which is a single-DoF fit. Multi-DoF curve-fitting is used for complex systems with closely-spaced modes. Used in experimental modal analysis and modal testing.

Cut-off frequency

The frequency of a filter beyond which the signal entering it is cut-off (filtered out).

Cycle

The full range of states or values through which a periodic (cyclic) phenomenon or function passes before completely repeating itself. The complete sequence of values of a periodic quantity that occur during one period. For a periodic waveform (signal), this corresponds to one period (or 1/frequency).

Cyclic frequency

Frequency of a periodic variation in cycles per unit time (Units: Hertz or Hz, or cycles or cycles). Typical symbol is f . [See also Angular frequency](#).

D'Alembert's principle

An equivalent version of Newton's Second Law where the acceleration is multiplied by mass, and the resulting "inertia force" is applied in the direction opposite to that of the acceleration. The dynamic systems become an equivalent static system in this manner.

DAC

Digital-to-analog conversion. Digital data from a digital device (e.g., computer) are interpolated and converted by a DAC into an analog signal for use with analog instruments.

Damage boundary curve

For a given acceleration, curve giving the critical velocity change and, for a given velocity change, the critical maximum shock acceleration that leads to a damage on the material (deformation, fracture, faulty operation after the shock, etc.).

Damped natural frequency

The natural frequency of free vibration of a damped linear system.

Damper

A device that dissipates mechanical energy and progressively diminishes the response of a mechanical system (in free motion). In the case of linear viscous damping, this device is sometimes called a dashpot. The resulting damping force is the product of the damping coefficient and the relative velocity of the two components of the damper.

Damping

The dissipation of energy of a mechanical system, which progressively diminishes (dampens) the magnitude of response (or the amplitude of vibration) of the system in free motion. The damping process converts and dissipates mechanical energy into other forms of energy such as thermal energy (heat transfer) and noise.

Damping capacity

Energy loss per cycle of the motion.

Damping coefficient

The constant by which the relative velocity of a body is multiplied to yield the viscous damping force acting on the body.

Damping constant

The same as damping coefficient.

Damping ratio

Ratio of actual damping coefficient to the critical damping coefficient in a system with viscous damping. Expressed mathematically, the damping ratio $\zeta = c/c_c$. If less than 1, the system will be underdamped and will exhibit oscillations when disturbed or excited. If larger than 1, the system will be overdamped and the system response will diminish and die out with no oscillations.

Damping redshift

Change in frequency of a harmonic oscillator due to damping. Predicted by the viscous damping model, it is virtually immeasurable because of the small size of the shift.

Dashpot

Same as “damper” but assumes a linear viscous damping model and generally has three orthogonal damping forces.

Daubechies wavelets

A family of orthogonal wavelets with compact support and a specified number of vanishing moments.

DC

Direct current.

DC bridge

A bridge circuit using a DC excitation. Compare with an AC bridge.

DC motor

An electric motor that uses a DC excitation. Requires a commutator for operation. Commonly used as a servomotor, where motion sensing and feedback control are employed for accurate generation of motion trajectories.

DC tachometer

A speed sensor that uses the principle of an electric generator (electromagnetic induction). The excitation is DC. The output DC voltage is proportional to the measured speed.

Detuning

Deviation of a passive vibration control system ([see passive vibration control](#)) from its original design due to structural parameters changes, change in the excitation frequency, or change in nature of disturbance.

Deflection

Movement (or deformation) of a structure or parts of a structure under applied loads. In the case of an elastic body or spring, the distance it moves when subjected to a static or dynamic force.

Degrees of freedom

Denoted by DoF or dof or df. Minimum number of independent coordinates necessary to determine completely the state (position and orientation) of the considered system. This definition assumes a holonomic system. For a general (nonholonomic) system, the definition must use “incremental” coordinates and corresponding “incremental” displacements. Often used to classify mechanical structures, such as robotic arms. In the finite element analysis, DoF may be associated with nodes or elements. Three-dimensional shell and beam elements have six DoF per node (three translations and three rotations).

Delayed resonator (DR) absorber

A form of a resonator absorber ([see resonator absorber](#)) to optimally utilize the effect of time-delay in the processed signal.

Delta function

Dirac delta function. A unit impulse function. A function whose value is infinity at one point and zero elsewhere, with the integral of the function equal to 1.

Demodulation

Recovering the original signal from a modulated signal by removing the carrier signal. A common method is to multiply (by digital or analog means) the modulated signal by the carrier signal and then low-pass filter the result.

Depth-of-cut selection

Technique where the depth-of-cut is chosen to avoid or suppress chatter in a machine tool. [See Chatter.](#)

Design (basis) earthquake

Denoted by DBE. The earthquake (as defined by various parameters, such as peak ground acceleration or PGA, response spectra, etc.) for which the structure will be, or was, designed.

Desorption

Release of gas molecules from a solid undergoing evacuation.

Determinacy of machine structure

A degree at which a physical structure complies with the law of cause and effect ([see causality](#)). This allows the system dynamic behavior to be modeled and analyzed mathematically, and the modeled system to be physically realizable.

Detonation

An explosive reaction that consists of the propagation of a shock wave through the explosive, accompanied by a chemical reaction that furnishes energy to sustain the shock propagation in a stable manner, with gaseous formation and pressure expansion following shortly thereafter.

DFT

Discrete Fourier transform or digital Fourier transform. A discrete version of the Fourier integral for use in numerical computation. The fast Fourier transform (FFT) uses a much more efficient algorithm for this computation.

Dielectric constant

A parameter of a capacitive material indicating the degree of its ability to store electric charges. Also known as permittivity.

Differential transformer

[See LVDT](#) and [RVDT](#). A transformer with a movable ferromagnetic element in its core. Serves as a noncontact displacement sensor.

Difference equation

A discrete version of a differential equation. Used in computer simulation of dynamic systems. In the nonhomogeneous case (i.e., when there is an input function) there is an equivalent z-transform transfer function (just like a nonhomogeneous differential equation having an equivalent Laplace transfer function or a frequency response function).

Diffraction parameter

This indicates the importance of the diffraction force. A larger parameter value means that the diffraction force is more important than the drag or inertia forces.

Diffuser

A component in a centrifugal pump adjacent to the impeller exit, which has multiple passages of increasing area for converting velocity (kinetic energy) to pressure (potential energy).

Digital filter

In contrast to an analog filter, it uses a digital processor and a filter algorithm to perform filtering on digital data.

Digital Fourier analysis

[See DFT](#) and [FFT](#). Fourier analysis using digital data. Converts time-domain information into frequency-domain (spectral) information. Can determine Fourier spectra, transfer functions, power spectra densities, coherence functions, etc. through this analysis.

Digital oscilloscope

An instrument that has the usual oscilloscope capabilities (acquisition and display of one or more signals) together with a variety of other capabilities such as extraction of signal parameters (mean, time constants, periods) and even FFT and spectral analysis.

Digital signal analyzer

Signal analyzer. Digital spectrum analyzer. A hardware digital device that carries out Fourier analysis and related operations on signals at very high speed (almost real time). Faster than a software-based analyzer.

Digital-to-analog conversion

[See DAC.](#)

Digital transducer

A transducer that can sense a signal and present it as a pulse sequence (pulse count or pulse rate) or digital data. It is generally very accurate, but necessarily introduces a quantization error.

Dilation

The squeezing or stretching of the mother wavelet in the time domain in order to analyze the signal in different scales.

Dipole

[See Monopole.](#) The second basic sound source where a pair of monopoles, close together, opposite in sign, and equal in magnitude are located along one axis. The sound sources like a compact vibrating body, with a characteristic axis or a point force acting in the medium that may be modeled as a dipole.

Dirac delta function

[See Delta function.](#)

Direct sensitivity

[See Cross sensitivity.](#)

Directivity

The dependency of a sound field on the angular position. Although the monopole sound field has no preferred direction, the dipole and the multipole sound fields have a particular dependency on the angular position. The dependency varies with the condition of the compactness of the sound source.

Discrete Fourier transform

[See DFT.](#) A mathematical transformation used to transform a discrete time signal (sampled data) into a discrete set of spectral values equally spaced in the discrete frequency domain. It can be used to numerically (computationally) determine the spectrum of any general (e.g., nonperiodic) time signal.

Discrete wavelet transform

Wavelet transform on a discrete set of scale-shift parameters.

Dislocation

Disruption to the order of an ideal crystal, e.g., by an extra plane of atoms inserted partway into the crystal to form an edge dislocation. Edge and screw dislocations are described by means of the Burgers vector.

Displacement

Change of position of a body, usually measured from the mean position or position of rest. Usually applies to the uniaxial case. In the case of angular motions, it may be termed a “rotation.” In a general multidimensional case, this is a vector quantity that specifies the change of a body or particle, and is usually measured from the mean position or position of rest. In general, it can be represented as a translation vector, a rotation vector, or both.

Dissipative muffler

A muffler where the acoustic performance is determined mainly by the presence of sound absorbing (e.g., flow-resistive) material. See [Muffler](#) and [Reactive muffler](#).

Distinct eigenvalues

The case where there are no repeated eigenvalues. All the eigenvalues are unequal.

Distributed-parameter system

A system where at least one member is continuous (e.g., beam, plate), needing one or more spatial coordinates to analytically represent (model) it. A partial differential equation in time and space is needed. Compare with lumped-parameter system.

Doppler effect

When the wave source moves towards the receiver, the received frequency increases. When it moves away from the receiver, the received frequency decreases. True for both sound and light.

Drag force

Force on a body in the direction of wind or any other fluid (liquid or gas).

Drift

The undesirable variation of the output of an instrument when the input conditions are kept constant.

Ductile detailing

Special requirements for civil engineering structures, such as close spacing of lateral reinforcement to attain confinement of a concrete core in reinforced concrete and masonry, appropriate relative dimensioning of beams and columns, hooks on main beam reinforcement within the column, etc.

Ductile structure

A structure that is able to undergo a repeated large displacement after yielding, without significant degradation of yield strength.

Ductility factor

The ratio of the total displacement (elastic plus inelastic) to the elastic (i.e., yield) displacement.

Duffing oscillator

Classic nonlinear elastic (mechanical) oscillator characterized by a double-well potential.

Dummy gauge

A strain gage in a bridge that is not active. Used for bridge completion and compensation (for temperature changes, etc.). Active gauge is the strained gauge, which is mounted on the deforming member.

Dunkerley's formula

A formula that provides a lower bound for the fundamental (first or lowest) natural frequency of a mechanical (vibrating) system.

Duration of shock pulse

The time required for the acceleration of a shock pulse to rise from some specified fraction of the maximum amplitude (peak) of the pulse and to decay to this value (see [Shock pulse](#)).

Dwell frequency

The frequency at which a "sine-dwell" test is carried out.

Dyadic

Follows a geometric sequence of ratio 2.

Dynamic absorber

See [Absorber](#) or [Vibration absorber](#).

Dynamic balancing

See [Balancing](#). Balancing achieved on two parallel planes of vibration perpendicular to the axis of rotation.

Dynamic magnification factor

The ratio of the maximum displacement of a single-DoF system excited by a harmonic force to the deflection that would result if a force of that magnitude was applied statically.

Eccentric mass

An equivalent point mass in a rotary device, located at a radial offset (eccentricity) from the axis of rotation such that the corresponding centrifugal force is equal to the imbalance force of the original device. The mass that needs to be placed on a rotor (eccentrically) in order to balance it.

Eccentricity

The distance between the geometric center and the center of mass of a rotor.

Eddy current damping

Damping due to eddy currents generated in a conducting surface and associated dissipation of the energy through electrical resistance to eddy currents.

Eddy current sensor

Eddy currents are generated on the surface of a conducting medium when a high frequency (e.g., radio frequency in the MHz level) magnetic field is applied to it. An eddy current sensor is a proximity sensor where the probe emits a high-frequency magnetic field towards the monitored object, which acts as a thin conducting layer. The inductance change caused by the eddy currents in the probe coil is a measure of the intensity of eddy currents and the distance (proximity) of the object. The inductance change can be measured using an inductance bridge circuit.

Effective isolation period

A linearized equivalent isolation period of a nonlinear isolation system.

Eigenfrequencies

Natural frequencies determined by an eigenvalue analysis.

Eigenfunctions

Mode-shape functions, in a general sense, including complex modes.

Eigenvalue analysis

Analysis carried out to obtain the roots of the characteristic equation of the matrix formulation of an engineering problem. In system dynamics and vibration problems, the imaginary parts of the eigenvalues are the natural frequencies of the system. The reciprocal of the imaginary parts are the time constants of the system. Imaginary parts divided by the corresponding undamped natural frequencies provide the modal damping ratios. The analysis also provides eigenvectors, which give the mode shape information. The analysis that provides both natural frequencies and mode shapes is called modal analysis. See [Eigenvalue problem](#). In stress analysis, the eigenvalues and eigenvectors give the values and the directions

of the principal stresses or principal strains. In other engineering problems, there are eigenvalue problems with corresponding interpretations.

Eigenvalues

The equation of motion for undamped free vibrations of a system with n DoF can be represented in matrix notation as the product of the characteristic matrix and the vector representing the corresponding displacement coordinates. For nontrivial solutions, the determinant of the characteristic matrix is set equal to zero, yielding a characteristic equation. The roots of the characteristic equation of the system are called eigenvalues. See [Eigenvalue analysis](#) for the interpretation of eigenvalues.

Eigenvalue problem

The mathematical formulation of the dynamics of a system as a problem of determining eigenvalues and eigenvectors of a matrix. This matrix is $M^{-1}K$, where M is the mass matrix and K is the stiffness matrix in the undamped case, giving natural frequencies, time constants and modal damping ratios. See [Eigenvalue analysis](#). In stress analysis, the eigenvalue analysis gives the values and directions of the principal stresses or principal strains. In other engineering problems, there are eigenvalue problems with corresponding interpretations.

Eigenvectors

Many engineering problems can be cast as the solution of eigenvalues and eigenvectors of a characteristic matrix. In vibrations problems, this matrix is $M^{-1}K$, where M is the mass matrix and K is the stiffness matrix, in the undamped case. The corresponding eigenvectors give mode shape vectors (see [Eigenvalue analysis](#)). In stress analysis, the eigenvectors give the direction of the principal stresses or strains.

Elastomer

A generic term that encompasses all types of rubber, natural or synthetic.

Elastomeric bearing

One type of base isolators, which are usually made of rubber or soft materials.

Elastomeric coupling

A flexible shaft coupling, which employs nonmetallic elastomeric elements for transmitting power, and accommodates shaft misalignment from one rotating shaft to another.

Electricite de France (EDF)

One type of seismic isolators, which consists of an elastomeric component and a sliding bearings in series.

Electrical impedance

The transfer function (voltage or current), in the frequency domain.

Electro-rheological (ER) fluid

Materials that undergo significant instantaneous reversible changes in characteristics when subjected to electric field.

Element

In finite element analysis, this is a small portion or a sub domain of a system having small but finite dimensions and bounded by straight or curved boundaries. Elements are connected to each other via a set of connection points called nodes. The minimum number of nodes for an element would be the corner nodes defining its shape.

EMA

See [Experimental modal analysis](#).

e.m.f.

Electromotive force. See [Back e.m.f.](#)

Emission

Emitting or radiation of sound energy or power from a noise source. Noise emission is controlled through noise government legislation.

Energy equivalence

A simplified analysis method of a dynamic system where a simplified (e.g., lumped-parameter) model (of reduced number of degrees of freedom) is established such that its energy (kinetic energy and potential energy) is equal to that of the original system. Information about the original system can be derived (approximately) by analyzing the equivalent system.

Ensemble average

The average of ensembles or samples (records) of possible outcomes. This is different from averaging a single record or signal (temporal average).

Enveloped spectrum

The envelope of a set of spectra obtained by different records of a vibration signal.

Environmental noise

Noise received by individuals indoors and outdoors, caused by noise sources that are controlled by others.

Environmental quality standard

World Health Organization (WHO) is the world body that recommends this regulatory standard of noise exposure. E.g., see *Guideline for Community Noise* published by WHO in 2000.

Epicenter

The projection on the surface of the earth directly above the hypocenter of an earthquake.

Equalization

In vibration testing, the spectrum of the actual excitation signal applied to the test object has to be (approximately) equal to the specified test spectrum. The process of achieving this by examining small frequency band of the actual spectrum and changing the spectral values (by adjusting the gains) is called equalization.

Equalizer

A device that achieves equalization in a dynamic test system.

Equipment interaction

Feedback effect between the motions of the structure and attached equipment.

Equipment tuning

When the natural frequency of a piece of equipment is such that undesirable resonances occur in vibratory response and equipment tuning may be necessary to avoid this condition. One option is to tune a vibration absorber (dynamic absorber) to this frequency.

Equivalent static acceleration

Steadily applied acceleration producing the same deformation of the structure as that resulting from the action of a shock. Also termed pseudoacceleration.

Equivalent mass

[See Energy equivalence.](#) The mass of a single-DoF model, in the “energy equivalence” method.

Equivalent stiffness

[See Energy equivalence.](#) The stiffness of a single-DoF model, in the “energy equivalence” method.

Equivalent viscous damping

The value of viscous damping assumed to analyze a vibratory motion, such that the dissipation of energy per cycle is the same for the viscous and the actual cases.

Ergodic hypothesis

For a stationary process, the assumption that the ensemble average can be approximated by the time (temporal) average.

Ergodic process

A stationary process where the ensemble average can be approximated by the time (temporal) average. This assumption is known as the ergodic hypothesis.

Euclidean norm

Square root of sum of squares (SRSS) of a set of independent values.

Euclidean space

[See Cartesian coordinates.](#) Space represented by a general Cartesian coordinate system with n coordinate axes. Cannot be represented in a physical space when $n > 3$.

Euler angles

A set of orthogonal rotation angles normally used to describe orientation of bodies in three-dimensional (3-D) space.

Euler–Bernoulli beam

[See Bernoulli–Euler beam.](#)

Euler’s method

First-order Runge–Kutta method of numerical integration.

Excel

Microsoft® spreadsheet software.

Excitation

Force (or even a motion such as support motion) applied to a mechanical system. This is the input to the system. The resulting response is the output.

Exciter

Shaker. The device that generates and applies an excitation to the test object in dynamic (vibration) testing.

Expansion joint

A connection between two or more seismically-isolated structures for the passage of occupants from one building to another, and also to let the adjacent buildings move relatively to each other during a seismic excitation.

Expected value

Also known as “mathematical expectation” of a random function. It is the integral of that function weighted by its probability density function. If the function is the random variable X , then the expected value gives the mean value (\bar{X}), which is the first moment statistic. If it is X^2 , then we get the second moment statistic. If it is $(X - \bar{X})^2$, then we get the variance, the square root of which is the standard deviation of a random parameter. Other higher-order statistics of X can be derived similarly.

Experimental modal analysis (EMA)

A method of determining a model of a dynamic (vibrating system) through testing and modal parameter extraction. A signal is applied to the system using an exciter. Various responses are acquired and analyzed (usually by Fourier analysis methods in the frequency domain) to determine the natural frequencies, damping ratios, and mode shapes of the system, and using these an analytical model (mass matrix, stiffness matrix, and a damping matrix) is computed for the system.

Explosion interaction

Two structures collide during an explosion.

Extrinsic

Opposite of intrinsic. A method where the device is used as the medium (or vehicle) in transmitting the objective (e.g., signal), rather than generating the objective. Some types of fiber-optic and ultrasound sensors use the extrinsic approach as well as the intrinsic approach.

Fast Fourier Transform (FFT)

A fast and efficient computer algorithm to calculate the discrete Fourier transform (DFT). The input data are samples of a time waveform from (e.g., digitized voltage measurements). The result is a display of discrete spectral points giving amplitude versus frequency, and phase versus frequency. The frequency interval is so small that the spectrum appears continuous in the display or printout.

Fatigue

Failure of a structural member exposed to a repeated load whose amplitude is well under the member's strength.

Fault

A zone of the Earth's crust within which the two sides have moved. Faults may be hundreds of miles long, from 1 to over 100 miles deep, and not readily apparent on the ground surface.

Fault detection

The process of determining if the overall machinery is healthy or a fault has occurred. Fault detection may be performed by such methods as oil analysis and vibration monitoring. Data gathering, data analysis (e.g., FFT, cepstrum, wavelet analysis), comparison to standards, comparison to limits set in-plant for specific equipment, etc., may be involved when detecting whether machinery is developing a faulty condition.

Fault diagnosis

The process of identifying the type, source, and severity of a failure (e.g., a faulty gearbox) for a detected fault. Vibration-based fault diagnosis may be performed by studying the abnormality of vibration features combined with the locations of the accelerometers generating those features.

Fault prognosis

Estimating the expected time to failure, and trends in the condition of the equipment being monitored, and planning and scheduling appropriate maintenance procedures.

FEA

Finite element analysis. [See also Finite element method \(FEM\)](#). A computational technique that starts by discretizing the continuum equations of the problem.

Feasible region

All sets of blade adjustment in jet engines that will reduce the aircraft vibration to within specifications.

Featural influence

The coefficients representing the weight of each vibration feature in the structure-based connectionist network.

Feed selection

Technique where the feed is chosen to avoid or suppress chatter.

Feedback control

A common control procedure where a sensor measures or monitors the system response and feeds the information into the controller. The controller compares the measurement with the desired value. If there is an error, then a correcting signal is generated by the controller, which is then applied to the system by the drive unit (or actuator).

Feedback resistor

The resistance element in the feedback path of an operational amplifier. It makes the device stable.

Feedforward action

A control signal generated without monitoring the response. Using a model of the system or measurement of unknown inputs may be used to generate it.

Feedforward control

See Feedforward action.

FEM

Finite element method. See FEA.

Ferromagnetic core

A member (e.g., rod or disk made of laminations) made of ferromagnetic material for use in a magnetic circuit (e.g., windings) to concentrate the field and reduce losses.

FFT

[See Fast Fourier transform.](#)

Fiber-optic

Devices made using optical fibers (a bundle of thin and flexible fibers that can carry light or laser signals).

Fictitious spring method

An analysis method for sliding isolated structures, in which a fictitious spring is introduced between the base mat and ground to simulate nonlinear behavior of friction.

Filter

An analog-hardware or software (programmed) device used to filter out some frequency bands of a signal (while allowing through the other bands).

Final peak sawtooth shock (FPS)

See [Terminal peak sawtooth shock \(TPS\)](#).

Finite difference

Computational methods involving a difference approximation for the derivatives.

Finite element method

A method for solving differential equations by approximating the solution by a linear combination of trial functions, which are typically polynomials.

Finite element method (FEM)

A numerical technique to solve the equations of an engineering (e.g., vibration) problem. A continuum is divided into a number of relatively small regions called elements that are interconnected at selected nodes. The kinetic energy or potential energy of the entire continuum is expressed as the sum of the element kinetic or potential energy. The solution is approximated by a linear combination of trial functions, which are typically polynomials. This leads to the assembled mass matrix and the assembled stiffness matrix, and finally to the finite element equations of the problem (vibration).

Fixed end

A boundary condition where the displacement and slope are zero (bending moment and shear force are not zero). Cantilever is obtained by fixing one end of a beam.

Flexible mount

An engine mount made of flexible material (e.g., elastomer or spring) to provide vibration or shock isolation.

Flexibility matrix

The a_{ij} element of this matrix is the displacement at i due to a unit force at j with all other forces equal to zero. Inverse of the stiffness matrix.

Flexural vibration

Bending vibration. The oscillatory motion of a flexible shaft (possibly with a rotor) or a beam or plate in any transverse plane of bending.

Flow resistance

Resistance due to friction between a fluid and some constriction (e.g., a pipe or duct) or between a gas and fibers in acoustic problems. The energy loss may take place in a very narrow layer of air adjacent to each fiber of acoustic material.

Flow resistivity

Unit area flow resistance per unit thickness of a porous material. Given by the applied air pressure difference across the two sides of the material divided by particle velocity through the material.

Fluid damping

Force of external friction whose magnitude is proportional to the square of the velocity, and whose direction is opposite the velocity.

Foil-type strain gauge

A strain gauge consisting of a thin metallic foil. As it is stretched (strained), its resistance increases, which can be measured using a bridge circuit to provide a strain reading.

Force isolation

[See Isolation](#). Vibration isolation of a system from a force source.

Force transmissibility

[See Transmissibility](#). Transmitted vibration force divided by an applied vibration force (or actuator force).

Forced vibration

The steady-state vibration caused by an external excitation (force or input). Typically (in linear problems in particular), forced vibration occurs at the frequency of the exciting force.

Forcing frequency

The frequency of the excitation function (force).

Fourier analysis

Analysis carried out using the Fourier transform. This provides frequency domain information (magnitude and phase with respect to frequency) of a time signal.

Fourier integral

See Fourier transform.

Fourier series expansion

Expressing a general periodic signal into a series (sum) of harmonic (sinusoidal, real or complex) components of integer multiples of a fundamental frequency.

Fourier spectrum

Frequency spectrum of a signal. The spectrum of a signal, as obtained by Fourier transform.

Fourier transform

An integral transform (weighted by a complex exponential function). This converts time-domain information (time signals) into frequency-domain information (frequency spectra) and vice versa.

Frahm absorber

[See Absorber](#). A dynamic (vibration) absorber.

Frame

Countable set of linearly dependent functions.

Free-body diagram

Diagram showing the basic components of an object and all the forces acting on them.

Free vibration

Vibration that occurs in a system after the removal of excitation. Typically, free vibrations occur at one or more natural frequencies.

Free vibration

The oscillatory motion (vibration) of a system that occurs in the absence of an external forcing function (excitation).

Frequency

The repetition rate or periodicity of a periodic event, usually expressed in cycles per second (hertz or Hz), or revolutions per minute (rpm). This is the cyclic frequency, which is the reciprocal of the period. The angular frequency (radians per second or rad/sec) is obtained by multiplying cyclic frequency by 2π .

Frequency domain

The representation of the system variables (including inputs and outputs) as functions of frequency. Related to the time domain through the Fourier transform. Vibration data or results are displayed or usually analyzed as a function of frequency. The independent variable is frequency (ω).

Frequency-domain analysis

Response analysis of a dynamic system with respect to frequency. Typically, uses Fourier analysis, frequency spectra, and transfer functions.

Frequency-domain index

A single number calculated from the frequency spectrum and used for trend analysis and comparison.

Frequency modulation (FM)

A signal modulation method, where a carrier signal is used to transmit another signal (modulating signal, carried signal) over a long distance without distortion. In this method, the amplitude of the carrier is fixed, but its frequency is varied according to the amplitude of the carried (modulating) signal. Typically, radio signals are transmitted by this FM method.

Frequency response

The amplitude and phase response characteristics of a system as functions of frequency under external excitation.

Frequency response function (FRF)

Output or input in the frequency domain, assuming zero initial conditions. Laplace transfer function can be converted into FRF by simply changing the Laplace variable into complex frequency variable $j\omega$. The FRF has amplification and phase change information of a response with respect to an input at various frequency values. It may be plotted as a Bode diagram or a Nyquist diagram.

Frequency transfer function (FTF)

Same as Frequency response function (FRF).

Friction pendulum system (FPS)

One type of sliding isolators, which has a spherical concave sliding surface to produce a recentering force for the isolated structure under excitations.

Fringes

A pattern of dark and light lines obtained when two light waves of nearly equal frequency are mixed. This method is used in some sensors, for example, for measuring small velocity changes (by Doppler effect).

Full bridge

A bridge circuit with four arms. It can be used to sense small changes in one of the arms (consisting of a resistor, inductor, capacitor, etc.). A half bridge contains two arms.

Full-scale drift

The drift (undesirable variation of the output when the input conditions are kept constant) of an instrument, when the input conditions correspond to its full-scale (maximum) value.

Fully differential capacitive sensor

A bridge in which all four components change in symmetric manner.

Fully operational

The highest performance level at which a structure is expected to operate with all functions, after an earthquake attack, if there is no (or at least very little) structural and nonstructural damage.

Fundamental frequency

Fundamental natural frequency. The lowest (first) natural frequency of a (vibrating) system.

Fundamental natural mode of vibration

The mode of vibration of a system having the lowest natural frequency.

Fuzzy logic

An approach to computing (soft computing) and knowledge-based decision making, based on the “degrees of membership” in a set, rather than the conventional binary membership (member or nonmember). Fuzzy data are matched with a fuzzy knowledge base to generate fuzzy inferences (decisions). A more general form of “true or false” boolean logic on which the modern computer is based, and incorporates such logic states as slightly true or very true.

FVC

Frequency to voltage converter.

***g* units**

Units of acceleration due to the Earth’s gravity (by international agreement, $g = 9.80665 \text{ m/sec}^2$ or 386.087 in/sec^2 or 32.1739 ft/sec^2). Divide an acceleration value by the value of g to obtain (as a ratio) the acceleration in g units.

Gabor transform

A sampled short-time Fourier transform.

Gaussian elimination

The process by which a matrix is converted by elementary row operations to an upper triangular matrix.

Generalized coordinates

A coordinate system, which does not necessarily use physical coordinates to represent the dynamics of the system. An example is the modal coordinates.

Generalized forces

See Generalized coordinates. When multiplied by the increment of the corresponding generalized coordinate, the product is equal to the actual incremental work done by that force in moving through that incremental motion.

Geometric modeling

The process of transcribing the geometry of a system into a finite element or CAD data base.

Geometric nonlinearity

Nonlinearity caused by geometrical constraints, such as rubber mount casing, or by trigonometric functions in the kinematic equations of the system (e.g., robot).

Gradient wind

Wind velocity above the boundary layer.

Green's function

The solution that represents the sound field generated by an impulsive source in space and in time. Useful in describing the sound field generated by a continuously distributed source, with convolution integration, both in free space and bounded space.

Ground vibration

A wave transmitted through the ground that causes the surface particles of ground to oscillate as it passes.

Guyan reduction

A procedure to reduce the model scale for vibration analysis by removing those DoF (called slave DoF) that can be approximately expressed by the rest of the DoF (called master DoF) through a static relation.

Gyroscopic action

A torque (or moment) is necessary to change the direction of angular momentum vector (the product of inertia and angular velocity vector) of a spinning member. Without such a torque, the member will remain oriented in a fixed direction.

Gyroscopic motion

Motion of bodies in 3-D space subjected to multiple angular rotations, causing gyroscopic effects.

Gyroscopic sensor

A sensor based on the gyroscopic principle, commonly used to measure angles from a fixed reference, when a physical surface representing such a reference is not available.

h-conversion

The process of achieving convergence or improving the accuracy of a finite element solution through increasing the number of elements, while keeping the element order the same.

Haar wavelet

The first known wavelet derived from a step function.

Half bridge

[See Full bridge.](#)

Half-power bandwidth

The frequency interval in a spectrum where the magnitude drops to $1/\sqrt{2}$ the peak, resonant value (i.e., half the power).

Half-power points

See Half-power bandwidth. The two frequency points representing the half-power bandwidth.

Half-sine shock

Simple shock for which the acceleration-time curve has the form of a half-period (positive or negative part) of a sinusoid.

Hamilton's principle

Variation of the difference of the system kinetic energy and the system potential energy plus the line integral of the virtual work done by the nonconservative forces during any time interval must be equal to zero.

Hammer test

An impact test where the test object is impacted with an instrumented hammer and the corresponding excitation and response signals of the object are measured. It can be used to determine natural frequencies and damping ratios.

Harmonic

A sinusoidal quantity having a frequency that is an integral multiple of the frequency of a periodic quantity to which it is related (normally the fundamental frequency).

Harmonic oscillator

This oscillator produces periodic oscillation described mathematically by either of the harmonic trigonometric functions (sine or cosine), which has only one frequency component (undamped natural frequency of the oscillator). Similar to an undamped simple oscillator.

Harmonic response analysis

Harmonic response analysis is used to determine the response of a vibration system to a harmonic (i.e., sinusoidal) excitation force. A typical output is a graph showing response (usually displacement of a certain degree of freedom) vs. frequency. The response has an amplitude (amplification) and a phase change with respect to the harmonic excitation, which are characteristics of the system itself.

Hearing loss

Permanent hearing loss is caused by excessive and prolonged noise exposure, which destroys the auditory sensor cells.

High-tech facility

Production lines for printed circuit boards, high precision devices, semiconductor devices, electronic appliances, etc., employing robotics, automation, and other modern and advanced technologies.

Holonomic system

A mechanical dynamic system where all of the constraints can be represented by algebraic equations (not differential equations). In this case, the number of DoF is equal to the number of independent coordinates needed to represent an arbitrary position and orientation of the system.

Homogeneous equation

An unforced ordinary differential equation. For a dynamic system with zero input, the right-hand side of the system differential equation will be zero, giving a homogeneous equation.

Hooke's Law

Linear spring equation. Deflection is proportional to the applied force. Strain is proportional to stress in one dimension.

Hydraulic actuator

A piston-cylinder (i.e., ram) device to which a controlled and pressurized fluid is sent, thereby moving the piston. This motion can be used to move another object. This describes a linear (rectilinear) actuator, although rotary hydraulic actuators are also available.

Hyperpatch or Volume

A portion of tri-cubic solid completely bounded by four areas (for tetrahedron volumes) or six areas (for brick volumes).

Hypocenter

The location of initial radiation of seismic waves (i.e., the first location of dynamic rupture).

Hysteresis

Greek word meaning “arrive late,” used to describe a specific nonlinear processes where the response curve when the input is increasing is different from that when the input is decreasing, resulting in a hysteresis loop. Examples include magnetic systems (due to residual magnetism) and plastic systems (due to residual stresses and strains).

Hysteresis loop

A diagram that describes the force–deformation relation of a nonlinear device of the hysteresis type. See Hysteresis. Vibration isolator with hysteretic damping produces a hysteresis loop, the area of which gives the energy dissipation in one cycle of vibration.

Hysteretic damping

Internal friction type damping in material where the energy dissipation per cycle is independent of frequency.

Imbalance

The eccentricity that exists between the center of mass of a rotor and the axis of rotation that generates centrifugal forces, resulting in vibrations and undesirable forces at the bearings.

IC engine

Internal combustion engine. A mixture of fuel and air is ignited in a cylinder, causing the piston of the cylinder to move.

Imission

Receiving, perceiving or observing radiated noise, causing noise exposure at a location near the noise source. Noise imission is legislated using an Environmental Quality Standard.

Impedance

Resistance exhibited by a “flow” variable (e.g., current, velocity) to an applied “effort” variable (e.g., voltage, force), expressed as a transfer function in the frequency domain. See [Mechanical impedance](#) and [Electrical impedance](#).

Impedance bridge

A bridge circuit with inductor or capacitor elements in addition to resistors in at least one of its four arms.

Impedance transformer

A device with a very high input impedance and very low output impedance. Typically, an operational amplifier with feedback.

Impeller

A bladed member of the rotor of a pump or compressor that imparts principal energy into the fluid that is being pumped or compressed.

Impulse

The product of the force on a body and the time during which that force acts, equal to the change in momentum.

Impulse response function

The response of a system to a unit impulse input. Inverse Fourier transform of the frequency response function (or inverse Laplace transform of the transfer function) of the system.

Incipient failures

Partial and usually gradual failure of a machine.

Inelastic response

A structure subjected to large excitations, resulting in yielding of longitudinal rebars.

Inertia

A property of matter where it resists a change in motion, including resistance to change from a position at rest.

Inertia asymmetry

The moments of inertia in two orthogonal planes are not equal.

Inertia block

A block or a heavy plate attached to the base of a machine in order to achieve good vibration isolation.

Inertia matrix

A matrix consisting of direct and cross moment of inertia terms in three dimension of a rigid body. Mass matrix. The matrix multiplied by the acceleration vector of a multi-DoF system in its Newtonian equations of motion expressed in the vector-matrix form.

Inertial actuator

A class of actuators in which the actuation force is generated through the addition of inertial masses and applying the resulting inertial forces on the system at the actuator point of attachment.

Influence coefficient

A coefficient representing the effect at a particular point of an action some other point.

Initial conditions (ICs)

The conditions of the response of a dynamic system at time $t = 0$. These are temporal conditions, different from boundary conditions, which are special conditions. The required number of ICs is equal to the “order” of the system, or the number of state variables needed for the system, or the order of the highest derivative of the input–output differential equation.

Inner ear

Cochlea is the main component of inner ear, where the actual reception of sound takes place. The mechanical motion caused by the sound wave is transmitted to basilar membrane and its associated sensing cells, where this motion is sensed as sound.

Inner modulation

Current structural vibration.

Input

The force or energy (or a motion such as support motion) applied to a mechanical system.

Input–output equation

A single differential equation with the response as the dependent variable and the input as the independent variable.

Insertion loss

The insertion loss of a muffler is defined as the difference between the sound pressure or acoustic power level at the same point in space before and after the muffler is connected to the noise source.

Instability

A self-induced excitation that can occur in rotating machinery, which does not require a sustained forcing phenomenon to initiate or maintain the motion. At the inception of instability, the rotor deflection will continue to build up with speed, and if further increased the large amplitudes of motion will normally result, causing damage to the machine.

Intensity

A metric of the effect, or the strength, of an earthquake hazard at a specific location, commonly measured on qualitative scales such as MMI, MSK, and JMA.

Internal friction

Damping that derives from structural defects internal to structural components of a vibrating system.

Interplate

Processes between the Earth's crustal plates.

Interval model

A linear regression model with interval coefficients to represent the range of aircraft vibrations caused by blade adjustments. This model can account for the stochastic and nonlinear nature of aircraft vibration.

Intraplate

Processes within the plates.

Intrinsic

Opposite of extrinsic. A method where the device is used to directly generate the objective (e.g., signal) rather than simply to transmit it. Some types of fiber-optic and ultrasound sensors use the intrinsic approach (as well as extrinsic approach).

Intrinsic loss factor

Factor in a subsystem to represent the loss of vibration power with respect to the total power.

ISO

International Organization for Standardization. Technical Committee 108, Subcommittee 5 is responsible for standards for Condition Monitoring and Diagnostics of Machines.

Isolation

Diminishing the transfer of vibration amplitude from a machine to another machine or a structure by the judicious selection of barrier materials and barrier configuration. Vibration isolation of a system from a vibration source. Inverse of "transmissibility."

Isolation period

Vibration period of the isolation system.

Isotropic

Being the same in all directions. [See Orthotropic.](#)

Jerk

The rate of change of acceleration with time (third derivative of displacement with respect to time).

Johnson noise

White noise (approx.), whose value depends on both bandwidth and resistance.

Journal bearings

Journal bearings consist of a circular section of shaft, called the journal, rotating inside a cylindrical bush, called the bearing. The space between the two is partially filled by the lubricating fluid, which is drawn up around the journal due to the effect of elasto-hydrodynamic lubrication.

Jump phenomenon

A nonlinearity where the frequency response of a system sharply shifts up or down (jumps) at a particular frequency, as the frequency of excitation to the system increases or decreases through this frequency.

K-normal

A modal vector z that is normalized with respect to the stiffness matrix K , such that $z^T K z = 0$

Keulegan–Carpenter number

The Keulegan–Carpenter number indicates the relative importance of the drag and inertia forces for small (small compared to the wavelength) diameter structures. A small Keulegan–Carpenter number means that the inertia force is more important than the drag force.

Key point

A coordinate location in space.

Kinematic design

Design of a structure by its motion, independent of mass and force.

Kinematics

Motion geometry of bodies.

Kinetic energy

Energy associated with motion (velocity).

Kronecker delta

A function of two indices, which is equal to one when the two indices are identical, and zero otherwise. It may be used to represent a unit matrix (or identity matrix), a diagonal matrix with unity diagonal elements.

Kurtosis

Fourth probability density moments sensitive to the impulsiveness in the vibration signal and, therefore, sensitive to the type of vibration signal generated in the early stages bearing fault of a rolling element.

LabVIEW

Industry standard equipment, software, and hardware marketed by National Instruments.

LaCoste zero-length spring

Spring of a vertical seismometer, which would collapse to zero length if wire of the coil was of infinitesimal diameter.

Lagrange's equations

Differential equations of motion of a dynamic system, obtained using the Lagrangian energy approach, in terms of a set of generalized coordinates. There are as many Lagrange's equations as there are generalized coordinates. The forcing terms are generalized forces.

Lagrangian

Equal to total kinetic energy minus the total potential energy of the system.

Laminated rubber bearing (LRB)

A type of elastomeric isolators that is usually composed of alternating layers of steel and hard rubber ensuring it is stiff enough to sustain the vertical loads, yet flexible under the lateral forces.

Laplace transform

An integral transform weighted by an exponential function of the Laplace variable s . It converts a derivative into a power of s , of the same order. Hence, a differential equation is converted into an algebraic equation. Related through the Fourier transform through $s = j\omega$, where ω = angular frequency and $j = \sqrt{-1}$. An input–output equation is converted into a transfer function.

Lateral force resisting system

A structural system for resisting horizontal forces due, for example, to earthquake or wind (as opposed to the vertical force resisting system, which provides support against gravity).

Learning

Adaptation of the interval coefficients to represent the range of vibration caused by blade adjustments more effectively.

Life safety

The third performance level in which a structure is expected to survive an earthquake. The life safety of occupants is not endangered either by structural collapse or the presence of heavy falling debris, although substantial damage may occur to both structural and nonstructural building components.

LIGO

Laser Interferometer Gravitational Wave Observatories of the U.S.

Limit cycle

An instability in a nonlinear system that is exhibited as a steady oscillation of amplitude that is independent of the input amplitude.

Limiting stable depth-of-cut

Depth-of-cut below which chatter will not occur for a given spindle speed of a machine tool.

Line noise

Noise at the frequency of the voltage signal in a power line (60 or 50 Hz) caused by the power lines in the vicinity of a system (e.g., through ground loops).

Line or line segment

A portion of a cubic spline curve bounded on both ends by a key point. A line may be straight or curved.

Linear quadratic regulator (LQR)

A linear feedback controller with constant gains, which minimizes a cost function consisting of the time integral of the sum quadratic functions (positive definite and semidefinite) in the state variables and input variables.

Linear system

A system is linear if it can be represented by a set of linear differential equations. The principle of superposition holds. Its magnitude of response is directly proportional to its magnitude of excitation for every part of the system.

Linear-variable differential transformer

See LVDT.

Load–displacement relationship

The relationship between the load on a structure and the corresponding displacement.

Logarithmic Decrement

Measure of damping. Equal to the natural logarithm of the ratio of successive amplitudes of free decay. It is inversely proportional to the magnification factor (quality factor), Q .

Long-term statistics

Statistics of the short-term parameters such as the significant wave height.

Lorentzian

Resonant response of a driven harmonic oscillator with damping. Also, the shape of spectral lines in atomic physics.

Lorenz force

Force on a current-carrying wire located orthogonally in a magnetic field.

Loudness level

The loudness of sound is determined by subjective comparison with the loudness of a pure tone of 1000 Hz. The level, measured in “phons,” is numerically equal to the sound pressure level, in decibels (dB), of the 1000 Hz tone.

LPA

Last point algorithm for performing numerical integration. Will not become unstable like Euler’s first point approximation does.

Lumped mass

A point presentation of the mass of a system. Results in a diagonal matrix.

Lumped mass matrix

The diagonal mass matrix obtained by lumping the inertia of a system by element masses at the nodes finite element mesh.

Lumped-parameter model

A model where the system components are represented by parameters (e.g., mass, stiffness, damping coefficient) concentrated at a finite number of points. An approximation of a distributed-parameter system.

LVDT

Linear variable differential transformer. A popular noncontact sensor for measuring linear (rectilinear) displacements. Operates by the transformer effect, with a movable ferromagnetic core element (attached to the sensed object).

M-normal

A modal vector z that is normalized with respect to the mass matrix M , such that $z^T M z = 0$.

Machinery failure

The inability of a machine to perform its required function due to some defect in the machine components.

Machining

Removal of excess material from a piece of material (workpiece) by moving a working tool over the surface of the workpiece to achieve a desired shape.

Magneto-rheological (MR) fluid

A magnetic fluid analogous to electro-rheological (ER) fluid. Typically consists of micron-sized, magnetically polarizable particles dispersed in a carrier medium such as mineral or silicon oil. When a magnetic field is applied to the fluid, particle chains are formed, and the fluid becomes a semisolid and exhibits viscoplastic characteristics.

Magnetorheological damping

Damping associated with a magnetic fluid and a magnetic field.

Magnitude

A measure of an earthquake's release of strain energy, measured on a variety of scales, of which the moment magnitude MW (derived from seismic moment) is preferred. The absolute value of a complex quantity (e.g., FRF).

Masks

Baseline spectra that are used with an allowable tolerance limit to "filter out" or block specific frequencies. Optical plates with windows for concentrating light from a source to generate better contrast in an optical pulse-generating transducer (e.g., optical encoder).

Masonry structure

A structure built from bricks and cement mortar that has relatively small lateral and tensile strength, which is vulnerable to an earthquake attack.

Mass law

For a single plate, the transmission loss depends on frequency and the surface density of the plate in the frequency range from the fundamental (lowest) natural frequency to the critical frequency of the plate.

Mass matrix

The matrix multiplied by the acceleration vector of a multi-DoF system, which, in its Newtonian equations of motion, is expressed in the vector-matrix form. Typically, a diagonal matrix with its diagonal elements giving the masses corresponding to various DoF of the system.

Mathematical expectation

Also known as "expected value." The mathematical expectation of a random function is the integral of that function weighted by its probability density function. If the function is the random variable X , the expected value gives the mean value (\bar{X}), which is the first moment statistic. If it is X^2 , we get the second moment statistic. If it is $(X - \bar{X})^2$ we get the variance, the square root of which is the standard deviation of a random parameter. Other higher order statistics of X can be derived similarly.

Matlab

MATLAB[®] is a commercial software package (tool) for numerical computation, visualization and symbolic manipulation. Various toolboxes are available for specialized computation on important subjects such as control and signal analysis.

Maximax shock response spectrum

Envelope of the absolute values of the positive and negative shock response spectra. [See Response spectrum.](#)

Mechanical design

Design of a structure or building utilizing the properties of electronic and mechanical subassemblies and parts.

Mechanical impedance

Force or velocity in the frequency domain. This transfer function is one of many used in the analysis and design of vibrating systems.

Mechanical looseness

A condition where two or more mechanical components, which are designed to be rigidly connected or in firm contact, can move relative to one another. See [Backlash](#) (in gears).

Mechatronics

Synergistic integration of electronic and electrical engineering, computer technology and control engineering with mechanical engineering, using concurrent and integrated design techniques. This area forms a crucial part in the design, manufacture, and maintenance of a wide range of engineering products and processes.

Mean free path

Distance a molecule travels on average in a gas between molecular collisions.

Measure of noise evaluation

Energy based indices like L_{Aeq} (equivalent A-weighted sound pressure level) for noise evaluation. All of these measures are legislated by the government, and are dependent on legislative regulations or standards.

Member

Any individual component of a structural frame. An element is within a set (membership = 1).

MEMS

Microelectromechanical systems. A relatively new and important field concerned with modeling, analysis, design, and development of very small mechanical devices with electrical or electronic features.

Mesodynamics

A new term to describe complex behavior of otherwise harmonic mechanical oscillators with energies approximating 10^{-11} J.

Mesomechanics

Focused on the complex behavior of granular materials.

Mexican hat wavelets

Obtained by calculating the second derivative of a Gaussian.

Meyer wavelets

Wavelets associated with enveloped trigonometric functions.

Microdynamics

Dynamics describing complex features of contact friction, largely advanced by NASA.

Microphone

A device for producing an electrical signal from an acoustic pressure (sound or voice). Standard equipment in acoustic or sound acquiring and generating systems.

Microphone array

A directional measuring device that consists of an array of miniature microphones distributed spatially in an acoustic field.

Middle ear

Consists of three small ear bones, the hammer, anvil and stirrup. Serves as an impedance transformer, which matches the low impedance of the air in ear canal with the high impedance of inner ear.

MIMO

Multi-input–multioutput system. A system with many inputs and many outputs. A multivariable system.

Mirror microphone system

A directional measuring device that consists of a reflector of elliptic or parabolic shape and an omnidirectional microphone located at its focus.

Misalignment

A condition when two rotating machines (or components) are not coupled together along a single axis (straight line) of rotation.

Mobility

The transfer function (velocity or force) in the frequency domain. The inverse of mechanical impedance.

Modal analysis

The dynamics of a system may be formulated as a problem of determining eigenvalues and eigenvectors of a matrix. This matrix is $M^{-1}K$, where M is the mass matrix and K is the stiffness matrix in the undamped case giving natural frequencies, time constants and modal damping ratios. See [Eigenvalue analysis](#) and [Eigenvalue problem](#). The imaginary parts of the eigenvalues are the natural frequencies of the system. The reciprocal of the imaginary parts are the time constants of the system. Imaginary parts divided by the corresponding undamped natural frequencies provide the modal damping ratios. The eigenvectors provide the mode shape information. The analysis that provides both natural frequencies and mode shapes is called modal analysis. This is the process of decomposing the vibrations (or response) of a complex system into its component modes of vibration (motion). One goal may be to find the locations and frequencies of maximum (undesirable) response for application of vibration control or suppression methods (e.g., stiffener and dampers).

Modal density

The number of mode shapes present in a unit spatial area or the number of natural frequencies in a unit frequency interval.

Modal matrix

The square matrix formed by placing all the independent mode shape vectors as column vectors.

Modal vector

A mode shape vector expressed as a column vector.

Mode

The condition where a mechanical system moves at one natural frequency while maintaining a characteristic shape (mode shape). Can also apply to nonmechanical systems.

Mode mixing

Transfer of energy among modes of different frequencies. This assumes nonlinearity and is not the same as beating.

Mode shape

The deflected characteristic shape, usually normalized, that a system would take when it vibrates at one of its natural frequencies. All elements move in step at this frequency while maintaining a specific shape. Some points will remain stationary throughout, which and they are called nodes. Only the shape of the curve would be known from a modal analysis. If the mode shapes are real, they correspond to natural modes. Otherwise, we have complex modes, which is the case in the presence of some types of damping.

Model identification

Experimental modeling. Determining an analytical model of a dynamic system using input–output test data. [See Experimental modal analysis.](#)

Model reduction

Reduction of the order or the number of DoF (of a vibrating system) by using some accuracy limits (error tolerance). Modal truncation is used, where modes above a specific frequency are neglected. Means of simplification and idealization based on the nature of the vibration problem.

Modulation

Embedding a signal within a carrier signal so that the original signal (carried signal or modulating signal) does not lose accuracy during transmission. Examples are amplitude modulation (AM), frequency modulation (FM), and pulse-width modulation (PWM).

Modulus of elasticity

Young's modulus. Direct stress divided by direct strain in one dimension.

Mohr's circle

A circle for representing stresses, strains, or moments of inertia at a particular point of system in different directions. The horizontal axis indicates the direction of the principal values and the vertical axis the shear (or cross) values. The angle around the circle is double the physical angle in the system.

Moment of inertia

A mass parameter that is measure of the resistance (inertia) of a body to angular acceleration about a given axis. Equal to the sum of (or integral to) the products of each element of mass in the body and the square of the element's distance from the axis.

Momentum

A property of a moving body that exists by virtue of its mass and motion, to resist any change to that motion. Equal to the product of the body's mass and velocity. It is a vector (with a direction as well as a magnitude) in the same direction as the velocity.

Monopole

An acoustic source with energy density concentrated at a single point in space. The most basic sound source, where the source region is compact and the generating motion has no preferred direction. Monopole produces a wave that spreads spherically outwards.

Mother wavelet

The function used to generate all the basis functions of the space by dilation and translation.

Motion isolation

[See Isolation](#). Vibration isolation of a system from a motion source.

Motion transmissibility

[See Transmissibility](#). Transmitted vibration motion divided by an applied vibration motion (or support motion).

Mounts

Usually, vibration mounts used for vibration isolation.

Muffler

A structural device that suppresses noise when fluid (e.g., hot and high-speed gas) flows through it. [See Dissipative muffler](#) and [Reactive muffler](#).

MTBF

Mean time between failures.

MTTF

Mean time to failure.

Multibody-spring-dashpot

Collection of rigid bodies joined together by springs and dashpots.

Multiresolution analysis

The process of studying a signal at different scales by use of different time windows to capture characteristics varying from coarse to fine.

Narrowband

Corresponding to a narrow (small) frequency interval (band).

Narrowband process

A random process where most of the energy is concentrated in a narrow band (interval) of frequency.

Natural frequency

The frequency of free vibrations of a system without the influence of an external forcing, except for an initial excitation to start the motion. Also a self-induced phenomenon. For a single-DoF system, $\omega_n = (k/m)^{1/2}$, where ω_n is the undamped natural frequency, k is the spring stiffness, and m is the mass. When damping is present, the natural frequency decreases to ω_d , which is the damped natural frequency given by $\omega_d = \sqrt{1 - \zeta^2} \omega_n$, where ζ = damping ratio. For a multi-DoF system, the natural frequencies are the frequencies of the normal modes of vibration.

Natural mode

[See Mode shape](#).

Natural period

The time period of one complete cycle of free vibration. The inverse of the natural frequency (cyclic).

Natural vibration analysis

[See Modal analysis](#). The natural vibration analysis is to determine the natural vibration frequencies and the associated mode shapes of a vibration problem when the excitation forces are zero. They are intrinsic characteristics of the vibration problem and independent of the excitation forces.

Near-fault ground motions

Ground motions, typically assumed to be within a distance of about 20 to 60 km from a ruptured fault, which usually have long-period velocity pulses that impart considerable momentum to a long-period structure.

Negative averaging

A baseline signal that is recorded and then subtracted from subsequent signals before analysis to reveal changes and transients.

Negative definite

A symmetric matrix is negative definite if $\mathbf{x}^t \mathbf{A} \mathbf{x} < 0$ for every nonzero vector \mathbf{x} .

Negative shock response spectrum

[See Shock response spectrum \(SRS\)](#). SRS plotted, considering the highest negative response due to the shock, without reference to the duration of the shock. It is the envelope of the negative primary and residual spectra.

Neural Network (NN)

A nonanalytical (computational) modeling technique, inspired by the human nervous system. Considered as a “learning” network. A network of massively parallel network is trained (by adjusting the network weights, etc.) to yield a known (correct) output for a given input. Once trained, it may be used as a computational model of the system. Further training and adaptations may be done subsequently. Several variations of this feed-forward network architecture are available (e.g., feedback, recurrent, dynamic, reinforcement learning).

Neutral axis

The axis along a bending beam where the stress and strain are zero. Undeformed axis when a beam is bent.

Nodal point

In finite elements: a point of connection between elements. A node will have a specific number of degrees of freedom, indicating its ability to move or rotate. In vibrations: a point or a line in the mode shape of a structure that does not move (see Node).

Node

[See Mode shape](#). Points that are stationary in a modal vibration. The mode shape curve passes through the relaxed configuration of the structure at these points.

Noise (1/f)

Also known as pink or flicker noise. Common in complex systems of both electronic and mechanical type.

Noise Criteria (NC)

NC curves are utilized for rating the background noise level in a room. Each curve specifies the maximum octave-band sound pressure level for a given NC rating. [See Preferred noise criteria \(PNC\)](#).

Noise regulation law

This regulatory standard defines the national minimum for noise suppression, for example, factory noise, construction work noise, and road traffic noise. The central government is the regulating agency. [See Emission](#).

Nomograph

A logarithmic frequency–velocity plotting graph sheet. The sheet gives constant displacement, constant velocity, and constant acceleration lines, properly graduated. A period axis (period = $1/\text{cyclic frequency}$) is given for convenience of plotting.

Nonclassical damping

Damping that cannot lead to modal decoupling of a structural system. For this case, the mode shapes of a structure can only be expressed in terms of complex (not real-valued) functions.

Nonholonomic system

A mechanical dynamic system where one or more of its constraints need differential relations (not algebraic equations) for mathematical representation. In this case, the number of DoF is equal to the number of independent “incremental” coordinates needed to represent an arbitrary increment (change) in position and orientation of the system, and is less than the number of independent coordinates needed to represent an arbitrary position and orientation of the system.

Nonlinearity

A characteristic that is not linear (e.g., hysteresis, saturation, deadband, jump phenomenon, nonlinear or nonproportional force–motion relationship). Represented by nonlinear equations. The principle of superposition does not hold. [See Linear system.](#)

Normal modes

[See Natural mode.](#) In a multiple DoF system, the normal modes are the free natural configurations in which the system vibrates. A mode is characterized by its natural frequency and mode shape. The mode shape depends only on the mass and stiffness of the system and how they are distributed, and not on damping. Normal modes exist for all undamped systems and only for a selected class of damped systems (e.g., proportional damping).

Normal wear period

A relatively long period of operation during which the frequency of failure occurrence is relatively low.

Notch filter

A bandstop filter when the band is very small.

Nyquist frequency

Half the sampling rate. The frequency above which the spectrum of a digital signal has no significance and should be ignored.

Nyquist plot

Plot of frequency transfer function (FTF) on a complex plane where the horizontal axis gives the real part, and the vertical axis gives the imaginary part of the FTF.

OBE

Operating basis earthquake. An earthquake representation (e.g., response spectrum) under which a nuclear power plant can operate safely.

Occupational Noise

Noise received at the workplace, indoors and outdoors, caused by all noise sources in the vicinity of the workplace.

ODS

Operational deflection shape of a structure.

Offset

Steady-state error in response of a device.

Oil whip

A condition that occurs when a subsynchronous instability (oil whirl) excites a critical speed (resonance), which then remains at a constant frequency regardless of speed changes.

Oil whirl

A condition that occurs when the lubrication in a lightly loaded journal bearing does not exert a constant force on the supported shaft, and a stable operating position is not maintained.

Oil whirl/whip

[See Whirling](#). The whirling motions that occur due to oil action in journal bearings when operated at or above double the critical speed of the rotor. The whirling motion is in the forward direction and its speed will match the critical speed of the rotor. The oil film is believed to rotate at half the velocity of the shaft due to friction drag. At rotational speeds near twice the critical speed, the oil film provides the stimulus as its speed matches the critical speed value resulting in large displacements and whipping.

Omnidirectional microphone

A microphone whose response does not depend on the direction of the incident sound.

Operating basis earthquake

[See OBE](#).

Operational

The second performance level in which a structure is expected to function in a limited manner after an earthquake because of some damage to structural or nonstructural members.

Optical encoder

A digital transducer that measures displacement. The encoder plate (disk) has light-passing areas (windows) on one or more tracks, with a light source on one side and a light sensor on the other side. As the plate moves, a pulse signal is generated by the light sensor. The pulse count gives displacement and a pulse rate gives speed.

Orbit

A plot of the displacement Y -direction (ordinate) versus the displacement in X -direction (abscissa).

Order

The order of the highest derivative of a differential equation (DE) and the highest difference in a difference equation. The order of a dynamic system corresponds to the number of first-order DEs needed to represent the system. Factor of rotational speed of a machine used to represent nondimensional frequency in tracking (monitoring) its spectral response (in the frequency domain). See also order tracking.

Order tracking

Cascade plots of machine response (vibration) spectra that are synchronously linked to the machine rotational speed via a tachometer.

Orthogonality

Generalized perpendicularity. If the vectors x and y are orthogonal, then $\mathbf{x}^T \mathbf{y} = \mathbf{y}^T \mathbf{x} = 0$. If the vectors x and y are orthogonal with respect to matrix P , then $\mathbf{x}^T P \mathbf{y} = \mathbf{y}^T P \mathbf{x} = 0$.

Orthotropic

Not uniform in all directions (not isotropic).

Oscillation

A periodically increasing and decreasing variation of a response. In forced oscillation, the force itself oscillates causing an oscillatory response. In free oscillations, the cause is the continuous interchange of energy between two forms (e.g., kinetic energy and potential energy), where the variation can be either constant amplitude (undamped) or decaying amplitude (damped). If the amplitude progressively increases, it is an unstable oscillation. No oscillations occur in overdamped systems because energy is more rapidly dissipated than it is interchanged, leaving no energy for a returning (reversed) response.

Outer modulation

Structural vibration delayed by one tooth passing period.

Outer ear

Composed of pinna, ear canal, and eardrum. Pinna produces only a small enhancement of the sounds arriving from the front of the listener. Ear canal works as a resonant cavity allowing for a nearly reflection-free termination, and thus a good impedance match of eardrum. Eardrum transforms sound wave to vibration in the membrane.

Overdamped response

No oscillations occur in overdamped systems because energy is more rapidly dissipated than it is interchanged between two forms (e.g., kinetic and potential), leaving no energy for a returning (reversed) response. For a simple DoF mass (m)–spring (k)–damper (c) system, the condition for overdamped behavior is $4k/m < (c/m)^2$.

Overall sound pressure level

The pressure is evaluated as the root mean square (RMS) of all components of pure tones. Can be converted into decibels (dB) as for any sound pressure.

Overlap index

Denotes the overlap in coverage of more than one gearbox component by one accelerometer location.

***p*-conversion**

The process of achieving convergence or improving the accuracy of a finite element solution through increasing the order of the elements, while keeping the number of elements the same.

Parametric instability

A self-excited motion, representing an instability that is induced by the periodic variation of the system parameters such as inertia, mass, and stiffness. The system cannot be represented by linear differential equations with constant coefficients.

Particle velocity

The fluctuating velocity of a material particle associated with a sound field (units: m/s). Using Newton's Second Law, we can solve for the particle velocity u in terms of sound pressure p .

Particular integral

A particular solution (just one solution) that is satisfied by a nonhomogeneous differential equation.

Particular solution

Same as particular integral.

Passive vibration control

A vibration control method in which a resilient member (stiffness) and an energy dissipater (damper) are utilized to either absorb the vibratory energy or dissipate it inside the damper. By definition, no external power source is needed in a “passive” system.

Patch or area

A portion of a bicubic surface completely bounded by three line segments (for triangular patches) or four line segments (for quadrilateral ones).

Peak

Maximum value of a varying quantity (or a spectrum) measured from the zero or mean value.

Peak ground acceleration (PGA)

The maximum amplitude of a recorded acceleration (similar to the ZPA, or zero period acceleration, which is the acceleration at infinite frequency).

Peak level

The highest absolute value in a vibration signal.

Peak-to-peak value

For an oscillating quantity, this is the algebraic difference between the maximum and minimum extremes of the quantity.

Pendulum

A simple pendulum. A point mass suspended from a fixed point by a string. A mechanical-swing oscillator whose motion is harmonic at small amplitudes, but nonlinear otherwise — an archetype of deterministic chaos. These are assumed to have just one DoF (the angle of swing). More complex pendula such as compound pendulum and double pendulum, which have more than one DoF, are available.

Perimeter

The edge or boundary of an area.

Period

Duration of one complete cycle in a cyclic waveform (e.g., vibration signal, pressure or particle local velocity in an acoustic system). The inverse of the cyclic frequency (Hz).

Period shift effect

Reducing the structural response by increasing the structural period.

Periodic monitoring

Regular and intermittent data gathering and analysis with portable and removable, monitoring equipment.

Periodic quantity

An oscillating quantity whose value repeats itself in cyclic (periodic) manner.

Phase

The fractional part of a period through which a variable (signal) has advanced, measured from an arbitrary reference. A time difference, expressed in degrees, between two signals gives their phase difference. A shift of one period of the signal is considered a phase shift of 2π (or 360°). Phase lag corresponds to a time delay and phase lead corresponds to a time advance of the signal.

Phase angle

The fractional part of a period through which the quantity has advanced as a measure from a reference independent variable.

Phase difference

[See Phase](#). The differences between the phase angles of two periodic quantities. In theory, only those components with the same frequency can be compared for phase.

Phase noise

See Phasor. In phasor representation, the noise vector that is perpendicular, rather than parallel, to the oscillator (primary signal) vector.

Phasor

A rotating vector of length (magnitude) a and angular speed ω . Its projection on the vertical axis gives a sinusoidal wave of amplitude a and angular frequency ω . The phase angle may be represented by the starting angle of the phasor from a reference line (e.g., vertical axis).

Phons

Unit of loudness level. [See Loudness level](#).

Photogate

Infrared beam device used for time interval measurement.

Physical pendulum

[See Pendulum](#). Contrasted with a simple pendulum, its motion at very small amplitudes is not harmonic — an archetype of mesodynamic complexity.

Physical realizability

Whether an analytical model is physically realizable (whether the cause–effect condition or causality is satisfied).

Pierson–Moskowitz spectrum

A parameter ocean-wave spectrum first derived for the North Atlantic, which is applicable for deep water, fully developed, and unidirectional seas.

Piezoelectric

A phenomenon exhibited by some materials in which application of a strain (or stress) causes the establishment of an electric field (or charge) and vice versa. The forward principle is used in piezoelectric accelerometers and the reverse principle is used in piezoelectric actuators.

Pinned beam

[See Simply supported beam](#).

Pitch control rod adjustments

Extension or contraction of pitch control rods by a number of notches to alter the pitch of the rotor blades. Positive pitch rod adjustments indicate extension.

Plane wave

A sound wave that is uniform over any plane normal to a specified axis. This is applicable when propagation of sound wave is one-dimensional and the amplitude of the sound pressure variation is constant. This is approximately valid locally for a sound field very far from the source region.

Poisson's ratio

Lateral strain divided by the direct strain (absolute value, disregarding the sign) in a member in tension in one dimension.

Poles

Eigenvalues of a system. The roots of the characteristic equation. The characteristic polynomial is the denominator of the transfer function.

Portevin–LeChatelier Effect

“Jerky” strain of a loaded specimen as a result of internal friction arising from mesoscale structural changes.

Post mortem

The investigation of root cause failure mechanisms.

Postprocessing

The process of calculating and graphically representing additional quantities and results (e.g., stresses, reactions) from the primary finite element solution results (e.g., displacements).

Positive definite

A symmetric matrix is positive definite if $\mathbf{x}^T \mathbf{A} \mathbf{x} > 0$ for every nonzero vector \mathbf{x} .

Positive shock response spectrum

SRS plotted, considering the highest positive response due to the shock, without reference to the duration of the shock. It is about the envelope of the positive primary and residual spectra.

Postshock

Shock pulses added after the specified shock test carried out on a shaker to cancel the velocity and displacement of the shaker table at the end of its movement (return to the rest position with a zero velocity).

Potential energy (PE)

Energy due to deformation of a spring or other flexible member (elastic PE) or due to elevated state (gravitational PE).

Potentiometer (Pot)

A displacement sensor consisting of a conductor with a constant voltage applied to it and a slider moving along it. The voltage of the slider is proportional to the displacement.

Power conversion factor

The ratio is sound power generated from a machine divided by the total power of the machine. This factor ranges from 10^{-8} to 10^{-5} for both mechanical and electrical machinery.

Power flow

Acoustic power translation from a subsystem to the next connected subsystem.

Power spectral density

The Fourier transform of the autocorrelation function of a signal. Also called power spectrum. It is a measure of how energy is distributed as a function of frequency for a random signal. A cross spectrum is similarly defined corresponding to the cross-correlation function of two signals.

Power supply

A device that supplies DC power to instruments and circuits. In a regulated power supply, the output voltage does not drop when connected to an external instrument.

Predictive maintenance

An equipment maintenance strategy based on measuring the condition of equipment in order to assess whether it will fail during some future period, and then taking appropriate action to avoid the consequences of that failure. The performance of the equipment is assessed using such approaches as condition monitoring, statistical process control, or the human experience. See also Preventive maintenance.

Preferred noise criteria (PNC)

See [Noise criteria \(NC\)](#). PNC curves are used to modify NC curves and are utilized in exactly the same manner as NC curves.

Preprocessing

The process of building up the geometric and finite element model for a physical system.

Preshock

Shock pulses added before the specified shock test carried out on a shaker to cancel the velocity and displacement of the shaker table at the end of its movement (return to the rest position with a zero velocity).

Pressure of sound

Incremental variation of pressure due to a sound wave, about the ambient atmospheric pressure, with an accompanying variation of the air density.

Pressure pulsations

The oscillatory pressure variations that occur at a point in a fluid system.

Preventive maintenance

An equipment maintenance strategy based on replacing, overhauling or refurbishing machine parts and components at a fixed interval, regardless of its state or condition at that time. See also Predictive maintenance.

Primary adaptation

In feature classification: the process of adapting each weight of the single-category-based classifier (SCBC) closer to the current value of the feature if the corresponding feature is classified as normal.

Primary (or initial) negative shock response spectrum

Shock response spectrum (SRS) plotted using the highest negative response observed during the shock.

Primary (or initial) positive shock response spectrum

Shock response spectrum (SRS) plotted using the highest positive response observed during the shock.

Principal axes of inertia

Orthogonal axes relative to which no cross inertia exist. The inertia matrix will be diagonal in this coordinate frame.

Principal axes of stiffness

Axes along which any deflection will not create resultant loading in any other direction. The stiffness matrix will be diagonal in this coordinate frame.

Principal directions

See [Principal axes](#).

Principal inertia

Moment of inertia about a principal axis where the cross inertia are zero and the inertia matrix is diagonal.

Principal stresses

Stresses along the principal axes where the shear stresses are zero.

Probability density function

A function that defines the likeliness (or probability) that a random parameter will take a particular value of the function variable. Derivative of the “probability distribution function.” This function completely defines the random parameter. In vibration, this can be used to determine the probability of realizing a particular instantaneous amplitude value from a vibration signal within a certain amplitude range.

Probability density moments

See [Expected value](#). Single number indices expressed as moments weighted by the probability density function.

Probability distribution function

A function that defines the probability that a random parameter will take a value less than or equal to a particular value of the function variable. Integral of the probability density function. This function completely defines the random parameter.

Process damping

In machining, damping due to the rubbing between the back side of tool and the surface of the machined part. This decreases chatter.

Propeller

Rotor with blades or a screw like device that imparts kinetic energy to a fluid (which can be converted into pressure and thrust). Used in compressors, pumps, jet engines. Provides thrust to push a boat through the water, or an aircraft through air.

Proportional damping

The damping matrix of a mechanical (vibrating) system is such that the modal vectors are real. The damping matrix is proportional to the mass matrix, stiffness matrix or both.

Pseudoacceleration

Product of the squared natural frequency $(2\pi f_n)^2$ and the highest relative displacement response of a linear one degree of freedom system to a shock input. This product has the dimension of acceleration but does not represent the acceleration of the mass, except when damping is zero. In such cases, this term is then strictly equal to the absolute acceleration of the mass.

Pseudovelocitv

Product of the natural frequency $(2\pi f_n)$ and the highest relative displacement response of the mass of a linear one degree of freedom system to a shock input. This product has the dimension of velocity but does not represent the velocity of the mass.

Pulse rise time

Interval of time required for a shock pulse to rise from some specified small fraction to a large fraction (typically 10% to 90%) of its maximum value.

Pyrotechnic shock (or pyroshock)

Transient response of a structure to loading induced by the ignition of pyrotechnic (explosive or propellant activated) devices. Pyroshocks are characterized by high peak acceleration, short duration and high-frequency content.

Quadrature error

The secondary signal that is at 90° phase to the primary signal, produced by an LVDT when the slider is symmetrically placed, while in theory it should be zero.

Quadrature signals

The two signals from a shaft encoder that are 90° out of phase, which are used to determine the direction of motion.

Quality factor (Q-factor)

A measure of the sharpness of a resonance or frequency selectivity of a vibratory linear one-degree-of-freedom system. Assuming a lightly damped single-DoF system, the Q-factor is related to damping ratio by $Q = 1/(2\zeta)$. Other approximate relations for Q are:

1. Transmissibility at resonance
2. $\pi/\text{logarithmic decrement}$
3. $2\pi W/\Delta W$ where W is the stored energy and ΔW the energy dissipation per cycle
4. $f_r/\Delta f$ where f_r is the resonant frequency and Δf is the bandwidth between the half-power points

Nonlinear damping causes it to vary with time. The concept is applicable to both mechanical and electrical systems.

Quantization error

The error created by the finite representation of numbers (i.e., finite number of digits or bits) within a computer (i.e., for a digital quantity).

Quefrency

[See Cepstrum](#). Similar to frequency, but in the Quefrency domain. The independent variable of a cepstrum (similar to spectrum).

Quefrency domain

[See Cepstrum](#). The domain of a cepstrum — inverse Fourier transform of a log of the Fourier transform of a signal.

Radiational sound

Sound in an acoustic field generated from a radiating source.

Random vibration

A vibration whose magnitude cannot be precisely predicted for any given instant of time.

Range of normal hearing

Human hearing is most sensitive in the range 2000 to 5000 Hz, where the threshold response is very close to 0 dB. At the other end of the scale, we have the threshold of pain, which is usually about 135 to 140 dB.

Reactive muffler

A muffler where there are one or more chambers, resonators, or finite sections of pipe, which collectively provide impedance mismatch for the acoustic energy traveling along the duct, causing noise suppression.

[See Muffler](#) and [Dissipative muffler](#).

Real-time

Refers to the relative response time for a particular process under computer control to occur after an action is taken. Should be consistent with the response time of the physical system.

Receptance

The transfer function of displacement or force in the frequency domain.

Rectangular shock

Simple shock for which the acceleration–time curve increases instantaneously up to a given value, remains constant throughout the signal and decreases instantaneously to zero. Practically, trapezoidal shocks are rather carried out.

Rectilinear

Along a straight line. Often (incorrectly) called “linear.”

Recurrence relation

Discrete equation (difference equation) that allows the computation of numbers in a series one by one.

Regenerative chatter

Unstable, self-excited interaction between machining forces and structural vibrations.

Relative displacement shock spectrum

[See Shock response spectrum.](#) SRS plotted, taking its ordinate (y -axis) the pseudoacceleration of the mass of a linear one DoF system.

Relaxation

Process characterized by an exponential variation, for example, sample strain response to a constant load.

Reluctance

Magnetic resistance. Resistance to magnetic field in a magnetic circuit (magnetic path).

Repeatability

The ability of a transducer to reproduce output readings accurately when the same measured value is applied to it repeatedly, under the same conditions (in the same direction, etc.). Repeatability is expressed as the maximum difference between output readings as a percent of full scale. This concept is also applicable to the operation of other instruments and machinery such as robots.

Required response spectrum

[See RRS.](#)

Residual base displacement

A permanent base displacement of an isolated structure after an earthquake.

Resilient friction base isolator (RFBI)

One type of sliding isolator, which is made of a central rubber core and Teflon-coated steel plates.

Resilient mechanism

An automatic recentering mechanism of isolators by which the isolated structure can return to its original position after an earthquake.

Resolution

The smallest change (in a parameter, signal, instrument output, etc.) that can be meaningfully detected and used.

Resonance

A resonance occurs in a mechanical system excited by a harmonic force if the excitation frequency is equal to the resonant frequency of the system. A small change in the frequency of excitation in either direction will cause the system response to decrease rapidly if the system damping is low. At a resonance, very little energy input into a structure results in a very large displacement (for low damping levels). Resonant frequency is almost equal to (but less than) the undamped natural frequency when the damping is low. Although the resonant frequency is nearly equal to natural frequency, the two concepts are not the same. Resonant frequency is excited by a harmonic forcing function at that frequency. The natural frequency is excited by an initial condition (corresponding the particular mode shape) followed by a free (unforced) response.

Resonance search

A vibration testing procedure whose objective is to identify and observe various resonances in a test object. A harmonic excitation with variable frequency may be used for this. [See Sine sweep](#).

Resonator absorber

A method in which a vibration absorber ([see Vibration absorber](#)) is tuned to have a natural frequency equal to the external excitation frequency to mimic optimally the vibratory energy from the primary system (system of concern). The absorber then “absorbs” the energy of vibration of the primary system, thereby suppressing those vibrations. Actually, the absorber generates a force in the opposite direction to the force of vibration of the primary system.

Response

The response of a device or system is the motion (or other output) resulting from an excitation (force, stimulus, or input) under specified conditions.

Response spectrum (RS)

A plot of maximum amplitudes (acceleration, velocity, or displacement) of a single-DoF oscillator (Single-DOF) as the natural period (or natural frequency) of the Single-DOF is varied across a spectrum of engineering interest (typically, for natural periods from 0.03 to 3 or more seconds, or frequencies of 0.3 to 30 Hz; in seismic applications). One RS curve is obtained for a specified damping ratio of the Single-DOF system.

Response spectrum analysis

Computation of the response spectrum (RS) of a given signal ([see Response spectrum](#)). This is quite different from spectral analysis (or spectrum analysis), which is to compute the Fourier spectrum of a signal. These are different from spectral density analysis, which determines the power spectral density function of a “random” signal.

Reverse whirling

Whirling is the rotation of a spinning rotor center of mass, which has an offset (due to shaft deflection) with respect to the axis through the bearings of its shaft. Reverse whirling occurs if the direction of this rotation about the bearing axis is in the opposite direction to the angular speed of spinning of the rotor with respect to a fixed frame of reference.

Reynolds number

A dimensionless parameter (that depends on viscosity and velocity), whose value determines if a fluid flow is laminar or turbulent.

Ridge

Curve of local maxima in a mean-square wavelet map.

Rigid bodies

Bodies exhibiting no deformation under acceleration or forces.

Rigid-body mode

A mode of motion that corresponds to zero natural frequency. Such a mode will exist in an unrestrained structure (no end fixtures) that is free to move as a rigid body without any deformation.

Rigid-body motion

A structural motion that results in no deformations or strains. By definition, these are zero frequency motions.

Rigid–perfectly plastic force–deformation characteristics

Characteristics of hysteretic loops produced by an ideal friction-damping device.

Rigid structure

A structure that cannot be deformed and whose shape cannot be changed.

RMS value

Root-mean-square value. Square root of the arithmetical average of a set of squared instantaneous values of a response quantity.

Rolling element bearings

A rolling element bearing generally consists of two rings (races or raceways) with a set of rolling elements running in their tracks. The rolling elements take the form of balls or various types of rollers. The outer race is located in a housing and the inner race on the shaft.

Root cause failure

The basic cause for a given failure.

Root Mean Square

See RMS value.

Rotating machinery

The group of electrical or mechanical machinery composed of a rotating component that rides on some form of bearings encased in a stationary casing (housing).

Rotor

The rotating part (as opposed to the stator) of an electrical or mechanical machine.

Rotor instability

An excitation mode, which is self-induced and does not require a sustained forcing phenomenon to initiate or maintain the motion. It occurs in machines operating at speeds well above the critical speeds of the rotor, and the rotor whirling speed is identical to the critical speed irrespective of the rotor (spinning) speed.

Rotor internal damping

A damping phenomenon, which occurs within the internal fibers of a material due to friction when there is relative movement between the fibers.

Rotor track

The vertical position of the blades of a rotor, usually measured by optical sensors.

Rotor tuning

The process of adjusting the rotor blades of a jet engine to reduce the system vibration (e.g., aircraft) and the spread of rotors.

Rotordynamics

The dynamics of rotating machinery.

Round-off error

The error created by the finite representation of numbers (i.e., finite number of digits) within a computer. Similar to Quantization error.

RRS

In a dynamic test, the response spectrum specification that has to be satisfied (enveloped) by the excitation signal.

Rub

A condition when a moving part comes into contact with, and slides against, a stationary part.

Run-to-failure maintenance

A strategy where maintenance is performed only when machinery has failed. [See Scheduled maintenance](#), Predictive maintenance, Preventive maintenance, and Condition-based maintenance.

Runge–Kutta

Numerical methods (integration schemes) based on approximating the solution by a Taylor series, and weighted averages of corresponding differences.

RVDT

Rotary variable differential transformer. [See LVDT](#). Similar to an LVDT, but for measuring angular displacements.

Safe shutdown earthquake (SSE)

An earthquake representation (e.g., by a response spectrum) for which a nuclear reactor can be safely shutdown without causing damage or fault in equipment due to the earthquake.

Sampling

The process of converting continuous signals into discrete values for digital processing.

Sampling frequency

The rate at which samples of a continuous time signal is recorded in discrete fixed time periods.

Sampling theorem

When a signal is sampled, its spectrum has no meaning beyond half the sampling frequency, called Nyquist frequency.

Saturation

A nonlinearity state in a device where a further increase in input no longer changes the output.

Scaling

To stretch or compress a function.

Scheduled maintenance

A strategy where maintenance is performed at set time intervals (or duty cycles) in order to maintain a significant margin between machine capacity and actual duty.

SEA

Statistical energy analysis.

Second moment of area

Similar to moment of inertia, except uses area elements rather than mass elements. (The two are proportional for uniform material density and constant thickness along the axis.)

Secondary (or Residual) negative shock response spectrum

SRS plotted, considering the highest negative response observed after the end of the shock.

Secondary (or Residual) positive shock response spectrum

SRS plotted, considering the highest positive response observed after the end of the shock.

Secondary system

A general term for equipment attached to a primary structural system.

Seismic

Measurements and activity concerning earth motion, such as earthquakes.

Seismic gap

A gap provided between a seismically isolated building and the ground so that the ground-level story can move in relation to the ground during earthquake excitations.

Seismic hazards

The phenomena or expectation of an earthquake-related agent of damage, such as fault rupture, vibratory ground motion (i.e., shaking), inundation (e.g., tsunami, seiche, dam failure), various kinds of permanent ground failure (e.g., liquefaction), fire, or hazardous material release.

Seismic isolation

Application of base isolation technology to structures subjected to earthquake motions.

Seismic risk

The product of the hazard and the vulnerability (i.e., the expected damage or loss, or associated full probability distribution).

Seismicity

The geographic and historical distribution of earthquakes.

Self excited instability

Same as Rotor instability.

Self-induced

Created within itself and does not require an external influence.

Self-organizing map (SOM)

A type of unsupervised neural network that yields a graphical representation of input data where similar input vectors are placed in close proximity.

Semiactive vibration control

A vibration control system in which both active and passive (see [Active vibration control](#) and [Passive vibration control](#)) treatments are combined to reduce the amount of external power necessary to achieve the desired vibration control performance.

Shaker

[See Exciter.](#)

Shape function

Is a spatial function (i.e., function of position vectors) describing the change of a variable within an element domain.

Shear balance method

An analysis method for sliding isolated structures, which uses the force balance condition of total shear under the isolation system to compute the friction force.

Shear force

An internal force acting normal to the longitudinal axis given by the algebraic sum of all forces to one side of the section chosen.

Shear wall

A structural wall between stories of a building to increase shear strength but at the expense of increasing stiffness.

Shifting

The process of translating (moving) a function with respect to some reference (coordinate system).

Shock

Transient condition where the equilibrium of a system is disrupted by a sudden applied force or by a sudden change in the direction or magnitude of a velocity vector. The time duration of this change is shorter than about twice the natural period of the excited mechanical system.

Shock duration

Interval of time during which the shock pulse has a higher acceleration value than some specified small fraction of its maximum value (usually 10%).

Shock machine (or shock test machine)

Device for subjecting a system to controlled and reproducible mechanical shock. Two principal categories are usually distinguished. Impulse machines: increase the velocity of the test item during the shock. The initial velocity is generally zero. Impact machines: decrease the velocity of the test item throughout the shock or change its direction.

Shock motion

An excitation involving motion of a foundation.

Shock programmer

Same as Shock simulator. Device on a shock machine that is used to format the applied shock waveform according to a desired shape during impact (usually half-sine, terminal peak sawtooth, and rectangular pulses).

Shock pulse

A substantial disturbance characterized by a rise of acceleration from a constant value to a substantial peak value, and decay of acceleration to the constant value in a very short period of time. Shock pulses are normally displayed graphically as curves of acceleration as functions of time.

Shock pulse index

An accelerometer tuned to have its resonant frequency excited by a specific shock can provide early warning of fault (e.g., deteriorating bearings). The sensor output level is the shock pulse index (also known as spike energy).

Shock response spectrum (SRS)

The response of an array of single-DoF systems to a shock input represented as the maximum response versus the natural frequency of single-DoF systems for a specified damping ratio. This response may be expressed in units of acceleration, velocity, or displacement.

Shock simulator

Same as shock programmer. Device on a shock machine that is used to format the applied shock waveform during impact according to a desired shape (usually half-sine, terminal peak sawtooth, and rectangular pulses).

Shock spectrum

See shock response spectrum. A plot (amplitude vs. natural frequency) of the response of a natural-frequency-variable single-DoF system to an applied shock for a specified damping ratio. This response may be expressed in units of acceleration, velocity, or displacement.

Shock wave

A strong pressure wave produced by explosions or other phenomena that create violent changes in pressure.

Shoring

Temporary support at the base floors of a structure during replacement of its originally fixed support to seismically isolated support.

Short-term statistics

Statistics of a random process that are only good for a few hours or a few days at the most. It is assumed that the significant wave height and the wave spectrum are invariant with time.

Short time FFT

Time sequence of concatenated FFT of short-period records of a signal.

Shroud of impeller

The circular section that forms a sidewall of a pump or compressor impeller.

Signal-to-noise ratio (SNR)

Determined by both electronic and mechanical noise (but not thermal noise due to the fluctuation–dissipation theorem).

Signature spectrum

A base-line frequency spectrum taken from new or recently overhauled machinery.

Significant wave height

A statistical description of random waves. Average of the highest one third of all waves or four times the variance. Consistently very close to the observed wave height.

Simple beam

See Simply supported beam. A beam restrained at its end only against vertical movement.

Simple harmonic motion

See Simple harmonic vibration.

Simple harmonic vibration

A motion such that the displacement, velocity and acceleration are pure sinusoidal functions of time. Sometimes called “harmonic motion.”

Simple oscillator

A single-DoF mass–spring–damper system (or an LRC electric circuit), which can produce damped oscillations at one frequency (damped natural frequency). An undamped simple oscillator is a harmonic oscillator, which can produce a periodic oscillation described mathematically by either of the harmonic trigonometric functions (sine or cosine), and has only one frequency component (undamped natural frequency).

Simple (or perfect) shock

Shock whose signal can be represented exactly in simple mathematical terms. Standards specify generally one of the three following: half-sine (approached by a versed sine waveform); terminal peak sawtooth; and rectangular shock (approached by a trapezoid waveform).

Simply supported beam

A beam pinned (or simply supported) at its ends so that the displacement and bending moment at these ends will be zero. Slopes and shear forces will not be zero.

Sine beat

A signal formed by adding two sine signals whose frequencies nearly equal, so as to generate beats. Such a signal is used for excitation in some types of vibration testing.

Sine-dwell

A vibration test where a shake applies a sinusoidal excitation of a specific frequency to the test object over a specific duration, changes the frequency, and repeats the dwell in specific frequency steps.

Sine sweep

A vibration test procedure where a harmonic excitation is applied to a test object (using an exciter or shaker) and the frequency of excitation is slowly and continuously varied at a specified rate.

Single-category-based classifier (SCBC)

The pattern classifier that performs abnormality scaling by comparing the value of its feature with its no-fault value.

Single-degree-of-freedom (single-DoF) system

A system with only one coordinate (strictly, one incremental coordinate to include nonholonomic systems) to define completely the configuration of the system at any instant.

Single plane balancing

See [Static balancing](#), which is synonymous.

SISO

Single-input–single-output system. A system with just one input and one output.

Skeleton

Wavelet transform values along a ridge.

Sliding bearing

A type of base isolator that protects a structure from ground excitations by using a sliding frictional interface at the base.

SNR

Signal-to-noise ratio, determined by both electronic and mechanical noise (but not thermal noise due to the fluctuation–dissipation theorem).

Soft foot

A condition that occurs when one of a machine's hold-down bolts are not tight enough to resist the dynamic forces exerted by the machine.

Soft story

A story of a building that is more flexible than the other stories so that the stories above this story are isolated from the ground shaking.

Softened compression stress–strain relationship

Viewing the shear action on a membrane element as a two-dimensional problem, the compressive strength of concrete in one direction is reduced by cracking due to tension in the perpendicular direction.

Softening parameter

When a membrane element is subjected to shear, the compressive strength of concrete is reduced to approximately 40 to 60%.

Soil–structure interaction

A dynamic interaction between a structure and its supporting soil, in which dynamic properties of one will affect the response of the other.

Solenoid

A linear (rectilinear) two-position (on–off) actuator. A ferromagnetic rod surrounded by a coil of many turns. An electric current through the coil will generate a flux that will move the rod, thereby turning on the solenoid. A version (linear motor) is able to provide continuous movements.

Sone

Unit of the loudness that is defined as the loudness of a 1000 jHz pure tone with a sound pressure level of 40 dB. This relationship is expressed as $S = 2^{(L_L - 40)/10}$, S (sone) and L (phons).

Sound absorbing material

Porous materials such as glass fiber blankets used to attenuate sound propagating in ducts to improve sound transmission loss and to reduce standing waves in air spaces.

Sound bridge

Structures such as studs or stud bolts connecting the plates added to a noise source in insulation lagging or the plates of a double wall. They can considerably reduce insertion loss of the lagging or transmission loss of the double wall.

Sound insulation lagging

Thin plates separated by airspace or sound absorbing materials added to noise sources such as pipes, ducts and machines to isolate their noise.

Sound intensity

The time-average rate of energy flow per unit area, denoted by the vector I (W/m^2).

Sound level

Sound pressure level that has been weighted according to particular weighting curves: A- B-, C-weighting networks and associated levels. The frequency response and decibel conversions from a flat response for each of these weightings are available.

Sound power level

The acoustic power radiated by a source with respect to the international reference of 10^{-12} (watts), expressed in decibels (dB).

Sound pressure

The difference between the instantaneous pressure at a fixed point in a sound field and the pressure at the same point without the sound (Pa). Alternatively, this may be defined as the ratio (dB) of the instantaneous pressure at a fixed point in a sound field with respect to a reference of 2×10^{-6} (Pa), for which a pure tone of sound is assumed.

Span

The distance between two consecutive supports of a beam, truss, bridge, guideway, etc.

Spatial coupling

Effect of multiple support motions occurring when the attached equipment is mounted at multiple locations of the structure.

Specific fan noise level

Ratio (dB) of sound power generated from a fan due to its pressurized flow with respect to some standard power level.

Specifications

Conditions that must be satisfied by operating or design parameters during operation or design of a product in order to satisfy the objectives of the product.

Spectral density

[See Power spectral density](#). Fourier transform of the autocorrelation function of a random signal (random process). It shows how the variance of the system is distributed over frequency. It may also be expressed as a “spectral energy density” since the unit of the variance often has the unit of energy.

Spectrogram

A graph of time vs. frequency, e.g., the Gabor distribution.

Spectrum

A description of a quantity as a function of frequency or wavelength. Fourier transform of a signal is called the Fourier spectrum (or simply a spectrum).

Spherical wave

When propagation of sound wave is described by radial (polar) coordinates, the sound field is represented by a “spherical wave,” which is generated by a point monopole.

Spike energy meter

An accelerometer tuned to have its resonant frequency excited by the impacts in a deteriorating bearing, thus giving an early warning of an impending failure.

Spindle speed selection

In machining: a technique where the spindle speed is chosen to avoid or suppress chatter.

Spindle speed variation

In machining: a technique where the spindle speed is continuously adjusted to suppress chatter.

Spring

The basic flexibility element characterized by its stiffness, force, or deflection. Stores elastic potential energy. In three-dimensional problems, a spring may assume three orthogonal stiffness parameters.

SRSS

Square-root of sum of squares of a set of values.

SSE

[See Safe shutdown earthquake.](#)

Stability

Stability of a dynamic system: If the natural (unforced) response of a system decays to zero, then the system is asymptotically stable. If for a finite excitation, the system response is bounded, we have bounded-input–bounded-output (BIBO) input. Stability of a numerical method: Numerical errors do not grow without bound.

Stability lobe diagram

Chatter stability chart in the process parameter space.

Standardized shock response spectrum

[See Shock response spectrum \(SRS\).](#) Standardized or reduced SRS plotted in dimensionless coordinates. The abscissa is the product of natural frequency and shock duration. The ordinate is the ratio spectrum value or shock pulse amplitude.

Standoff distance

Distance away from a specific structure that determines the amount of damage that would occur if an explosion of a specific size was detonated. For standoff threats, the distance away from a potential vantage point with direct line of sight to the asset.

State space formulation

A generalized analytical model for a dynamic system expressed as a minimum set of first-order ordinary differential equations (state equations). The associate variables are the state variables that may include structural displacements and velocities, which will represent the dynamic state of the system.

Static balancing

[See Balancing.](#) Balancing achieved on a single plane of vibration perpendicular to the axis of rotation.

Static loading

Constant loading of a member.

Stationary process

A random process where the statistics can be considered independent of time. Stationary process is used synonymously with weakly stationary process where the first-order statistics such as the mean and the variance are independent of time, and the second-order statistics such as the autocorrelation function depend on the difference in time.

Statistically determinate

A structure is considered statistically determinate if all the support reactions and internal forces in the members can be determined solely by the equations of static equilibrium.

Stator

The stationary structure surrounding the rotating member (rotor) of a rotating electrical or mechanical machine.

Steady-state error

Offset. The error in the response of a system under steady-state conditions.

Steady-state vibration

Steady-state vibration exists in a system if the velocity of each particle is a continuous periodic quantity.

Stiffness

Characteristic parameter of a spring element. Ratio of change of force (or torque) to the corresponding change in translational (or rotational) deflection of an elastic element, i.e., force required to deflect an elastic element through a unit distance. Typical units are Newtons/meter (N/m).

Stiffness asymmetry

The stiffness (or flexibility) is not symmetrical in two or more orthogonal directions.

Stiffness law

Transmission loss characteristic of a single plate that the transmission loss depends on frequency and equivalent stiffness of the plate below the first-order natural frequency of the plate.

Stiffness matrix

The matrix multiplied by the displacement vector in the Newtonian form of differential equations of motion of a mechanical (vibrating) system, expressed in the vector-matrix form.

Stochastic process

An indexed collection of correlated (in general) random variables.

Stochastic resonance

Counterintuitive increase of SNR when the noise level is raised. Only possible in nonlinear systems.

Stokes law

Viscous friction force on a sphere of radius R , given by $6\mu Rv$, where μ is the fluid's viscosity.

Strain

Change in length divided by length. A nondimensional measure of the physical deformation or deflection resulting from stress (force per unit area).

Strain gauge

A miniature resistive element (metal foil or semiconductor) whose resistance changes when stretched (deformed), which can be measured using a Wheatstone bridge circuit. When properly mounted on (i.e., bonded to) a structural member, it can measure the local direct strain in the member.

Stress–strain curve of a steel bar in concrete

A steel bar in concrete is stiffened by tensile stress of concrete. It relates the average stress to the average strain of a large length of bar crossing several cracks.

Stretched exponentials

Discovered with Leyden jars (capacitors), a multiexponential model used by some to explain features of anelasticity.

Stribeck damping

A sophisticated friction model where the coefficient of friction drops rapidly and then increases gradually (somewhat linearly) as the relative velocity increases from zero.

Stroke

The maximum rectilinear movement that is possible in a device.

Strouhal frequency

Frequency at which the vortices are shed from a fixed cylinder subjected to a constant velocity flow. It is proportional to the diameter of the structure and inversely proportional to the stream velocity.

Structural influence

The coefficient that represents the proximity effect of the accelerometer generating a feature of a machine (gearbox) component.

Structural wall

An in-plane wall to reduce the relative interstory distortions of a building caused by seismic-induced motions.

Structure-based connectionist network (SBCN)

In machine monitoring for fault detection, this network takes advantage of the integration capability of neural networks, but avoids the need for supervised training. In the SBCN, the network weights are defined according to the “structural” knowledge of the monitored machine (e.g., gearbox) and the type of fault represented by various vibration features. The structural influences in the SBCN, which represent the proximity effect of faults on accelerometers, are determined according to the RMS value of the frequency response of a simplified lumped-mass model of the monitored machine (e.g., gearbox).

Structure-borne noise

Type of noise that is based on the generation and propagation of timewise varying motions and forces in solid bodies, as well as on the associated sound radiation.

Subharmonic

Sinusoidal quantity of a frequency that is an integral submultiple of a fundamental frequency.

Subharmonic resonancy

A phenomenon observed in sliding isolation where the isolated system possesses extra harmonic resonant frequencies in the low-frequency range in addition to the original ones as a result.

Substructured online hybrid test

A test in which only inelastic parts of a structure are experimentally tested, while the remaining elastic parts are modeled in a computer. Both parts are interconnected using online communications so that the complete structural responses are obtained.

Substructuring

Modeling, analysis and design development method where subsystems are developed first and assembled together (interconnected) through appropriate connecting elements. The analysis is simplified by using interconnection laws and making use of the results for the subsystems.

Subsystem structure

A structure that is regarded as a subsystem in the analyzing process of statistical energy analysis (SEA).

Sweep rate

The rate at which the frequency is changed in a sine-sweep test.

Symmetric matrix

The corresponding elements of a symmetric matrix about its main diagonal are identical. Specifically, $a_{ij} = a_{ji}$ where a is an element, i is the row number, and j is the column number. The transpose does not change the matrix in this case.

Synchronous averaging

Averaging of the vibration signal synchronous with the running speed of the machinery being monitored.

Synchronous whirling

[See Whirling](#). The angular velocity of whirling rotation of the rotor geometric center is equal to the rotational speed (spin) of the rotor shaft.

Tachometer

A speed sensor. [See DC tachometer](#). AC tachometers have a primary coil with an AC signal (carrier signal), a secondary coil whose induced signal is demodulated to determine the speed, and a rotor that is either a permanent magnet of a closed conduction (as in induction motor).

Thermal bearings

Flexible bearings used in long span bridges for accommodating the changes of deck length due to varying temperature to protect bridge piers from receiving large lateral forces.

Terminal peak sawtooth shock (TPS)

Same as Final peak sawtooth shock (FPS). A simple shock for which the acceleration–time curve has the shape of a triangle where acceleration increases linearly up to a maximum value and then instantly decreases to zero.

Test factor

Where the shock test specification is derived from measurements of the real environment, this is the coefficient applied to mean SRS of the measured shock pulses to take into account the variability of the resistance of the test item and the very small number of specimens tested (often only one specimen).

Test response spectrum

[See TRS](#).

Thermoelastic damping

Energy dissipation (damping) due to the anharmonic, interatomic potential independent of defects.

Threshold

The minimum value a stimulus may have to create a desired effect.

Threshold of hearing

This is defined for binaural listening as the lowest sound pressure in free field that one can just hear as the signal reduced.

Threshold speed

The speed at which a stimulus is perceptible or can produce an effect.

Throttling

Reducing the fluid flow in a system by a valve or regulator.

Time constant

The inverse of the real part (disregarding the negative sign) of an eigenvalue. Inversely proportional to the speed of response and the level of stability.

Time-dependent effects

Normally referred to material properties that are influenced by motion history.

Time domain

Domain of analysis of a dynamic (vibrating) system where the independent variable is time (t). In this domain, vibration data (and systems) are represented, displayed or analyzed as a function of time.

Time-domain analysis

Analysis of dynamic (vibration) systems and response (motion) results, which are described with respect to time.

Time-domain simulation

Computer simulation of the response of a dynamic system as a function of time. Technique to analyze chatter where delay-differential equations defining the machining forces and structural vibrations are numerically simulated in the time domain.

Time-history analysis

The analysis of a response of a dynamic system (e.g., structure) with respect to time.

Time waveform index

A single number representative of a waveform, calculated using a raw vibration signal and used for trending and comparisons.

TNT equivalent

The weight of trinitrotoluene (TNT) that has an equivalent energy output to that of a specified weight of another explosive compound.

Tool chatter

Self-excited vibration between the cutting tool and the workpiece due to a cutting tooth machining over a portion of the workpiece that was machined by a previous tooth of the cutter. This causes uneven chip thickness and consequently, excessive self-excited vibrations.

Tool condition monitoring (TCM)

A method by which the condition or state of cutting tools can be monitored.

Tool condition monitoring system (TCMS)

A combination of sensors and algorithms to achieve TCM.

Tool wear

The loss of material on the edges of a cutting tool due to machining.

Tooth passing frequency

Frequency at which the cutting tool teeth pass a given point during a spindle revolution.

Tooth passing period

Time interval for two successive cutting tool teeth to pass a given point during a spindle revolution.

Tornado

A violently rotating column of air in contact with, and extending between, a convective cloud and the surface of the Earth. It is the most destructive of all storm-scale atmospheric phenomena. They can occur anywhere in the world given the right conditions, especially after landfall of hurricanes.

Torque whirl

A whirling instability that can occur in overhung, long, slender, rotors with high load torque values. [See Whirling.](#)

Torsional response

Response causing a twisting motion.

Torsional stiffness

Torque applied to a member divided by the resulting angular displacement (twist) of the member.

Torsional vibrations

Oscillatory angular motion causing twisting of a shaft (carrying a rotor) in a rotating machine.

Tracking analyzer

Device used to record and analyze data from machines with variable speed.

Transducer

A device that senses a physical quantity is called a sensor. A transducer is a device that converts the sensed signal (measurand) into a form (typically, an electrical output signal of sufficient value) proportional to the measured variable. Often, the terms sensor and transducer are used interchangeably.

Transfer function

The ratio of the output of a dynamic system to its input in the Laplace domain or frequency domain ([see Frequency domain](#) and [FRF](#)) assuming zero initial conditions.

Transient-response analysis

Sometimes called time-history analysis, this determines the dynamic response of a dynamic system (e.g., structure, machine) under the action of time-varying excitation. Excitation forces are explicitly defined in the time domain. Computed response usually includes the time-varying displacements, velocities, accelerations, strains, and stresses.

Transient vibration

The vibratory motion of a mechanical system as it changes from one state to another as a function of time. This may be a decaying or growing signal but not a steady vibration. It may consist of forced or free vibration or both.

Transmissibiliy

Transmitted vibration (force or motion) divided by an applied vibration (force or motion). Inverse of Isolation.

Transmission loss

The difference between incident and transmitted acoustic intensity levels. It is used to rate the sound insulating properties of a wall or some other structure or device. For a muffler, this is the ratio between the energy in incident sound wave at the muffler inlet and energy transmitted at the muffler outlet into perfectly absorbing termination.

Transmitted power

An acoustic power that is transmitted from a subsystem to another subsystem.

Trapezoidal shock

Simple shock for which the acceleration–time curve grows linearly up to a given value, remains constant during a certain time, and then decreases linearly to zero.

Trim tab adjustments

Trim tabs are adjustable surfaces on the trailing edge of the rotor blades of a rotating machine (e.g., jet engine). They affect the aerodynamic pitch moment of their foils and consequently, their vibration characteristics. Tab adjustments are measured in thousandths of an inch (thou), with positive and negative changes representing upward and downward tabbing, respectively.

TRS

Test-response spectrum. The response spectrum of the excitation signal that is applied to a test object during testing.

Truncation error

The error created by deleting a signal after a finite time period to obtain a finite segment before digitally analyzing it. This is equivalent to multiplying the signal by a rectangular window. The error can be reduced (or ripples in the frequency spectrum of the truncated signal can be suppressed) by using other types of window functions with smoothing at the two ends.

Tuning

The process of adjusting the controller parameters in order to achieve the required performance (e.g., vibration control).

Unbalance (or imbalance)

A condition when the center of mass of a rotating component is not coincident with the center of rotation.

Unbalance response

The displacement vibratory response of a rotor to its mass imbalance as a function of rotor speed.

Uncertainty factor

Where the shock test specification is derived from measurements of a real environment, this is the coefficient applied to the mean SRS of the measured shock pulses to take into account the variability of the shock environment and the variability of the resistance of the material.

Uncertainty principle

The product of uncertainties of conjugate variables is greater than or equal to a constant, which in quantum mechanics is Planck's constant. Also known by the name Heisenberg.

Undamped natural frequency

The frequency of free vibration resulting from only elastic and inertial forces of the system while neglecting damping.

Undamped system

A system where there is no energy dissipation. It has energy storage capability (e.g., inertia elements to store kinetic energy and springs to store elastic potential energy). If there is no external force applied on the system, then the system will experience free steady vibrations. Motion of the system are established by an initial disturbance (i.e., initial conditions).

Undetermined coefficient method

Use a trial solution consisting of the sum of possible set of functions multiplied by unknown coefficients. Substitute in the equation to be solved and equate like terms to determine the unknown coefficients.

Uplift force

Force perpendicular to the flow.

Van der Pol oscilaltor

Classic nonlinear electronic oscillator.

Variable frequency drives

A controlling device to vary the frequency of AC supplied to an electric motor in order to vary proportionately the speed of rotation of the motor.

Variable structure control (VSC)

A class of nonlinear switching controllers whose structure consists of different phases. Typically associated with a discontinuity function (e.g., signum function). When the system response enters a different phase, a different controller (corresponding to the particular phase) is switched on.

VCC

Voltage to current converter.

Velocity

A vector quantity that specifies the magnitude and direction of the rate of change of displacement with time along a specified axis with respect to a reference frame (m/sec). First derivative of displacement with respect to time. It may refer to angular motion as well as to uniaxial (rectilinear) motion. Where the reference frame is not inertial, the velocity is often designated "relative velocity."

Velocity change

Variation of the velocity during a shock, i.e., integral of the acceleration time-history signal over the shock duration.

Velocity of sound

Velocity of sound wave propagation. In air, it is proportional to the square root of ambient pressure and of the inverse of ambient density, or it is proportional to the square root of the absolute temperature. For example, in stationary air, the velocity is 340.4 m/sec at 15°C.

Velocity shock

Shock motion characterized by a sudden velocity change of the support (base) of a system.

Versed-sine (or Haversine) shock

Simple shock for which the acceleration–time curve has the form of one period of the curve representative of the function $[1 - \cos(\quad)]$, with this period starting from the zero value of the function. It is thus a signal ranging between two minima of a sine wave.

VFC

Voltage to frequency converter.

Vibration

The oscillating, reciprocating, or other periodic motion of a rigid or elastic body or medium (such as a floor) when its position or state of equilibrium has been changed.

Vibration absorber

A secondary system (usually a mass–spring–damper trio with zero or low damping) to protect the primary device from vibrating. Typically, the secondary system vibrates at its natural frequency (resonance) generating an opposing force to suppress vibration in the primary system.

Vibration absorption

Addition of a vibration absorber to protect the primary device from vibrating.

Vibration analyzer

The device that could monitor and analyze the machine conditions using the machine's vibration signals.

Vibration control

Means of controlling vibration using external or internal forces and loads.

Vibration features

Aspects of vibration that can illuminate the effect of individual faulty components of a machine (e.g., gearbox) on vibration. Usually, vibration features are defined as functions of specific frequencies affected by the components.

Vibration isolation

[See Isolation.](#) Isolating the source of vibration from the concerned system protecting a device from vibration of its point of attachment. Motion isolation and force isolation are of interest.

Vibration measurements

For a bladed rotating machine (e.g., jet engine, turbine, compressor), obtained at the frequency of once per blade revolution (1 per rev) by two accelerometers, A and B, attached to the sides of the cockpit. The vibration data is vectorially combined into two components: $A + B$, representing the vertical (heave) vibration of the system (e.g., aircraft), and $A - B$, representing its roll vibration.

Vibration meter

Small, handheld, inexpensive, simple-to-use, self-contained device that gives an overall vibration level reading.

Vibration mode

[See Mode shape.](#) For a flexible plate, the vibration represents the particular spatial configuration of vibration amplitude (i.e., mode shape) with phase information of the moving elements, and the associated natural frequency. The actual vibration of the plate is obtained by the superposition of the

distinct vibration modes. For continuous (i.e., distributed-parameter) systems (e.g., plate), there are infinite distinct modes, many of which at the high-frequency end can be neglected depending on the frequency range of operation.

Vibration modeling

The process of converting an engineering vibration problem into a mathematical model, whereby the major vibration characteristics of the original problem can be accurately predicted.

Vibration mounts

Devices that are placed at the base (or legs) of a machine or equipment to reduce its vibration problems and specifically, to reduce the vibration forces transmitted from the machine or equipment to the support structure and its environment. A key purpose is vibration isolation. Inertia blocks may be attached to the machine base and the mounts.

Vibration response

The output of a vibrating system for an arbitrary input.

Vibration signature

A unique frequency response or pattern that corresponds to a particular input or excitation signal.

Vibration standards

National and international vibration standards and guidelines published by recognized professional organizations and regulatory agencies. The objective of these publications is to establish and control quality, safety, durability and reliable performance of rotating machinery.

Viscoelasticity

Model of anelasticity where an elastic solid also has fluid like (viscous) properties.

Viscous damping

The dissipation of energy that occurs when a particle in a vibrating system is resisted by a force that has a magnitude proportional to the magnitude of the relative velocity of the particle and a direction opposite to the direction of the particle.

Volume coefficient of elasticity of air

Generally, isothermal conditions prevail for frequencies below 100 Hz, whereas adiabatic conditions prevail above 1 kHz. In between these limits, there is a volume coefficient of elasticity (similar to bulk modulus) that varies between 1.0×10^5 and 1.4×10^5 N/m².

Volute

One of the major components of a centrifugal pump forming the casing around the impeller, which channels the flow exiting the impeller into the outlet of the pump while converting the velocity energy generated by the impeller into pressure energy.

Vortex

Any circular or rotary flow in the atmosphere that possesses vorticity.

Vulnerability

The expected damage given a specified value of a hazard parameter.

Wake

Region surrounded by the shear layers originating from separation points.

Wake excitation

Excitation caused by the vortices in the wake.

Waterfall plots

Successive spectra plotted with respect to time and displayed in a three-dimensional manner. Also known as Cascade plots.

Wavelength

In acoustics, the distance between successive two peaks in the repetitive spatial variation of the pressure or the particle local velocity.

Wavelet

Functions having representations in the time and frequency domains of small support set.

Wavelet analysis

Similar to Fourier analysis, wavelet analysis is the breaking up of a time waveform into shifted and scaled versions of a wavelet. A wavelet is a waveform of limited duration with an average value of zero.

Wavelet transform

Representation of a function as a series of wavelets.

Wear-in failures

Failures that occur at the beginning of a machine's useful life, usually characterized by a relatively high rate of failure.

Wearout failures

Failures that occur as a machine reaches the end of its design life.

WECPNL

Acronym of weighted equivalent continuous perceived noise level. It is very close to L_{Aeq} in concept and it would not be difficult to change the assessment index from WECPNL to L_{Aeq} . WECPNL is used for the assessment of aircraft noise.

Whipping

A term used to describe relatively large motion associated with whirling of a rotor. Typically, occurs when the whirling speed matches the critical speed of the rotor.

Whirling

Condition when the rotor shaft bends so that the center of mass of the rotor rotates about the fixed axis through the bearings while spinning about the shaft geometric axis. [See Synchronous whirl.](#)

White noise process

A random process where the energy is equally distributed over the entire frequency domain. It is a mathematical simplification rather than a real process.

Wideband

Corresponding to a wide (large) frequency band.

Wideband process

A random process where most of the energy is in a wideband of frequency.

Wiener–Khinchine relationship

Relates the autocorrelation function to the spectral density of a random process.

Young's modulus

[See Modulus of elasticity.](#)

Zener model

Classic description of damping that involves relaxation processes — named after the individual who also contributed to a well-known voltage controlling diode.

Zero drift

[See Drift.](#) The drift in a device under conditions of zero output.

Zero period acceleration

See ZPA.

Zero shift

Slow variation of the average of a signal due to the fact that high accelerations make the crystal of the accelerometer work in a temporarily nonlinear field. This shift can affect the calculation of the shock response spectrum.

Zeros

The roots of the numerator polynomial equation of a transfer function. Together with poles, they represent the entire system (transfer function) and govern the system behavior (stability, phase, speed of response, percentage overshoot, rise time, etc.).

ZPA

Zero period acceleration. The acceleration shown on a RS or shock SRS at infinite frequency. This can be used as a representative parameter of a signal (e.g., earthquake ground motion) for testing and designing a system.
